

# Metals Handbook

Desk Edition

*ASM*  
INTERNATIONAL

*Metals Handbook Desk Edition*, Second Edition was published in 1998. It was prepared under the direction of the ASM International Handbook Committee. The *Desk Edition* was edited by Joseph R. Davis.

### Editorial Advisory Board

- **Peter J. Blau**, Oak Ridge National Laboratory
- **Rodney R. Boyer**, Boeing Commercial Airplane Group
- **Kenneth H. Eckelmeyer**, Sandia National Laboratories
- **Dennis D. Huffman**, The Timken Company
- **Lawrence J. Korb**, Rockwell International
- **David V. Neff**, Metaullics Systems Company LP
- **David LeRoy Olson**, Colorado School of Mines
- **Dennis B. O'Neil**, Caterpillar Inc.
- **Thomas S. Piwonka**, University of Alabama
- **S. Lee Semiatin**, Wright Laboratory
- **George F. Vander Voort**, Buehler Ltd.
- **Harry W. Walton**, The Torrington Company

### Foreword to the Print Edition

ASM International is proud to mark the 75th anniversary of ASM Handbooks. In 1923, the American Society for Steel Treating (later the American Society for Metals, now ASM International) published a small loose-leaf collection of data sheets--the first edition of what became known as *Metals Handbook*. The series has developed over the years into a multivolume collection of reference books--each volume a thorough, comprehensive, and authoritative treatise on the subject to which it is devoted. The series--now titled *ASM Handbook*--continues to evolve and expand to serve the changing needs of metallurgy professionals throughout the world. One example of this evolution is the release this year of the *ASM Handbook* on CD-ROM.

This year also marks the 50th anniversary of the classic 1948 edition of *Metals Handbook*--the last "regular" edition to be contained in one volume. The 1948 edition was the inspiration for the first *Metals Handbook Desk Edition*, published almost 15 years ago. This Second Edition is intended to serve the same function as its two predecessors: to provide an accessible, convenient, and practical single-volume first reference to all of metals technology.

It was with some trepidation that ASM International entered into the project to revise and update the *Desk Edition*. The task seemed overwhelming. The *ASM Handbook* series had grown to 20 current volumes--almost twice as many as were in existence when the first *Desk Edition* was compiled. Would it be possible to create a work that included all of the vital information from the first edition, plus the most significant knowledge and data compiled in the years since its release, and still remain within the physical limits of a single volume?

We believe that the new *Metals Handbook Desk Edition* more than meets that objective. The credit for this monumental achievement belongs to Joseph R. Davis. Joe was Handbook Editor for many years at ASM, and his extraordinary knowledge of the handbooks along with his considerable editorial skills made him uniquely qualified to oversee this project. We are grateful to Joe for his hard work and for his commitment to creating the best *Desk Edition* possible. To assist in this effort, Joe assembled an outstanding Editorial Advisory Board, made up of many longtime handbook contributors and friends of ASM, and we extend our thanks to them as well. We also wish to recognize the ASM editorial and production staff members for their dedicated efforts on this Volume.

Of course, we are especially grateful to the thousands of metallurgy professionals who have contributed to ASM Handbooks over the past 75 years. Their willingness to share their knowledge and expertise--as authors, reviewers, volume organizers, and Handbook Committee members--has made this book possible. With their ongoing support, ASM Handbooks will continue to thrive for at least another 75 years.

Alton D. Romig, Jr.  
President, ASM International

Michael J. DeHaemer  
Managing Director, ASM International

## Preface

The *Metals Handbook Desk Edition* is intended to serve as a comprehensive single-volume reference source on the properties, selection, processing, testing, and characterization of metals and their alloys. Although the information presented in this Volume is drawn principally from the 20 volumes of the *ASM Handbook* series, it should not be considered simply an abridged version of the larger work. Instead, the *Metals Handbook Desk Edition* draws upon the complete arsenal of ASM products--both print and electronic--as well as other key sources of information originating from other publications, company literature, technical societies, and government agencies.

## Volume Content

Because of the familiarity, success, and ease-of-use of the original *Desk Edition* published in 1984, it was determined from the outset of the project that the editorial approach and outline for the new edition should follow in a similar manner. The challenge in successfully revising the first edition was to determine what strategic additions (or reductions) and improvements should be made. Complicating this task was the fact that a complete edition cycle of the *ASM Handbook* (including completely new volumes on corrosion, tribology, materials characterization, and other topics) had been published since the earlier edition was produced. To ensure that the best product possible resulted from the revision/updating process, a 12-member Editorial Advisory Board representing industry, academia, and research laboratories was formed. All board members have been key contributors to the Handbook series or have been involved with other important ASM activities over the past decade. Under their guidance, an outline was established for the second edition that divided the book into five major parts: General Information; Irons, Steels, and High-Performance Alloys; Nonferrous Alloys and Special-Purpose Materials; Processing; and Testing, Inspection, and Materials Characterization.

**General Information** contains a glossary of more than 3000 terms, a collection of common engineering tables, and graphs comparing properties of metals and nonmetals. It also includes contributions on crystal structure, practical uses of phase diagrams, engineering design, and factors to be considered in the materials selection process.

**Irons, Steels, and High-Performance Alloys.** Emphasis is placed on properties and selection of ferrous alloys and heat-resistant superalloys. Important relationships between structure and properties in irons and steels are described. The effects of modern steelmaking practices on properties are examined, as is the influence of improved melting/refining methods on superalloy performance. New or expanded information is presented on austempered ductile irons, high-strength low-alloy steels, stainless steels (including duplex stainless steels), and powder metallurgy steels.

**Nonferrous Alloys and Special-Purpose Materials** comprises 14 major sections that describe the properties and selection of conventional (structural) nonferrous alloys and materials used for such special-purpose applications as magnetic or electrical devices, biomedical devices, and advanced aircraft/aerospace components. Metal-matrix composites and structural intermetallics--more recently developed materials not covered in the previous *Desk Edition*--are also described.

**Processing.** Processes extending through the entire life-cycle of a component are described, including extractive metallurgy, casting, forming, heat treatment, joining, surface cleaning, finishing and coating, and recycling. An entirely new section on powder metallurgy has also been added. The increased coverage of recycling technology reflects the response of the metals industry to environmental concerns.

**Testing, Inspection, and Materials Characterization.** In addition to offering information on failure analysis, fractography, nondestructive testing, mechanical testing, and metallography, a new section describes in practical terms the selection of characterization methods for bulk elemental analysis, bulk microstructural analysis, and surface analysis. New information on wear testing and tests for evaluating stress-corrosion cracking and hydrogen embrittlement is also presented.

## Acknowledgments

Before acknowledging contributors to the present volume, it is important to recognize the outstanding work of the first edition's editors: Timothy L. Gall and Howard E. Boyer (sadly, Howard passed away in 1990). Tim was truly the driving force behind the original *Desk Edition*. His vision, combined with Howard's superlative technical craftsmanship, resulted in what most consider the "flagship" publication of ASM.

In order to build upon the foundation of the first edition, the present editor had to call on many old friends and colleagues. In addition to serving on the Editorial Advisory Board, the following individuals were major contributors to the second edition: Kenneth H. Eckelmeyer (Sandia National Laboratories) authored the Section "Materials Characterization" and co-authored the article "Very High Density Metals." Ken, who has contributed numerous handbook articles over the years, was also a key member of the Organizing Committee for *Materials Characterization*, Volume 10 of the *ASM Handbook*, published in 1986. George F. Vander Voort (Buehler Ltd.) revised the Section "Metallography" and contributed to the Section "Fractography." George, who is the most prolific author in the 75 year history of the *Metals/ASM Handbook*, has contributed definitive reviews on embrittlement mechanisms in irons and steel, the use of light microscopy for metallographic and fractographic analysis, and image analysis for quantitative determination of microstructural constituents. Rodney R. Boyer (Boeing Commercial Airplane Group) revised the Section "Titanium and Titanium Alloys" and helped revise other articles throughout the Handbook that deal with titanium alloys. Rod also served as the principal editor of the *Materials Properties Handbook: Titanium Alloys*, published by ASM in 1994. Thomas S. Piwonka (University of Alabama) authored the Section "Casting." Tom also served as a section chairman and contributing author for *Casting*, Volume 15 of the *ASM Handbook*, published in 1988. Peter J. Blau (Oak Ridge National Laboratory) authored the article "Wear Testing." Peter also served as volume chairman of *Friction, Lubrication, and Wear Technology*, Volume 18 of the *ASM Handbook*, published in 1992.

Other notable contributors include Hugh Baker (Consulting Editor, ASM International), who authored the Section "Structure and Properties of Metals" and reviewed the Section "Magnesium and Magnesium Alloys." Hugh, who served on the Handbook staff from 1970 to 1979, was also the editor of *Alloy Phase Diagrams*, Volume 3 of *ASM Handbook*, published in 1992. Matthew J. Donachie (Rensselaer at Hartford) and Stephen J. Donachie (Special Metals Corporation) revised the Section "Superalloys." Matt, who edited the *Superalloys Source Book* published by ASM in 1984, also authored the article "Biomaterials." Erhard Klar (OMG Americas, retired) authored the Section "Powder Metallurgy" and reviewed several other P/M-related articles. Erhard also served as volume coordinator of *Powder Metallurgy*, Volume 7 of the *ASM Handbook*, published in 1984. Brajendra Mishra (Colorado School of Mines) authored the Sections "Steelmaking Practices and Their Influence on Properties" and "Extractive Metallurgy." John C. Bittence (Welshfield Studios) revised the Section "Recycling and Life-Cycle Analysis" and assisted in editing the Sections "Forming" and "Forging."

The efforts of the ASM staff must also be acknowledged. In particular, I would like to thank veteran technical editors Steven R. Lampman and Edward J. Kubel, Jr. for their help in completing the Sections "Failure Analysis," "Nondestructive Testing," and "Mechanical, Wear, and Corrosion Testing," and Scott D. Henry, Assistant Director of Technical Publications, for his unflagging support and patience throughout the project. The kind assistance of the ASM Library is also duly noted.

As a result of the collective experience and talent of all those listed above, the rich tradition of the *Metals Handbook* continues. Whether in print form, CD-ROM format, via the Internet, or some other remarkable vehicle made possible by the computer age, it will undoubtedly continue to serve the metallurgical community well into the next millennium. The best is yet to come!

Joseph R. Davis  
Davis & Associates, Chagrin Falls, Ohio

## **Source Acknowledgments**

Major sources for the Sections in this Handbook are listed below. Additional source information is provided in the reference lists that appear in many of the articles.

### ***Structure and Properties of Metals***

Much of this Section was adapted from *Alloy Phase Diagrams*, Volume 3, *ASM Handbook*, 1992, pages 1-1 to 1-29.

### ***Design Considerations and Materials Selection***

Much of this Section was adapted from various articles appearing in *Materials Selection and Design*, Volume 20, *ASM Handbook*, 1997.

### ***Structure/Property Relationships in Irons and Steels***

Much of this Section was adapted from various articles appearing in *Materials Selection and Design*, Volume 20, *ASM Handbook*, 1997, pages 357-382.

### ***Carbon and Alloy Steels***

This Section was condensed from *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Vol 1, *ASM Handbook*, 1990, pages 105 to 822. Supplemental information was also adapted from the *ASM Specialty Handbook: Carbon and Alloy Steels*, 1996, and *Fatigue and Fracture*, Vol 20, *ASM Handbook*, 1996.

### ***Cast Irons***

This Section was condensed from the *ASM Specialty Handbook: Cast Irons*, 1996, p 3 to 130.

### ***Ferrous Powder Metallurgy Materials***

This Section was condensed from *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1, *ASM Handbook*, 1990, pages 800 to 821 and from *Powder Metallurgy*, Volume 7, *ASM Handbook*, 1984, pages 79 to 99.

### ***Tool Steels***

This Section was condensed from the *ASM Specialty Handbook: Tool Materials*, 1995, pages 10 to 20, 21 to 31, 119 to 153, and 383 to 395.

### ***Stainless Steels***

Much of this Section was condensed from the *ASM Specialty Handbook: Stainless Steels*, 1994. Supplemental information was also adapted from the *ASM Specialty Handbook: Heat-Resistant Materials*, 1997, pages 123 to 178.

### ***Superalloys***

For more detailed information on superalloys, the reader is referred to the *ASM Specialty Handbook: Heat-Resistant Materials* (see, in particular, pages 219 to 344).

### ***Aluminum and Aluminum Alloys***

This Section was assembled from a variety of sources, including *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 3 to 215; the *ASM Specialty Handbook: Aluminum and Aluminum Alloys*, 1993, pages 3 to 159; and *Corrosion*, Volume 13, *ASM Handbook*, 1987, pages 583 to 609. Updated statistical information and property data were obtained from the Aluminum Association Inc.

### ***Copper and Copper Alloys***

This Section was assembled from a variety of sources, including *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 216 to 427, *Corrosion*, Volume 13, *ASM Handbook*, 1987, pages 610 to 640, and *Materials Selection and Design*, Volume 20, *ASM Handbook*, 1997, pages 389 to 393. Updated statistical information and composition/property data were obtained from the Copper Development Association Inc.

### ***Magnesium and Magnesium Alloys***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 455 to 479, and from *Corrosion*, Volume 13, *ASM Handbook*, 1987, pages 740 to 754.

### ***Titanium and Titanium Alloys***

For more detailed information on titanium and titanium alloys, the reader is referred to the *Materials Properties Handbook: Titanium Alloys* published by ASM International in 1994 and to *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2 of *ASM Handbook*, 1990 (see pages 586 to 660).

### ***Zinc and Zinc Alloys***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 527 to 542, and from *Corrosion*, Volume 13, *ASM Handbook*, 1987, pages 432 to 445 and 755 to 769.

### ***Tin and Tin Alloys***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 517 to 526.

### ***Lead and Lead Alloys***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 543 to 556, and from *Corrosion*, Volume 13, *ASM Handbook*, 1987, pages 784 to 792.

### ***Nickel and Nickel Alloys***

This Section was condensed from *Corrosion*, Volume 13, *ASM Handbook*, 1987, pages 641 to 657, and *Materials Selection and Design*, Volume 20, *ASM Handbook*, 1997, pages 393 to 396.

### ***Cobalt and Cobalt Alloys***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 446 to 454.

### ***Zirconium and Hafnium***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 661 to 669, and from *Corrosion*, Volume 13, *ASM Handbook*, 1987, p 707 to 721.

### ***Precious Metals and Alloys***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 688 to 719.

### ***Refractory Metals and Alloys***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 557 to 585, and from the *ASM Specialty Handbook: Heat-Resistant Materials*, 1997, pages 361 to 382.

### ***Cemented Carbides and Cermets***

This Section was condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 950 to 977, and from *Friction, Lubrication, and Wear Technology*, Volume 18, *ASM Handbook*, 1992, pages 795 to 800.

### ***Special-Purpose Materials***

Portions of this Section were condensed from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 761 to 1089. Supplemental information was also adapted from the *ASM Specialty Handbook: Aluminum and Aluminum Alloys*, 1993, pages 160 to 179 (aluminum-matrix composites), *ASM Specialty Handbook: Heat-Resistant Materials*, 1997, p 389 to 414 (structural intermetallics), and *Friction, Lubrication, and Wear Technology*, Volume 18, *ASM Handbook*, 1992, pages 741 to 765 (sliding bearings and hardfacing alloys).

### ***Forming***

This Section was condensed from *Forming and Forging*, Volume 14, *ASM Handbook*, 1988.

### ***Forging***

This Section was condensed from *Forming and Forging*, Volume 14, *ASM Handbook*, 1988.

### ***Powder Metallurgy***

More detailed information on powder metallurgy can be found in *Powder Metal Technologies and Applications*, Volume 7, *ASM Handbook*, 1998.

### ***Machining***

This Section was condensed from *Machining*, Volume 16, *ASM Handbook*, 1989, and the *Machining Data Handbook*, 3rd ed., published by Metcut Research Associates, Inc., Cincinnati, OH. Supplemental information was also taken from *Surface Engineering*, Volume 5, *ASM Handbook*, 1994, and the *ASM Specialty Handbook: Tool Materials*, 1995.

### ***Heat Treating***

This Section was condensed from *Heat Treating*, Volume 4, *ASM Handbook*, 1991.

### ***Joining***

This Section was condensed from *Welding, Brazing, and Soldering*, Volume 6, *ASM Handbook*, 1993.

### ***Surface Engineering***

This Section was condensed from *Surface Engineering*, Volume 5, *ASM Handbook*, 1994. Supplemental information was also taken from *Materials Selection and Design*, Volume 20, *ASM Handbook*, 1997, pages 470 to 490.

### ***Recycling and Life-Cycle Analysis***

This Section was condensed from *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1, *ASM Handbook*, 1990, pages 1023 to 1033; from *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials*, Volume 2, *ASM Handbook*, 1990, pages 1205 to 1232; and from *Materials Selection and Design*, Volume 20, *ASM Handbook*, 1997, pages 96 to 103 and 131 to 138.

### ***Failure Analysis***

This Section was condensed from *Failure Analysis and Prevention*, Volume 11, *ASM Handbook*, 1986, and *Fatigue and Fracture*, Volume 19, *ASM Handbook*, 1996, pages 371 to 380.

### ***Fractography***

Parts of this Section were condensed from *Fractography*, Volume 12, *ASM Handbook*, 1987. Updated material from the previous *Metals Handbook Desk Edition*, 1984, is also included.

### ***Nondestructive Testing***

This Section was condensed from *Nondestructive Evaluation and Quality Control*, Volume 17, *ASM Handbook*, 1989.

### ***Mechanical, Wear, and Corrosion Testing***

This Section was condensed from *Mechanical Testing*, Volume 8, *ASM Handbook*, 1985, and from *Fatigue and Fracture*, Volume 19, *ASM Handbook*, 1996.

## **General Information**

### ***Officers and Trustees of ASM International(1997-1998)***

#### **Officers**

- **Alton D. Romig, Jr.**, President and Trustee , Sandia National Laboratories
- **Hans H. Portisch**, Vice President and Trustee , Krupp VDM Austria GmbH
- **Michael J. DeHaemer**, Secretary and Managing Director , ASM International
- **W. Raymond Cribb**, Treasurer , Brush Wellman Inc.
- **George Krauss**, Immediate Past President , Colorado School of Mines

#### **Trustees**

- **Nicholas F. Fiore**, Carpenter Technology Corporation
- **Gerald G. Hoeft**, Caterpillar Inc.
- **Jennie S. Hwang**, H-Technologies Group Inc.
- **Thomas F. McCardle**, Kolene Corporation
- **Bhakta B. Rath**, U.S. Naval Research Laboratory
- **C. (Ravi) Ravindran**, Ryerson Polytechnic University
- **Darrell W. Smith**, Michigan Technological University
- **Leo G. Thompson**, Lindberg Corporation
- **James C. Williams**, GE Aircraft Engines

### ***Members of the ASM Handbook Committee (1997-1998)***

- **Michelle M. Gauthier**, (Chair 1997-;Member 1990-) , Raytheon Electronic Systems
- **Craig V. Darragh**, (Vice Chair 1997-;Member 1989-) , The Timken Company
- **Bruce P. Bardes** (1993-) , Materials Technology Solutions Company
- **Rodney R. Boyer** (1982-1985; 1995-) , Boeing Commercial Airplane Group
- **Toni M. Brugger** (1993-) , Carpenter Technology Corporation
- **R. Chattopadhyay** (1996-) , Consultant
- **Rosalind P. Cheslock** (1994-)
- **Aicha Elshabini-Riad** (1990-) , Virginia Polytechnic Institute & State University
- **Henry E. Fairman** (1993-) , MQS Inspection Inc.
- **Michael T. Hahn** (1995-) , Northrop Grumman Corporation
- **Larry D. Hanke** (1994-) , Materials Evaluation and Engineering Inc.
- **Jeffrey A. Hawk** (1997-) , U.S. Department of Energy
- **Dennis D. Huffman** (1982-) , The Timken Company
- **S. Jim Ibarra, Jr.** (1991-) , Amoco Corporation
- **Dwight Janoff** (1995-) , FMC Corporation
- **Paul J. Kovach** (1995-) , Stress Engineering Services Inc.
- **Peter W. Lee** (1990-) , The Timken Company
- **William L. Mankins** (1989-)
- **Mahi Sahoo** (1993-) , CANMET
- **Wilbur C. Simmons** (1993-) , Army Research Office

- **Karl P. Staudhammer** (1997-) , Los Alamos National Laboratory
- **Kenneth B. Tator** (1991-) , KTA-Tator Inc.
- **Malcolm C. Thomas** (1993-) , Allison Engine Company
- **George F. Vander Voort** (1997-) , Buehler Ltd.
- **Jeffrey Waldman** (1995-) , Drexel University
- **Dan Zhao** (1996-) , Essex Group Inc.

#### *Previous Chairs of the ASM Handbook Committee*

- **R.J. Austin**, (1992-1994) (Member 1984-)
- **L.B. Case**, (1931-1933) (Member 1927-1933)
- **T.D. Cooper**, (1984-1986) (Member 1981-1986)
- **E.O. Dixon**, (1952-1954) (Member 1947-1955)
- **R.L. Dowdell**, (1938-1939)(Member 1935-1939)
- **J.P. Gill**, (1937) (Member 1934-1937)
- **J.D. Graham**, (1966-1968) (Member 1961-1970)
- **J.F. Harper**, (1923-1926) (Member 1923-1926)
- **C.H. Herty, Jr.**, (1934-1936)(Member 1930-1936)
- **D.D. Huffman**, (1986-1990)(Member 1982-)
- **J.B. Johnson**, (1948-1951)(Member 1944-1951)
- **L.J. Korb**, (1983) (Member 1978-1983)
- **R.W.E. Leiter**, (1962-1963)(Member 1955-1958, 1960-1964)
- **G.V. Luerssen**, (1943-1947)(Member 1942-1947)
- **G.N. Maniar**, (1979-1980) (Member 1974-1980)
- **W.L. Mankins**, (1994-1997)(Member 1989-)
- **J.L. McCall**, (1982) (Member 1977-1982)
- **W.J. Merten**, (1927-1930) (Member 1923-1933)
- **D.L. Olson**, (1990-1992) (Member 1982-1988, 1989-1992)
- **N.E. Promisel**, (1955-1961)(Member 1954-1963)
- **G.J. Shubat**, (1973-1975) (Member 1966-1975)
- **W.A. Stadler**, (1969-1972)(Member 1962-1972)
- **R. Ward**, (1976-1978) (Member 1972-1978)
- **M.G.H. Wells**, (1981) (Member 1976-1981)
- **D.J. Wright**, (1964-1965) (Member 1959-1967)

#### *Staff*

ASM International staff who contributed to the development of the Volume included Scott D. Henry, Assistant Director of Reference Publications; Grace M. Davidson, Manager of Handbook Production; Bonnie R. Sanders, Manager of Copy Editing; Kathleen S. Dragolich, Production Coordinator; Erika K. Baxter and Alexandra B. Hoskins, Copy Editors; Alexandru Popaz-Pauna, Candace K. Mullet, and Jill A. Kinson, Production Assistants. Editorial assistance was provided by Denise Kelly, Heather Lampman, and Mary Jane Riddlebaugh. The Volume was prepared under the direction of William W. Scott, Jr., Director of Technical Publications.

#### *Conversion to Electronic Files*

*Metals Handbook Desk Edition* was converted to electronic files in 2000. The conversion was based on the first printing (1998). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Gayle Kalman, Scott Henry, and Robert Braddock. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

Source: *Corrosion Tests and Standards: Application and Interpretation*, ASTM, 1995, p 27

(a) Density of gases is given in g/L at 0 °C and 760 mm Hg (1 atm). Density of liquids is given in g/cm<sup>3</sup> at 20 °C.

(b) Because air is a mixture, it does not have a true molecular weight. This is the average molecular weight of its constituents.

(c) Subl. indicates that the substance sublimates at the temperature listed.

**Fig. 2** Strength versus density for various engineered materials. Strength is yield strength for metals/alloys and polymers, compressive strength for ceramics (note the broken property envelope lines), tear strength for elastomers, and tensile strength for composites. It should be noted that the tensile strength of engineering ceramics is about 15 times smaller than its compressive strength. Abbreviation key: CFRP, carbon-fiber reinforced polymer; GFRP, glass-fiber reinforced polymer; KFRP, kevlar-fiber reinforced polymer; PMMA, polymethyl methacrylate; Mel, melamines; PP, polypropylene; PC, polycarbonate; PS, polystyrene; PVC, polyvinyl chloride; HDPE, high-density polyethylene; LDPE, low-density polyethylene; PTFE, polytetrafluoroethylene; PU, polyurethane

**Table 15 Guide to the Unified Numbering System (UNS) for metals and alloys**

For additional details on the UNS, see the combined ASTM E 527/SAE J1066 standard, "Recommended Practice for Numbering Metals and Alloys."

UNS series	Metal/alloy
Nonferrous metals and alloys	
A00001-A99999	Aluminum and aluminum alloys
C00001-C99999	Copper and copper alloys
E00001-E99999	Rare earth and rare earth-like metals and alloys
E00001-E00999	Actinium
E01000-E20999	Cerium
E21000-E45999	Mixed rare earths (e.g., mischmetal)
E46000-E47999	Dysprosium
E48000-E49999	Erbium
E50000-E51999	Europium
E52000-E55999	Gadolinium
E56000-E57999	Holmium
E58000-E67999	Lanthanum
E68000-E68999	Lutetium
E69000-E73999	Neodymium
E74000-E77999	Praseodymium
E78000-E78999	Promethium

E79000-E82999	Samarium
E83000-E84999	Scandium
E85000-E86999	Terbium
E87000-E87999	Thulium
E88000-E89999	Ytterbium
E90000-E99999	Yttrium
L00001-L99999	Low-melting-point metals and alloys
L00001-L00999	Bismuth
L01001-L01999	Cadmium
L02001-L02999	Cesium
L03001-L03999	Gallium
L04001-L04999	Indium
L06001-L06999	Lithium
L07001-L07999	Mercury
L08001-L08999	Potassium
L09001-L09999	Rubidium
L10001-L10999	Selenium
L11001-L11999	Sodium
L13001-L13999	Tin
L50001-L59999	Lead

M00001-M99999	Miscellaneous nonferrous metals and alloys
M00001-M00999	Antimony
M01001-M01999	Arsenic
M02001-M02999	Barium
M03001-M03999	Calcium
M04001-M04999	Germanium
M05001-M05999	Plutonium
M06001-M06999	Strontium
M07001-M07999	Tellurium
M08001-M08999	Uranium
M10001-M19999	Magnesium
M20001-M29999	Manganese
M30001-M39999	Silicon
P00001-P99999	Precious metals and alloys
P00001-P00999	Gold
P01001-P01999	Iridium
P02001-P02999	Osmium
P03001-P03999	Palladium
P04001-P04999	Platinum
P05001-P05999	Rhodium

P06001-P06999	Ruthenium
P07001-P07999	Silver
R00001-R99999	Reactive and refractory metals and alloys
R01001-R01999	Boron
R02001-R02999	Hafnium
R03001-R03999	Molybdenum
R04001-R04999	Niobium (Columbium)
R05001-R05999	Tantalum
R06001-R06999	Thorium
R07001-R07999	Tungsten
R08001-R08999	Vanadium
R10001-R19999	Beryllium
R20001-R29999	Chromium
R30001-R39999	Cobalt
R40001-R49999	Rhenium
R50001-R59999	Titanium
R60001-R69999	Zirconium
Z00001-Z99999	Zinc and zinc alloys
<b>Ferrous metals and alloys</b>	
D00001-D99999	Specified mechanical properties of steels

F00001-F99999	Cast irons (gray, malleable, and ductile irons)
G00001-G99999	AISI and SAE carbon and alloy steels (except tool steels)
H00001-H99999	AISI and SAE H-steels (carbon, carbon-boron, and alloy H-steels)
J00001-J99999	Cast steels (except tool steels)
K00001-K99999	Miscellaneous steels and ferrous alloys
S00001-S99999	Heat- and corrosion-resistant (stainless) steels
T00001-T99999	Tool steels
<b>Welding filler metals</b>	
W00001-W99999	Welding filler metals, covered and tubular electrodes, classified by weld deposit composition
W00001-W09999	Carbon steel with no significant alloying elements
W10000-W19999	Manganese-molybdenum low-alloys steels
W20000-W29999	Nickel low-alloy steels
W30000-W39999	Austenitic stainless steels
W40000-W49999	Ferritic stainless steels
W50000-W59999	Chromium low-alloy steels
W60000-W69999	Copper-base alloys
W70000-W79999	Surfacing alloys
W80000-W89999	Nickel-base alloys

Table 16 SI prefixes--names and symbols

Exponential expression	Multiplication factor	Prefix	Symbol
$10^{24}$	1,000,000,000,000,000,000,000,000	yotta	Y
$10^{21}$	1,000,000,000,000,000,000,000	zetta	Z
$10^{18}$	1,000,000,000,000,000,000	exa	E
$10^{15}$	1,000,000,000,000,000	peta	P
$10^{12}$	1,000,000,000,000	tera	T
$10^9$	1,000,000,000	giga	G
$10^6$	1,000,000	meta	M
$10^3$	1,000	kilo	k
$10^2$	100	hecto <sup>(a)</sup>	h
$10^1$	10	deka <sup>(a)</sup>	da
$10^0$	1	BASE UNIT	
$10^{-1}$	0.1	deci <sup>(a)</sup>	d
$10^{-2}$	0.01	centi <sup>(a)</sup>	c
$10^{-3}$	0.001	milli	m
$10^{-6}$	0.000,001	micro	$\mu$
$10^{-9}$	0.000,000,001	nano	n
$10^{-12}$	0.000,000,000,001	pico	p
$10^{-15}$	0.000,000,000,000,001	femto	f
$10^{-18}$	0.000,000,000,000,000,001	atto	a

10 <sup>-21</sup>	0.000,000,000,000,000,000,001	zepto	z
10 <sup>-24</sup>	0.000,000,000,000,000,000,000,001	yocto	y

(a) Nonpreferred. Prefixes should be selected in steps of 10<sup>3</sup> so that the resultant number before the prefix is between 0.1 and 1000. These prefixes should not be used for units of linear measurement, but may be used for higher order units. For example, the linear measurement, decimeter, is nonpreferred, but square decimeter is acceptable.

Table 17 Base, supplementary, and derived SI units

Measure	Unit	Symbol	Formula
Base units			
Amount of substance	mole	mol	
Electric current	ampere	A	
Length	meter	m	
Luminous intensity	candela	cd	
Mass	kilogram	kg	
Thermodynamic temperature	kelvin	K	
Time	second	s	
Supplementary units			
Plane angle	radian	rad	
Solid angle	steradian	sr	
Derived units			
Absorbed dose	gray	Gy	J/kg
Acceleration	meter per second squared	m/s <sup>2</sup>	
Activity (of radionuclides)	becquerel	Bq	

Angular acceleration	radian per second squared	rad/s <sup>2</sup>	
Angular velocity	radian per second	rad/s	
Area	square meter	m <sup>2</sup>	
Concentration (of amount of substance)	mole per cubic meter	mol/m <sup>3</sup>	
Current density	ampere per square meter	A/m <sup>2</sup>	
Density, mass	kilogram per cubic meter	kg/m <sup>3</sup>	
Dose equivalent	sievert	Sv	J/kg
Electric capacitance	farad	F	C/V
Electric charge density	coulomb per cubic meter	C/m <sup>3</sup>	
Electric conductance	siemens	S	A/V
Electric field strength	volt per meter	V/m	
Electric flux density	coulomb per square meter	C/m <sup>2</sup>	
Electric potential, potential difference, electromotive force	volt	V	W/A
Electric resistance	ohm	Ω	V/A
Energy, work, quantity of heat	joule	J	N · m
Energy density	joule per cubic meter	J/m <sup>3</sup>	
Entropy	joule per kelvin	J/K	
Force	newton	N	kg · m/s <sup>2</sup>
Frequency	hertz	Hz	1/s
Heat capacity	joule per kelvin	J/K	
Heat flux density	watt per square meter	W/m <sup>2</sup>	

Illuminance	lux	lx	$\text{lm/m}^2$
Inductance	henry	H	$\text{Wb/A}$
Irradiance	watt per square meter	$\text{W/m}^2$	
Luminance	candela per square meter	$\text{cd/m}^2$	
Luminous flux	lumen	lm	$\text{cd} \cdot \text{sr}$
Magnetic field strength	ampere per meter	$\text{A/m}$	
Magnetic flux	weber	Wb	$\text{V} \cdot \text{s}$
Magnetic flux density	tesla	T	$\text{Wb/m}^2$
Molar energy	joule per mole	$\text{J/mol}$	
Molar entropy	joule per mole kelvin	$\text{J/mol} \cdot \text{K}$	
Molar heat capacity	joule per mole kelvin	$\text{J/mol} \cdot \text{K}$	
Moment of force	newton meter	$\text{N} \cdot \text{m}$	
Permeability	henry per meter	$\text{H/m}$	
Permittivity	farad per meter	$\text{F/m}$	
Power, radiant flux	watt	W	$\text{J/s}$
Pressure, stress	pascal	Pa	$\text{N/m}^2$
Quantity of electricity, electric charge	coulomb	C	$\text{A} \cdot \text{s}$
Radiance	watt per square meter steradian	$\text{W/m}^2 \cdot \text{sr}$	
Radiant intensity	watt per steradian	$\text{W/sr}$	
Specific heat capacity	joule per kilogram kelvin	$\text{J/kg} \cdot \text{K}$	
Specific energy	joule per kilogram	$\text{J/kg}$	

Specific entropy	joule per kilogram kelvin	J/kg · K	
Specific volume	cubic meter per kilogram	M <sup>3</sup> /kg	
Surface tension	newton per meter	N/m	
Thermal conductivity	watt per meter kelvin	W/m · K	
Velocity	meter per second	m/s	
viscosity, dynamic	pascal second	Pa · s	
Viscosity, kinematic	square meter per second	m <sup>2</sup> /s	
Volume	cubic meter	m <sup>3</sup>	
Wavenumber	1 per meter	1/m	

**Fig. 3** Fracture toughness versus strength for various engineered materials. Strength is yield strength for metals/alloys and polymers, compressive strength for ceramics (note the broken property envelope lines), tear strength for elastomers, and tensile strength for composites. It should be noted that the tensile strength of engineering ceramics is about 15 times smaller than its compressive strength. Abbreviation key: CFRP, carbon-fiber reinforced polymer; GFRP, glass-fiber reinforced polymer; KFRP, kevlar-fiber reinforced polymer; PMMA, polymethyl methacrylate; Mel, melamines; PP, polypropylene; PC, polycarbonate; PS, polystyrene; PVC, polyvinyl chloride; HDPE, high-density polyethylene; LDPE, low-density polyethylene; PTFE, polytetrafluoroethylene; PU, polyurethane

### Table 19 Alphabetical listing of common conversion factors

Conversion factors are written as a number greater than one and less than ten with six or fewer decimal places. This number is followed by the letter E (for exponent), a plus or minus symbol, and two digits that indicate the power of 10 by which the number must be multiplied to obtain the correct value. For example: 3.523 907 E - 02 is  $3.523\,907 \times 10^{-2}$  or 0.035 239 07. An asterisk (\*) after the sixth decimal place indicates that the conversion factor is exact and that all subsequent digits are zero. All other conversion factors have been rounded off.

To convert from	to	Multiply by
abampere	ampere (A)	1.000 000* E+01
abcoulomb	coulomb (C)	1.000 000* E+01
abfarad	farad (F)	1.000 000* E+09
abhenry	henry (H)	1.000 000* E-09
abmho	siemens (S)	1.000 000* E+09
abohm	ohm ( $\Omega$ )	1.000 000* E-09
abvolt	volt (V)	1.000 000* E-08
ampere hour	coulomb (C)	3.600 000* E+03
angstrom	meter (m)	1.000 000* E-10

## The Chemical Elements

Hugh Baker, Consulting Editor, ASM International

---

THE CHEMICAL ELEMENTS are the basic chemical substances; that is, they cannot be decomposed by chemical change or made by chemical union. These elements follow a periodic pattern related to the atomic mass of each that allows them to be arranged into a convenient table (see the periodic table shown in Fig. 1 and the corresponding Tables 1 and 2). As shown in the periodic table, most of the elements have metallic characteristics, and the table can be used to learn much about the chemical (and physical) nature of each metal.

**Table 1 Names and symbols for the elements (in alphabetical order)**

Name	Symbol
Actinium	Ac
Aluminum	Al
Americium	Am
Antimony	Sb <sup>(a)</sup>
Argon	Ar
Arsenic	As
Astatine	At
Barium	Ba
Berkelium	Bk
Beryllium	Be
Bismuth	Bi
Bohrium	Bh
Boron	B
Bromine	Br
Cadmium	Cd

Calcium	Ca
Californium	Cf
Carbon	C
Cerium	Ce
Cesium	Cs
Chlorine	Cl
Chromium	Cr
Cobalt	Co
Copper <sup>(b)</sup>	Cu
Curium	Cm
Dubnium	Db
Dysprosium	Dy
Einsteinium	Es
Erbium	Er
Europium	Eu
Fermium	Fm
Fluorine	F
Francium	Fr
Gadolinium	Gd
Gallium	Ga
Germanium	Ge

Gold <sup>(c)</sup>	Au
Hafnium	Hf
Hassium	Hs
Helium	He
Holmium	Ho
Hydrogen	H
Indium	In
Iodine	I
Iridium	Ir
Iron <sup>(d)</sup>	Fe
Krypton	Kr
Lanthanum	La
Lawrencium	Lr
Lead <sup>(e)</sup>	Pb
Lithium	Li
Lutetium	Lu
Magnesium	Mg
Manganese	Mn
Meitnerium	Mt
Mendelevium	Md
Mercury <sup>(f)</sup>	Hg

Molybdenum	Mo
Neodymium	Nd
Neon	Ne
Neptunium	Np
Nickel	Ni
Niobium <sup>(g)</sup>	Nb
Nitrogen	N
Nobelium	No
Osmium	Os
Oxygen	O
Palladium	Pd
Phosphorus	P
Platinum	Pt
Plutonium	Pu
Polonium	Po
Potassium <sup>(h)</sup>	K
Praseodymium	Pr
Promethium	Pm
Protactinium	Pa
Radium	Ra
Radon	Rn

Rhenium	Re
Rhodium	Rh
Rubidium	Rb
Ruthenium	Ru
Rutherfordium	Rf
Samarium	Sm
Scandium	Sc
Seaborgium	Sg
Selenium	Se
Silicon	Si
Silver <sup>(i)</sup>	Ag
Sodium <sup>(j)</sup>	Na
Strontium	Sr
Sulfur	S
Tantalum	Ta
Technetium	Tc
Tellurium	Te
Terbium	Tb
Thallium	Tl
Thorium	Th
Thulium	Tm

Tin <sup>(k)</sup>	Sn
Titanium	Ti
Tungsten <sup>(l)</sup>	W
Ununnilium	Uun
Unununium	Uuu
Uranium	U
Vanadium	V
Xenon	Xe
Ytterbium	Yb
Yttrium	Y
Zinc	Zn
Zirconium	Zr

- (a) Symbol based on the Latin word *stibium*.
- (b) Symbol based on the Latin word *cuprum*.
- (c) Symbol based on the Latin word *aurum*.
- (d) Symbol based on the Latin word *ferrum*.
- (e) Symbol based on the Latin word *plumbum*.
- (f) Symbol based on the Latin word *hydrargyrum*.
- (g) Originally named *columbium* (Cb). In 1948, IUPAC agreed upon *niobium* as the official name.
- (h) Symbol based on the Latin word *kalium*.

(i) Symbol based on the Latin word *argentum*.

(j) Symbol based on the Latin word *natrium*.

(k) Symbol based on the Latin word *stannum*.

(l) The origin of the symbol W is *wolfram*, named after the tungsten mineral *wolframite*.

**Table 2 List of elements in atomic number/atomic weight order**

At. No.	Symbol	Name	Atomic wt	Notes
1	H	Hydrogen	1.00794(7)	(a)(b)(c)
2	He	Helium	4.002602(2)	(a)(b)

109	Mt	Meitnerium	[266]	(e)(f)
110	Uun	Ununnilium	[269]	(e)(f)
111	Uuu	Unununium	[272]	(e)(f)

The data were obtained from the IUPAC Commission on Atomic Weights and Isotopic Abundances. More detailed information can be obtained by referring to *Pure Appl. Chem.*, Vol. 68, 1996, p 2339-2359.

- (a) Geological specimens are known in which the element has an isotopic composition outside the limits for normal material. The difference between the atomic weight of the element in such specimens and that given in the table may exceed the stated uncertainty.
- (b) Range in isotopic composition of normal terrestrial material prevents a more precise value being given; the tabulated value should be applicable to any normal material.
- (c) Modified isotopic compositions may be found in commercially available material because it has been subject to an undisclosed or inadvertent isotopic fractionation. Substantial deviations in atomic weight of the element from that given in the table can occur.
- (d) Commercially available Li materials have atomic weights that range between 6.94 and 6.99; if a more accurate value is required, it must be determined for the specific material.
- (e) Element has no stable nuclides. The value enclosed in brackets, for example, [209], indicates the mass number of the longest-lived isotope of the element. However three such elements (Th, Pa, and U) do have a characteristic terrestrial isotopic composition, and for these an atomic weight is tabulated.

- (f) The names and symbols for elements 110-111 are under review. The temporary system recommended by J. Chatt, *Pure Appl. Chem.*, Vol 51, 1979, p 381-384 is used above. The names of elements 101 to 109 were confirmed at the IUPAC General Assembly held in Geneva (press release 30 Aug 1997).

**Fig. 1** Periodic table of the elements. Values in brackets indicate the mass number of the longest lived isotope of the radioactive element.

In the periodic table (Fig. 1), the elements are arranged in the order of increasing *atomic number* (the number of protons in the nucleus), but those that have the same number of electrons inhabiting their outermost electron shells (and, therefore, having similar chemical behavior) are grouped under each other; hence, the vertical columns of related elements in the periodic table are called *groups*. As atomic number increases, more orbital electrons must be accommodated in the shells, and as each outermost shell is filled a new outermost shell (and a new *period* of the table) is begun. Because the additional shells are larger than the preceding shells, there is room for more electrons and the periods get longer: from two (period 1) to eight and eight (periods 2 and 3), then to eighteen and eighteen (periods 4 and 5), and finally to thirty-two and (probably) thirty-two (periods 6 and 7).

Over the years, various conventions have been used to identify each group in the periodic table. For example, the 1948 Edition of the *Metals Handbook* used a system similar to that adopted by the International Union of Pure and Applied Chemistry (IUPAC) in 1970 in which the left-side and right-side elements in periods 4 through 7 are distinguished by the addition of the letters "A" and "B," respectively (see Fig. 1), the only difference being that the Handbook used small (lower-case) letters with the Roman numerals rather than capital (upper-case) letters. In contrast to the 1970 IUPAC system, which was commonly used in Europe, the Chemical Abstracts Service (CAS) of the American Chemical Society and many other U.S. chemists applied the "B" to the additional groups (groups 3 through 12) in periods 4 through 7 and "A" to the rest. Other conventions that have been occasionally followed in the past are to use "0" instead of VIIIA or VIIIB to identify group 18, and to use Arabic numerals instead of Roman numerals. The most recent (1988) IUPAC recommendation is to eliminate both practices and to use Arabic numerals 1 through 18 instead.

Another common practice is to identify groups of similar elements with collective names. For example, the elements lithium, sodium, potassium, rubidium, cesium, and francium in group 1 are called *alkali metals* from the Arabic for "the ashes" (hydrogen, which is not normally a solid, is not included), and all the elements in group 2 are called *alkaline earth metals*. While not yet approved by IUPAC, the term *pnictogens* or *pnictides* has been applied to the elements in group 15; the term is from the Greek for "stifle, choke, or strangle," which alludes to nitrogen, that is, "burnt air." The term *chalcogens* has been applied to group 16 elements; the term is from the Greek for "copper," which first alluded to the common occurrence of oxygen and sulfur in many copper ores, but later referred to all these elements that were "ore formers." The term *halogens* (from the Greek for "salt") has been applied to group 17, and the elements in group 18 are called *noble gases* or *inert gases*. Sometimes hydrogen is positioned at the top of the halogen group in addition to its normal position at the top of group 1.

Rows of some similar elements are similarly named. For example, the elements in rows 3 through 10, whose atoms have an incomplete *d* subshell of electrons, are called *transition elements* or *transition metals*. IUPAC 1988, however, also includes the atoms in row 11 in the group of transition elements, while other organizations include *all* the elements between rows 2 and 12. The elements lanthanum through lutetium (atomic numbers 57 through 71) are termed *lanthanide elements*, *lanthanide metals*, or simply *lanthanides*. The lanthanides together with group 3 elements yttrium (atomic number 39) and scandium (atomic number 21) are called *rare earth elements*, *rare earth metals*, or simply *rare earths*. The elements actinium through lawrencium (atomic numbers 89 through 103) are similarly termed *actinide elements*, *actinide metals*, or simply *actinides* (or sometimes second-series rare earths), while those from thorium (atomic number 90) through lawrencium (atomic number 103) are termed *actinoids*.

As stated earlier, most of the chemical elements are *metals*. (The word "metal" is derived from the Greek "metallon," which is believed to have originated in a verb meaning to seek, search after, or inquire about.) In modern science, a metal is any element that tends to lose electrons from the outer shells of its atoms, with the resulting positive ions held together in a unique crystal structure by the cloud of these free electrons in a mechanism that has been called *metallic bonding*. This type of atomic bonding is in contrast to ionic bonding and to covalent bonding. In *ionic bonding*, transfer of valence (outer shell) electrons between dissimilar atoms produces stable outer shells in each and results in positive and negative ions that are mutually attracted by coulombic forces, but do not form a crystal. In *covalent bonding*, valence electrons are shared, rather than exchanged, and a nonmetallic crystal can form, for example, the diamond form of carbon.

The cloud of free electrons in metallic crystals gives rise to the three physical characteristics typical of solid metals: metals are good conductors of electricity, good conductors of heat, and they have a lustrous appearance. In addition, most elemental metals are malleable, ductile, generally denser than other elemental substances, and usually form positive ions. Those elements that do not display the characteristics of the metallic elements are called *nonmetals* (see the periodic table). However, there are some elements that act as metals under some circumstances and act like nonmetals

under different circumstances. These are now called *semimetals*, but have been called *metalloids* (like metals). As shown, the boundaries separating the regions in the periodic table covered by the three classes of elements are not distinct except that nonmetals never form positive ions.

# Crystal Structure of Metallic Elements

Hugh Baker, Consulting Editor, ASM International

---

## Introduction

CRYSTAL STRUCTURE, as defined broadly, is the arrangement of atoms or molecules in the solid state. Crystal structure also involves consideration of defects, or abnormalities, in the idealized atomic/molecular arrangements. The collective arrangement of these atoms on a scale much greater than that of the individual atom is referred to as the microstructure of the material.

This article briefly reviews the terms and basic concepts associated with crystal structures that have been widely studied and are of the most importance to metallurgists. More detailed information on the crystal structure of metals can be found in Volume 9, *Metallography and Microstructures*, of the *ASM Handbook* and in the Selected References listed at the conclusion of this article.

## Crystallographic Terms and Basic Concepts

A *crystal* is a solid consisting of atoms or molecules arranged in a pattern that is repetitive in three dimensions. The arrangement of the atoms or molecules in the interior of a crystal is called its *crystal structure*. The *unit cell* of a crystal is the smallest pattern of arrangement that can be contained in a parallelepiped, the edges of which form the *a*, *b*, and *c* axes of the crystal. The three-dimensional aggregation of unit cells in the crystal forms a *space lattice*, or *Bravais lattice* (see Fig. 1).

**Fig. 1** A space lattice. (Bold lines outline a unit cell.)

**Crystal Systems.** Seven different *crystal systems* are recognized in crystallography, each having a different set of axes, unit-cell edge lengths, and interaxial angles (see Table 1). Unit-cell *edge lengths* *a*, *b*, and *c* are measured along the corresponding *a*, *b*, and *c* axes (see Fig. 2). Unit-cell faces are identified by capital letters: face *A* contains axes *b* and *c*, face *B* contains *c* and *a*, and face *C* contains *a* and *b*. (Faces are not labeled in Fig. 2.) Interaxial angle  $\alpha$  occurs in face *A*, angle  $\beta$  in face *B*, and angle  $\gamma$  in face *C* (see Fig. 2).

**Table 1 Relationships of edge lengths and of interaxial angles for the seven crystal systems**

Crystal system	Edge lengths	Interaxial angles	Examples
Triclinic (anorthic)	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma \neq 90^\circ$	HgK
Monoclinic	$a \neq b \neq c$	$\alpha = \gamma = 90^\circ \neq \beta$	$\beta$ S; CoSb <sub>2</sub>
Orthorhombic	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90^\circ$	$\alpha$ S; Ga; Fe <sub>3</sub> C (cementite)
Tetragonal	$a = b \neq c$	$\alpha = \beta = \gamma = 90^\circ$	$\beta$ Sn (white); TiO <sub>2</sub>
Hexagonal	$a = b \neq c$	$\alpha = \beta = 90^\circ; \gamma = 120^\circ$	Zn; Cd; NiAs
Rhombohedral <sup>(a)</sup>	$a = b = c$	$\alpha = \beta = \gamma = 90^\circ$	As; Sb; Bi; calcite
Cubic	$a = b = c$	$\alpha = \beta = \gamma = 90^\circ$	Cu; Ag; Au; Fe; NaCl

(a) Rhombohedral crystals (sometimes called trigonal) also can be described by using hexagonal axes (rhombohedral-hexagonal).

**Fig. 2** Crystal axes and unit-cell edge lengths. (Unit-cell faces are shown in the illustration, but to avoid confusion, they are not labeled.)

**Lattice Dimensions.** It should be noted that the unit-cell edge lengths and interaxial angles are unique for each crystalline substance. The unique edge lengths are called *lattice parameters*. The term *lattice constant* also has been used for the length of an edge, but the values of edge length are not constant, varying with composition within a phase field and also with temperature due to thermal expansion and contraction. (Reported lattice-parameter values are assumed to be room-temperature values unless otherwise specified.) Interaxial angles other than  $90^\circ$  or  $120^\circ$  also can change slightly with changes in composition. When the edges of the unit cell are not equal in all three directions, all unequal lengths must be stated to completely define the crystal. The same is true if all interaxial angles are not equal. When defining the unit-cell size of an alloy phase, the possibility of crystal ordering occurring over several unit cells should be considered.

**Lattice Points.** As shown in Fig. 1, a space lattice can be viewed as a three-dimensional network of straight lines. The intersections of the lines (called *lattice points*) represent locations in space for the same kind of atom or group of atoms of

identical composition, arrangement, and orientation. There are five basic arrangements for lattice points within a unit cell. The first four are: primitive (simple), having lattice points solely at cell corners; base-face centered (end-centered), having lattice points centered on the *C* faces, or ends of the cell; all-face centered, having lattice points centered on all faces; and innercentered (body-centered), having lattice points at the center of the volume of the unit cell. The fifth arrangement, the primitive rhombohedral unit cell, is considered a separate basic arrangement, as shown in the following section on crystal-structure nomenclature. These five basic arrangements are identified by capital letters as follows: *P* for the primitive cubic, *C* for the cubic cell with lattice points on the two *C* faces, *F* for all-face-centered cubic, *I* for innercentered (body-centered) cubic, and *R* for primitive rhombohedral.

**Crystal-Structure Nomenclature.** When the seven crystal systems are considered together with the five space lattices, the combinations listed in Table 2 and shown in Fig. 3 are obtained. These fourteen combinations form the basis of the system of *Pearson symbols* developed by William B. Pearson, which are widely used to identify crystal types. As can be seen in the table, the Pearson symbol uses a small letter to identify the crystal system and a capital letter to identify the space lattice. To these is added a number equal to the number of atoms in the unit cell conventionally selected for the particular crystal type. When determining the number of atoms in the unit cell, it should be remembered that each atom that is shared with an adjacent cell (or cells) must be counted as only a fraction of an atom. The Pearson symbols for some simple metal crystals are shown in Fig. 4, along with schematics illustrating the atom arrangements in the unit cell.

**Table 2 The 14-space (Bravais) lattices and their Pearson symbols (see also Fig. 2)**

Crystal system	Space lattice	Pearson symbol
Triclinic (anorthic)	Primitive	<i>aP</i>
Monoclinic	Primitive	<i>mP</i>
	Base centered <sup>(a)</sup>	<i>mC</i>
Orthorhombic	Primitive	<i>oP</i>
	Base centered <sup>(a)</sup>	<i>oC</i>
	Body centered	<i>oI</i>
	Face centered	<i>oF</i>
Tetragonal	Primitive	<i>tP</i>
	Body centered	<i>tI</i>
Hexagonal	Primitive	<i>hP</i>
Rhombohedral	Primitive	<i>hR</i>
Cubic	Primitive	<i>cP</i>

	Body centered	$cI$
	Face centered	$cF$

- (a) The face that has a lattice point at its center may be chosen as the  $c$  face (the  $xy$  plane), denoted by the symbol  $C$ , or as the  $a$  or  $b$  face, denoted by  $A$  or  $B$ , because the choice of axes is arbitrary and does not alter the actual translations of the lattice.

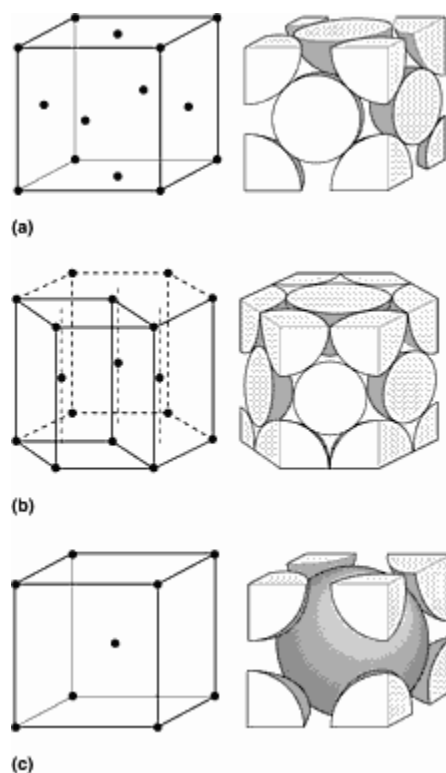

**Fig. 3** The 14-space (Bravais) lattices illustrated by a unit cell of each: (1) triclinic, primitive; (2) monoclinic, primitive; (3) monoclinic, base centered; (4) orthorhombic, primitive; (5) orthorhombic, base centered; (6) orthorhombic, body centered; (7) orthorhombic, face centered; (8) tetragonal, primitive; (9) tetragonal, body centered; (10) hexagonal, primitive; (11) rhombohedral, primitive; (12) cubic, primitive; (13) cubic, body centered; (14) cubic, face centered

**Fig. 4** Unit cells and atom positions for some simple metal crystals. Also listed are the space lattice and crystal system, space-group notation, and prototype for each crystal. The lattice parameters reported are for the prototype crystal. In order to show the atom arrangements more clearly, the atoms in these drawings are shown much smaller than their true effective size in real crystals.

Several of the many possible crystal structures possible are so commonly found in metallic systems that they are often identified by three-letter abbreviations that combine the space lattice with crystal system. For example, bcc for body-centered cubic (two atoms per unit cell), fcc is used for face-centered cubic (four atoms per unit cell), and cph for close-packed hexagonal (two atoms per unit cell). (The latter space-lattice/crystal system is also commonly referred to as hexagonal close-packed, hcp, in metallurgical literature.)

It should be noted that in the schematic representations shown in Fig. 4, the different kinds of atoms in the prototype crystal illustrated are drawn to represent their relative sizes, but in order to show the arrangements more clearly, all the atoms are shown much smaller than their true effective size in real crystals. A more true representation of the effective diameters of the atoms in a unit cell is shown in Fig. 5 for three common crystals.

**Fig. 5** Unit cells and atom positions for (a) face-centered cubic, (b) close-packed hexagonal, and (c) body-centered cubic unit cells. The positions of the atoms are shown as dots at the left of each pair of drawings, while the atoms themselves are shown close to their true effective size by spheres or portions of spheres at the right of each pair.

Each atom arrangement shown in Fig. 4 (and all other arrangements) is characterized by efficient atom packing and a high *coordination number*, which is the number of nearest neighbors surrounding each atom in the cell. Both the fcc and cph structures have a coordination number of 12, while for bcc it is 8 (plus 6 additional neighbors only slightly farther distant).

Space-group notation is a symbolic description of the space lattice and symmetry of a crystal. It consists of the symbol for the space lattice followed by letters and numbers that designate the symmetry of the crystal. The space-group notation for each unit cell illustrated in Fig. 4 is identified next to it.

To assist in classification and identification, each crystal-structure type is assigned a representative substance (element or phase) having that structure. The substance selected is called the *structure prototype* for that structure. Generally accepted prototypes for some metal crystals are listed in Fig. 4.

Many metals, and some nonmetals, exist in more than one crystalline form, a phenomenon known as *polymorphism*. When found in elemental solids, the condition is known as *allotropy*. The prevailing crystal structure depends on both the temperature and external pressure. For example, at atmospheric pressure, iron is bcc at temperatures below 912 °C (1674 °F), fcc between 912 and 1394 °C (1674 and 2541 °F), and above 1394 °C iron reverts to the bcc form until melting at 1538 °C (2800 °F). Titanium, zirconium, and hafnium all exhibit a transition from a cph structure to bcc on heating. Another familiar example is carbon: hexagonal graphite is the stable allotrope at ambient conditions, whereas the fcc allotrope diamond is formed at extremely high pressures. Crystallographic information for the allotropes of the metallic elements can be found in Table 3. Here the data are presented in terms of the Pearson symbol, space group, and prototype of the structure. Low-temperature structures are included for the diatomic and rare gases, which show many similarities with respect to the metallic elements.

Source: *Alloy Phase Diagrams*, Vol 3, *ASM Handbook*, ASM International, 1992, p 14-10 to 14-12

(a) HP, high pressure.

(b) The lattice parameter of the unit cells are considered to be accurate  $\pm 2$  in the last reported digit.

An important source of information on crystal structures for many years was *Structure Reports* (*Strukturbericht* in German). In this publication, crystal structures were classified by a designation consisting of a capital letter (*A* for elements, *B* for AB-type phases, *C* for AB<sub>2</sub>-type phases, *D* for other binary phases, *E* for ternary phases, and *L* for superlattices), followed a number consecutively assigned (within each group) at the time the type was reported. To further distinguish among crystal types, inferior letters and numbers, as well as prime marks, were added to some designations. Because the Strukturbericht designation cannot be conveniently and systematically expanded to cover the large variety of crystal structures currently being encountered, the system is falling into disuse. Relations among Strukturbericht designations and Pearson symbols, space groups, structure prototypes can be found in the Appendix to Volume 3, *Alloy Phase Diagrams*, of the *ASM Handbook*.

**Solid-Solution Mechanisms.** There are only two mechanisms by which a metal crystal can dissolve atoms of a different element. If the atoms of the solute element are sufficiently smaller than the atoms comprising the solvent crystal, the solute atoms can fit into the spaces between the larger atoms to form an *interstitial solid solution* (see Fig. 6a). The only solute atoms small enough to fit into the interstices of metal crystals, however, are hydrogen, nitrogen, carbon, and boron. (The other small-diameter atoms, such as oxygen, tend to form compounds with metals rather than dissolve in them.) The rest of the elements dissolve in solid metals by replacing a solvent atom at a lattice point to form a *substitutional solid solution* (see Fig. 6b). When both small and large solute atoms are present, the solid solution can be both interstitial and substitutional. The addition of foreign atoms by either mechanism results in distortion of the crystal lattice and an increase in its internal energy. This distortion energy causes some hardening and strengthening of the alloy called *solution hardening*. The solvent phase becomes saturated with the solute atoms and reaches its limit of homogeneity when the distortion energy reaches a critical value determined by the thermodynamics of the system.

**Fig. 6** Solid-solution mechanisms. (a) Interstitial. (b) Substitutional

**Ordered Solutions.** As mentioned earlier, some alloy solutions in the ordered state have periodic structures having unit cells many times larger than in the disordered state, the long period being either along one axis, as in Fig. 7, or along two axes, as in Fig. 8. The length of a superperiod formed by *long-period ordering* depends on the alloy system and the composition within the system. Figure 7 shows an AuCu II structure having a one-dimensional long-range *superlattice*, with boundaries between the *antiphase domains* at intervals of five unit cells of the disordered state. It is orthorhombic when ordered, and face-centered cubic when disordered. Figure 8 shows a two-dimensional long-period superlattice as in certain AB<sub>3</sub> alloys (Cu-Pd, Au-Zn, Au-Mn), having antiphase boundaries spaced at intervals  $M_1$  and  $M_2$  and unit-cell dimensions  $a$ ,  $b$ , and  $c$ , in the ordered state. This superlattice is orthorhombic when ordered, and face-centered cubic when disordered.

**Fig. 7** AuCu II structure; a one-dimensional, long-period superlattice, having antiphase boundaries spaced at intervals of five unit cells of the disordered state

**Fig. 8** Two-dimensional, long-period superlattice, having antiphase boundaries spaced at intervals  $M_1$  and  $M_2$  and unit-cell dimensions  $a$ ,  $b$ , and  $c$  in the ordered state. The palladium atom has different positions in the small cubes in domains I, II, III, and IV.

## Crystal Defects and Plastic Flow

Crystal defects are important features in all real crystals. Some of the most significant defects are described below.

**Point defects** include vacant atom positions that are occupied in perfect crystals. These vacancies increase in number as temperature is increased, and by jumping about from one lattice site to another they cause diffusion.

Interstitial B atoms are those located between the A atoms of the normal perfect-crystal array; thus, the carbon atoms in bcc ferrite are interstitials in that they fit between the iron atoms of its bcc structure, which is similar to the  $cI2$  type illustrated in Fig. 4. Substitutional B atoms are located at atom positions formerly occupied by A atoms in a normal, perfect-crystal array. A B atom in either substitutional or interstitial solid solution is another common form of point defect.

There are also many close pairs and clusters of point defects, such as divacancies, trivacancies, and interstitial-vacancy pairs.

**Line Defects.** *Dislocations* are *line defects* that exist in all real crystals. An *edge dislocation*, which is the edge of an incomplete plane of atoms within a crystal, is represented in cross section in Fig. 9. In this illustration, the incomplete plane extends part way through the crystal from the top down, and the edge dislocation (which is indicated by the standard symbol ( $\perp$ )) is its lower edge.

**Fig. 9** A section through an edge dislocation, which is perpendicular to the plane of the illustration and is indicated by the symbol  $\perp$ .

If forces, as indicated by the arrows in Fig. 10, are applied to a crystal, such as the perfect crystal shown in Fig. 10(a), one part of the crystal will slip. The edge of the slipped region, shown as a dashed line in Fig. 10(b), is a dislocation. The portion of the line at the left near the front of the crystal and perpendicular to the arrows, in Fig. 10(b), is an edge dislocation, because the displacement involved is perpendicular to the dislocation.

**Fig. 10** Four stages of slip deformation by formation and movement of a dislocation (dashed line) through a crystal

The *slip deformation* in Fig. 10(b) has also formed another type of dislocation. The part of the slipped region near the right side, where the displacement is parallel to the dislocation, is called a *screw dislocation*. In this part, the crystal no longer is made of parallel planes of atoms, but instead consists of a single plane in the form of a helical ramp (screw).

As the slipped region spreads across the slip plane, the edge-type portion of the dislocation moves out of the crystal leaving the screw-type portion still embedded, as shown in Fig. 10(c). When all of the dislocation finally emerges from the crystal, the crystal is again perfect, but with the upper part displaced one unit cell from the lower part, as shown in Fig. 10(d). Thus, Fig. 10 illustrates the mechanism of *plastic flow* by the slip process, which is actually flow by dislocation movement.

The displacement that occurs when a dislocation passes a point is described by a vector, known as the Burgers vector (**b**). The direction of the vector with respect to the dislocation line and the length of the vector with respect to the identity distance in the direction of the vector are the fundamental characteristics of a dislocation. The perfection of a crystal lattice is restored after the passage of a dislocation, as indicated in Fig. 10(d), provided no additional defects are generated in the process.

Each dislocation that remains in a crystal is the source of local stresses. The nature of these microstresses is indicated by the arrows in Fig. 11, which presents (qualitatively) the stresses acting on small volumes at different positions around the

dislocation at the lower edge of the incomplete plane of atoms. Interstitial atoms usually cluster in regions where tensile stresses make more room for them, as in the lower central part of Fig. 11.

**Fig. 11** Crystal containing an edge dislocation, indicating qualitatively the stress (shown by the direction of the arrows) at four positions around the dislocation

Individual crystal grains, which have different lattice orientations, are separated by large-angle boundaries (*grain boundaries*). In addition, the individual grains are separated by small-angle boundaries (*subboundaries*) into *subgrains* that differ very little in orientation. These subboundaries may be considered as arrays of dislocations; *tilt boundaries* are arrays of edge dislocations, *twist boundaries* are arrays of screw dislocations. A tilt boundary is represented in Fig. 12 by the series of edge dislocations in a vertical row. Compared with large-angle boundaries, small-angle boundaries are less severe defects, obstruct plastic flow less, and are less effective as regions for chemical attack and segregation of alloying constituents. In general, mixed types of grain-boundary defects are common. All grain boundaries are sinks into which vacancies and dislocations can disappear and may also serve as sources of these defects; they are important factors in creep deformation.

**Fig. 12** Small-angle boundary (subboundary) of the tilt type, which consists of a vertical array of edge dislocations

**Stacking faults** are two-dimensional defects that are planes where there is an error in the normal sequence of stacking of atom layers. Stacking faults may be formed during the growth of a crystal. They may also result from motion of *partial dislocations*. Contrary to a *full dislocation*, which produces a displacement of a full distance between the lattice points, a partial dislocation produces a movement that is less than a full distance.

**Twins** are portions of a crystal that have certain specific orientations with respect to each other. The twin relationship may be such that the lattice of one part is the mirror image of that of the other, or one part may be related to the other by a certain rotation about a certain crystallographic axis. *Growth twins* may occur frequently during crystallization from the liquid or the vapor state, by growth during annealing (by recrystallization or by grain-growth processes), or by the movement between solid phases such as during phase transformation. Plastic deformation by shear may produce *deformation twins* (*mechanical twins*). Twin boundaries generally are very flat, appearing as straight lines in micrographs, and are two-dimensional defects of lower energy than large-angle grain boundaries. Twin boundaries are, therefore, less effective as sources and sinks of other defects and are less active in deformation and corrosion than are ordinary grain boundaries.

**Cold Work.** Plastic deformation of a metal at a temperature at which annealing does not rapidly take place is called *cold work*, that temperature depending mainly on the metal in question. As the amount of cold work builds up, the distortion caused in the internal structure of the metal makes further plastic deformation more difficult, and the strength and hardness of the metal increases.

# Alloy Phase Diagrams and Microstructure

Hugh Baker, Consulting Editor, ASM International

---

## Introduction

ALLOY PHASE DIAGRAMS are useful to metallurgists, materials engineers, and materials scientists in four major areas: (1) development of new alloys for specific applications, (2) fabrication of these alloys into useful configurations, (3) design and control of heat treatment procedures for specific alloys that will produce the required mechanical, physical, and chemical properties, and (4) solving problems that arise with specific alloys in their performance in commercial applications, thus improving product predictability. In all these areas, the use of phase diagrams allows research, development, and production to be done more efficiently and cost effectively.

In the area of alloy development, phase diagrams have proved invaluable for tailoring existing alloys to avoid overdesign in current applications, designing improved alloys for existing and new applications, designing special alloys for special applications, and developing alternative alloys or alloys with substitute alloying elements to replace those containing scarce, expensive, hazardous, or "critical" alloying elements. Application of alloy phase diagrams in processing includes their use to select proper parameters for working ingots, blooms, and billets, finding causes and cures for microporosity and cracks in castings and welds, controlling solution heat treating to prevent damage caused by incipient melting, and developing new processing technology.

In the area of performance, phase diagrams give an indication of which phases are thermodynamically stable in an alloy and can be expected to be present over a long time when the part is subjected to a particular temperature (e.g., in an automotive exhaust system). Phase diagrams also are consulted when attacking service problems such as pitting and intergranular corrosion, hydrogen damage, and hot corrosion.

In a majority of the more widely used commercial alloys, the allowable composition range encompasses only a small portion of the relevant phase diagram. The nonequilibrium conditions that are usually encountered in practice, however, necessitate the knowledge of a much greater portion of the diagram. Therefore, a thorough understanding of alloy phase diagrams in general and their practical use will prove to be of great help to a metallurgist expected to solve problems in any of the areas mentioned above.

## Common Terms

**Phases.** All materials exist in gaseous, liquid, or solid form (usually referred to as a "phase"), depending on the conditions of state. *State variables* include composition, temperature, pressure, magnetic field, electrostatic field, gravitational field, and so forth. The term "phase" refers to that region of space occupied by a physically homogeneous material. However, there are two uses of the term: the strict sense normally used by physical scientists and the somewhat less strict sense normally used by materials engineers. In the strictest sense, homogeneous means that the physical properties throughout the region of space occupied by the phase are absolutely identical, and any change in condition of state, no matter how small, will result in a different phase. For example, a sample of solid metal with an apparently homogeneous appearance

is not truly a single-phase material because the pressure condition varies in the sample due to its own weight in the gravitational field.

In a phase diagram, however, each single-phase field (phase fields are discussed in a later section) is usually given a single label, and engineers often find it convenient to use this label to refer to all the materials lying within the field, regardless of how much the physical properties of the materials continuously change from one part of the field to another. This means that in engineering practice, the distinction between the terms "phase" and "phase field" is seldom made, and all materials having the same phase name are referred to as the same phase.

**Equilibrium.** There are three types of equilibria: stable, metastable, and unstable. These three are illustrated in a mechanical sense in Fig. 1. Stable equilibrium exists when the object is in its lowest energy condition; metastable equilibrium exists when additional energy must be introduced before the object can reach true stability; unstable equilibrium exists when no additional energy is needed before reaching metastability or stability. Although true stable equilibrium conditions seldom exist in metal objects, the study of equilibrium systems are extremely valuable, because it constitutes a limiting condition from which actual conditions can be estimated.

**Fig. 1** Mechanical equilibria. (a) Stable. (b) Metastable. (c) Unstable

**Polymorphism.** The structure of solid elements and compounds under stable equilibrium conditions is crystalline, and the crystal structure of each is unique. Some elements and compounds, however, are *polymorphic* (multishaped), that is, their structure transforms from one crystal structure to another with changes in temperature and pressure, each unique structure constituting a distinctively separate phase. The term *allotropy* (existing in another form) is usually used to describe polymorphic changes in chemical elements (see the table contained in Appendix 2 to this article).

**Metastable Phases.** Under some conditions, metastable crystal structures can form instead of stable structures. Rapid freezing is a common method of producing metastable structures, but some (such as  $\text{Fe}_3\text{C}$ , or "cementite") are produced at moderately slow cooling rates. With extremely rapid freezing, even thermodynamically unstable structures (such as amorphous metallic "glasses") can be produced.

**Systems.** A physical *system* consists of a substance (or a group of substances) that is isolated from its surroundings, a concept used to facilitate study of the effects of conditions of state. By "isolated," it is meant that there is no interchange of mass with its surroundings. The substances in alloy systems, for example, might be two metals such as copper and zinc; a metal and a nonmetal such as iron and carbon; a metal and an intermetallic compound such as iron and cementite; or several metals such as aluminum, magnesium, and manganese. These substances constitute the *components* comprising the system and should not be confused with the various phases found within the system. A system, however, also can consist of a single component, such as an element or compound.

**Phase Diagrams.** In order to record and visualize the results of studying the effects of state variables on a system, diagrams were devised to show the relationships between the various phases that appear within the system under equilibrium conditions. As such, the diagrams are variously called *constitutional diagrams*, *equilibrium diagrams*, or *phase diagrams*. A single-component phase diagram can be simply a one- or two-dimensional plot showing the phase changes in the substance as temperature and/or pressure change. Most diagrams, however, are two- or three-dimensional plots describing the phase relationships in systems made up of two or more components, and these usually contain fields (areas) consisting of mixed-phase fields, as well as single-phase fields. The plotting schemes in common use are described in greater detail in subsequent sections of this article.

**System Components.** Phase diagrams and the systems they describe are often classified and named for the number (in Latin) of components in the system, as shown below:

No. of components	Name of system or diagram
One	Unary
Two	Binary
Three	Ternary
Four	Quaternary
Five	Quinary
Six	Sexinary
Seven	Septenary
Eight	Octanary
Nine	Nonary
Ten	Decinary

**The phase rule**, first announced by J. Willard Gibbs in 1876, relates the physical state of a mixture to the number of constituents in the system and to its conditions. It was also Gibbs that first called the homogeneous regions in a system by the term "phases." When pressure and temperature are the state variables, the rule can be written as follows:

$$f = c - p + 2$$

where  $f$  is the number of independent variables (called *degrees of freedom*),  $c$  is the number of components, and  $p$  is the number of stable phases in the system.

## Unary Diagrams

**Invariant Equilibrium.** According to the phase rule, three phases can exist in stable equilibrium only at a single point on a unary diagram ( $f = 1 - 3 + 2 = 0$ ). This limitation is illustrated as point 0 in the hypothetical unary pressure-temperature ( $PT$ ) diagram shown in Fig. 2. In this diagram, the three states (or phases)--solid, liquid, and gas--are represented by the three correspondingly labeled fields. Stable equilibrium between any two phases occurs along their mutual boundary, and *invariant equilibrium* among all three phases occurs at the so-called *triple point*, 0, where the three boundaries intersect. This point also is called an *invariant point* because at that location on the diagram, all externally controllable factors are fixed (no degrees of freedom). At this point, all three states (phases) are in equilibrium, but any changes in pressure and/or temperature will cause one or two of the states (phases) to disappear.

**Fig. 2** Pressure-temperature phase diagram

**Univariant Equilibrium.** The phase rule says that stable equilibrium between two phases in a unary system allows one degree of freedom ( $f = 1 - 2 + 2$ ). This condition, which is called *univariant equilibrium* or *monovariant equilibrium*, is illustrated as lines 1, 2, and 3 that separate the single-phase fields in Fig. 2. Either pressure or temperature may be freely selected, but not both. Once a pressure is selected, there is only one temperature that will satisfy equilibrium conditions, and conversely. The three curves that issue from the triple point are called *triple curves*: line 1 representing reaction between the solid and the gas phases is the *sublimation curve*; line 2 is the *melting curve*; and line 3 is the *vaporization curve*. The vaporization curve ends at point 4, called a *critical point*, where the physical distinction between the liquid and gas phases disappears.

**Bivariant Equilibrium.** If both the pressure and temperature in a unary system are freely and arbitrarily selected, the situation corresponds to having two degrees of freedom, and the phase rule says that only one phase can exist in stable equilibrium ( $p = 1 - 2 + 2$ ). This situation is called *bivariant equilibrium*.

## Binary Diagrams

If the system being considered comprises two components, it is necessary to add a composition axis to the *PT* plot, which would require construction of a three-dimensional graph. Most metallurgical problems, however, are concerned only with a fixed pressure of one atmosphere, and the graph reduces to a two-dimensional plot of temperature and composition (*TX*) diagram.

The Gibbs phase rule applies to all states of matter, solid, liquid, and gaseous, but when the effect of pressure is constant, the rule reduces to:

$$f = c - p + 1$$

The stable equilibria for binary systems are summarized as follows:

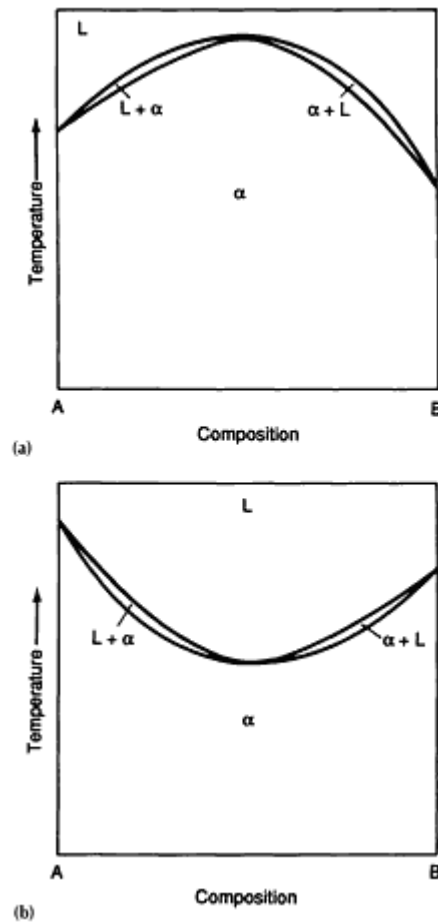

No. of components	No. of phases	Degrees of freedom	Equilibrium
2	3	0	Invariant
2	2	1	Univariant
2	1	2	Bivariant

**Miscible Solids.** Many systems are composed of components having the same crystal structure, and the components of some of these systems are completely miscible (completely soluble in each other) in the solid form, thus forming a *continuous solid solution*. When this occurs in a binary system, the phase diagram usually has the general appearance of that shown in Fig. 3. The diagram consists of two single-phase fields separated by a two-phase field. The boundary between the liquid field and the two-phase field in Fig. 3 is called the *liquidus*; that between the two-phase field and the solid field is the *solidus*. In general, a liquidus is the locus of points in a phase diagram representing the temperatures at which alloys of the various compositions of the system begin to freeze on cooling or finish melting on heating; a solidus is the locus of points representing the temperatures at which the various alloys finish freezing on cooling or begin melting on heating. The phases in equilibrium across the two-phase field in Fig. 3 (the liquid and solid solutions) are called *conjugate phases*.

**Fig. 3** Binary phase diagram showing miscibility in both the liquid and solid states

If the solidus and liquidus meet tangentially at some point, a maximum or minimum is produced in the two-phase field, splitting it into two portions as shown in Fig. 4. It also is possible to have a gap in miscibility in a single-phase field; this is shown in Fig. 5. Point  $T_c$ , above which phases  $\alpha_1$  and  $\alpha_2$  become indistinguishable, is a critical point similar to point 4 in Fig. 2. Lines  $a-T_c$  and  $b-T_c$ , called *solvus* lines, indicate the limits of solubility of component B in A and A in B, respectively.

**Fig. 4** Binary phase diagrams with solid-state miscibility where the liquidus shows (a) a maximum and (b) a minimum

**Fig. 5** Binary phase diagram with a minimum in the liquidus and a miscibility gap in the solid state

The configuration of these and all other phase diagrams depends on the thermodynamics of the system, as discussed in the section on "Thermodynamics and Phase Diagrams," which appears later in this article.

**Eutectic Reactions.** If the two-phase field in the solid region of Fig. 5 is expanded so it touches the solidus at some point, as shown in Fig. 6(a), complete miscibility of the components is lost. Instead of a single solid phase, the diagram now shows two separate solid *terminal phases*, which are in three-phase equilibrium with the liquid at point *P*, an invariant point that occurred by coincidence. (Three-phase equilibrium is discussed in the following section.) Then, if this two-phase field in

the solid region is even further widened so that the solvus lines no longer touch at the invariant point, the diagram passes through a series of configurations, finally taking on the more familiar shape shown in Fig. 6(b). The three-phase reaction that takes place at the invariant point  $E$ , where a liquid phase freezes into a mixture of two solid phases, is called a *eutectic* reaction (from the Greek for *easily melted*). The alloy that corresponds to the eutectic composition is called a *eutectic alloy*. An alloy having a composition to the left of the eutectic point is called a *hypoeutectic alloy* (from the Greek word for *less than*); an alloy to right is a *hypereutectic alloy* (meaning *greater than*).

**Fig. 6** Binary phase diagrams with invariant points. (a) Hypothetical diagram of the type of shown in Fig. 5, except that the miscibility gap in the solid touches the solidus curve at invariant point  $P$ ; an actual diagram of this type probably does not exist. (b) and (c) Typical eutectic diagrams for (b) components having the same crystal structure, and (c) components having different crystal structures; the eutectic (invariant) points are labeled  $E$ . The dashed lines in (b) and (c) are metastable extensions of the stable-equilibria lines.

In the eutectic system described above, the two components of the system have the same crystal structure. This, and other factors, allows complete miscibility between them. Eutectic systems, however, also can be formed by two components having different crystal structures. When this occurs, the liquidus and solidus curves (and their extensions into the two-phase field) for each of the terminal phases (see Fig. 6c) resemble those for the situation of complete miscibility between system components shown in Fig. 3.

**Three-Phase Equilibrium.** Reactions involving three conjugate phases are not limited to the eutectic reaction. For example, a single solid phase upon cooling can change into a mixture of two new solid phases, or two solid phases can, upon cooling, react to form a single new phase. These and the other various types of invariant reactions observed in binary systems are listed in Table 1 and illustrated in Fig. 7 and 8.

Table 1 Invariant reactions

Type	Reaction
Eutectic (involves liquid and solid)	$L_1 \rightarrow S_1 + S_2$ Monotectic
	$L_2 \rightarrow S_1 + S_2$ Eutectic
	$L \rightarrow S_1 + S_2$ Catatctic (metatectic)
Eutectoid (involves solid only)	$S_1 \rightarrow S_2 + S_3$ Monotectoid
	$S_2 \rightarrow S_1 + S_3$ Eutectoid
Peritectic (involves liquid and solid)	$L_1 + S_1 \rightarrow L_2$ Syntectic
	$L + S_1 \rightarrow S_2$ Peritectic
Peritectoid (involves solid only)	$S_1 + S_2 \rightarrow S_3$ Peritectoid

Fig. 7 Hypothetical binary phase diagram showing intermediate phases formed by various invariant reactions and a polymorphic transformation

**Fig. 8** Hypothetical binary phase diagram showing three intermetallic line compounds and four melting reactions

**Intermediate Phases.** In addition to the three solid terminal-phase fields,  $\alpha$ ,  $\beta$ , and  $\epsilon$ , the diagram in Fig. 7 displays five other solid-phase fields,  $\gamma$ ,  $\delta$ ,  $\delta'$ ,  $\eta$ , and  $\sigma$ , at intermediate compositions. Such phases are called *intermediate phases*. Many intermediate phases have fairly wide ranges of homogeneity, such as those illustrated in Fig. 7. However, many others have very limited or no significant homogeneity range.

When an intermediate phase of limited (or no) homogeneity range is located at or near a specific ratio of component elements that reflects the normal positioning of the component atoms in the crystal structure of the phase, it is often called a compound (or *line compound*). When the components of the system are metallic, such an intermediate phase is often called an *intermetallic compound*. (Intermetallic compounds should not be confused with chemical compounds, where the type of bonding is different than in crystals and where the ratio has chemical significance.) Three intermetallic compounds (with four types of melting reactions) are shown in Fig. 8.

In the hypothetical diagram shown in Fig. 8, an alloy of composition AB will freeze and melt isothermally, without the liquid or solid phases undergoing changes in composition; such a phase change is called *congruent*. All other reactions are *incongruent*; that is, two phases are formed from one phase on melting. Congruent and incongruent phase changes, however, are not limited to line compounds: the terminal component B (pure phase  $\epsilon$ ) and the highest-melting composition of intermediate phase  $\delta'$  in Fig. 7, for example, freeze and melt congruently, while  $\delta'$  and  $\epsilon$  freeze and melt incongruently at other compositions.

**Metastable Equilibrium.** In Fig. 6(c), dashed lines indicate the portions of the liquidus and solidus lines that disappear into the two-phase solid region. These dashed lines represent valuable information, as they indicate conditions that would exist under metastable equilibrium, such as might theoretically occur during extremely rapid cooling. Metastable extensions of some stable equilibria lines also appear in Fig. 2 and 6(b).

## Ternary Diagrams

When a third component is added to a binary system, illustrating equilibrium conditions in two dimensions becomes more complicated. One option is to add a third composition dimension to the base, forming a solid diagram having binary diagrams as its vertical sides. This can be represented as a modified isometric projection, such as shown in Fig. 9. Here, boundaries of single-phase fields (liquidus, solidus, and solvus lines in the binary diagrams) become surfaces; single- and two-phase areas become volumes; three-phase lines become volumes; and four-phase points, while not shown in Fig. 9, can exist as an invariant plane. The composition of a binary eutectic liquid, which is a point in a two-component system, becomes a line in a ternary diagram, as shown in Fig. 9.

**Fig. 9** Ternary phase diagram showing three-phase equilibrium. Source: Ref 1

While three-dimension projections can be helpful in understanding the relationships in the diagram, reading values from them is difficult. Ternary systems, therefore, are often represented by views of the binary diagrams that comprise the

faces and two-dimensional projections of the liquidus and solidus surfaces, along with a series of two-dimensional horizontal sections (*isotherms*) and vertical sections (*isopleths*) through the solid diagram.

**Vertical sections** are often taken through one corner (one component) and a congruently melting binary compound that appears on the opposite face; when such a plot can be read like any other true binary diagram, it is called a quasi-binary section. One possibility of such a section is illustrated by line 1-2 in the isothermal section shown in Fig. 10. A vertical section between a congruently melting binary compound on one face and one on a different face might also form a quasi-binary section (see line 2-3).

**Fig. 10** Isothermal section of a ternary diagram with phase boundaries deleted for simplification

All other vertical sections are not true binary diagrams, and the term *pseudobinary* is applied to them. A common pseudobinary section is one where the percentage of one of the components is held constant (the section is parallel to one of the faces), as shown by line 4-5 in Fig. 10. Another is one where the ratio of two constituents is held constant, and the amount of the third is varied from 0 to 100% (line 1-5).

**Isothermal Sections.** Composition values in the triangular isothermal sections are read from a triangular grid consisting of three sets of lines parallel to the faces and placed at regular composition intervals (see Fig. 11). Normally, the point of the triangle is placed at the top of the illustration, component A is placed at the bottom left, B at the bottom right, and C at the top. The amount of constituent A is normally indicated from point C to point A, the amount of constituent B from point A to point B, and the amount of constituent C from point B to point C. This scale arrangement is often modified when only a corner area of the diagram is shown.

**Fig. 11** Triangular composition grid for isothermal sections;  $x$  is the composition of each constituent in mole fraction or percent

**Projected Views.** Liquidus, solidus, and solvus surfaces by their nature are not isothermal. Therefore, equal-temperature (isothermal) contour lines are often added to the projected views of these surfaces to indicate the shape of the surfaces (see Fig. 12). In addition to (or instead of) contour lines, views often show lines indicating the temperature troughs (also called "valleys" or "grooves") formed at the intersections of two surfaces. Arrowheads are often added to these lines to indicate the direction of decreasing temperature in the trough.

**Fig. 12** Liquidus projection of a ternary phase diagram showing isothermal contour lines. Source: adapted from Ref 1

**Reference cited in this section**

1. F.N. Rhines, *Phase Diagrams in Metallurgy: Their Development and Application*, McGraw-Hill, 1956

**Thermodynamic Principles**

The reactions between components, the phases formed in a system, and the shape of the resulting phase diagram can be explained and understood through knowledge of the principles, laws, and terms of thermodynamics, and how they apply to the system.

**Table 2 Composition conversions**

The following equations can be used to make conversions in binary systems:

$$\text{wt\% A} = \frac{\text{at.\% A} \times \text{at. wt of A}}{(\text{at.\% A} \times \text{at. wt of A}) + (\text{at.\% B} \times \text{at. wt of B})} \times 100$$

$$\text{at.\% A} = \frac{\text{wt\% A/at. wt of A}}{(\text{at.\% A/at. wt of A}) + (\text{wt\% B/at. wt of B})} \times 100$$

The equation for converting from atomic percentages to weight percentages in higher-order systems is similar to that for binary systems, except that an additional term is added to the denominator for each additional component. For ternary systems, for example:

$$\text{wt\% A} = \frac{\text{at.\% A} \times \text{at. wt of A}}{(\text{at.\% A} \times \text{at. wt of A}) + (\text{at.\% B} \times \text{at. wt of B}) + (\text{at.\% C} \times \text{at. wt of C})} \times 100$$

$$\text{at.\% A} = \frac{\text{wt\% A/at. wt of A}}{(\text{wt\% A/at. wt of A}) + (\text{wt\% B/at. wt of B}) + (\text{wt\% C/at. wt of C})} \times 100$$

The conversion from weight to atomic percentages for higher-order systems is easy to accomplish on a computer with a spreadsheet

program.

**Internal Energy.** The sum of the kinetic energy (energy of motion) and potential energy (stored energy) of a system is called its *internal energy*,  $E$ . Internal energy is characterized solely by the state of the system.

**Closed System.** A thermodynamic system that undergoes no interchange of mass (material) with its surroundings is called a *closed system*. A closed system, however, can interchange energy with its surroundings.

**First Law.** The *First Law of Thermodynamics*, as stated by Julius von Mayer, James Joule, and Hermann von Helmholtz in the 1840s, says that "energy can be neither created nor destroyed." Therefore, it is called the "Law of Conservation of Energy." This law means the total energy of an isolated system remains constant throughout any operations that are carried out on it; that is for any quantity of energy in one form that disappears from the system, an equal quantity of another form (or other forms) will appear.

For example, consider a closed gaseous system to which a quantity of heat energy,  $\delta Q$ , is added and a quantity of work,  $\delta W$ , is extracted. The First Law describes the change in internal energy,  $dE$ , of the system as follows:

$$dE = \delta Q - \delta W$$

In the vast majority of industrial processes and material applications, the only work done by or on a system is limited to pressure/volume terms. Any energy contributions from electric, magnetic, or gravitational fields are neglected, except for electrowinning and electrorefining processes such as those used in the production of copper, aluminum, magnesium, the alkaline metals, and the alkaline earth metals. With the neglect of field effects, the work done by a system can be measured by summing the changes in volume,  $dV$ , times each pressure causing a change. Therefore, when field effects are neglected, the First Law can be written:

$$dE = \delta Q - PdV$$

**Enthalpy.** Thermal energy changes under constant pressure (again neglecting any field effects) are most conveniently expressed in terms of the *enthalpy*,  $H$ , of a system. Enthalpy, also called *heat content*, is defined by:

$$H = E + PV$$

Enthalpy, like internal energy, is a function of the state of the system, as is the product  $PV$ .

**Heat Capacity.** The *heat capacity*,  $C$ , of a substance is the amount of heat required to raise its temperature one degree, that is:

$$C = \frac{\delta Q}{dT}$$

However, if the substance is kept at constant volume ( $dV = 0$ ):

$$\delta Q = dE$$

and

$$C_v = \left( \frac{\delta Q}{\delta T} \right)_v = \left( \frac{dE}{dT} \right)_v$$

If, instead, the substance is kept at constant pressure (as in many metallurgical systems):

$$C_p = \left( \frac{dE}{dT} \right) + \left( \frac{PdV}{dT} \right)_p$$

and

$$C_p = \left[ \frac{d(E + PV)}{dT} \right]_p$$

$$C_p = \left( \frac{dH}{dT} \right)_p$$

**Second Law.** While the First Law establishes the relationship between the heat absorbed and the work performed by a system, it places no restriction on the source of the heat or its flow direction. This restriction, however, is set by the *Second Law of Thermodynamics*, which was advanced by Rudolf Clausius and William Thomson (Lord Kelvin). The Second Law says that "the spontaneous flow of heat always is from the higher temperature body to the lower temperature body." In other words, "all naturally occurring processes tend to take place spontaneously in the direction that will lead to equilibrium."

**Entropy.** The Second Law is most conveniently stated in terms *entropy*,  $S$ , another property of state possessed by all systems. Entropy represents the energy (per degree of absolute temperature,  $T$ ) in a system that is not available for work. In terms of entropy, the Second Law says that "all natural processes tend to occur only with an increase in entropy, and the direction of the process always is such as to lead to an increase in entropy." For processes taking place in a system in equilibrium with its surroundings, the change in entropy is defined as follows:

$$dS = \frac{\delta Q}{T} = \frac{dE + PdV}{T}$$

**Third Law.** A principle advanced by Theodore Richards, Walter Nernst, Max Planck, and others, often called the *Third Law of Thermodynamics*, states that "the entropy of all chemically homogeneous materials can be taken as zero at absolute zero temperature" (0 K). This principle allows calculation of the absolute values of entropy of pure substances solely from heat capacity.

**Gibbs Energy.** Because both  $S$  and  $V$  are difficult to control experimentally, an additional term, *Gibbs energy*,  $G$ , is introduced, whereby:

$$G \equiv E + PV - TS \equiv H - TS$$

and

$$dG = dE + PdV + VdP - TdS - SdT$$

However,

$$dE = TdS - PdV$$

Therefore,

$$dG = VdP - SdT$$

Here, the change in Gibbs energy of a system undergoing a process is expressed in terms of two independent variables--pressure and absolute temperature--which are readily controlled experimentally. If the process is carried out under conditions of constant pressure and temperature, the change in Gibbs energy of a system at equilibrium with its surroundings (a reversible process) is zero. For a spontaneous (irreversible) process, the change in Gibbs energy is less than zero (negative); that is, the Gibbs energy decreases during the process, and it reaches a minimum at equilibrium.

## Thermodynamics and Phase Diagrams

The areas (fields) in a phase diagram, and the position and shapes of the points, lines, surfaces, and intersections in it, are controlled by thermodynamic principles and the thermodynamic properties of all of the phases that comprise the system.

**Phase-Field Rule.** The phase rule specifies that at constant temperature and pressure, the number of phases in adjacent fields in a multicomponent diagram must differ by one.

**Theorem of Le Châtelier.** The *theorem of Henri Le Châtelier*, which is based on thermodynamic principles, says that "if a system in equilibrium is subjected to a constraint by which the equilibrium is altered, a reaction occurs that opposes the constraint, that is, a reaction that partially nullifies the alteration." The effect of this theorem on lines in a phase diagram can be seen in Fig. 2. The slopes of the sublimation line (1) and the vaporization line (3) show that the system reacts to increasing pressure by making the denser phases (solid and liquid) more stable at higher pressure. The slope of the melting line (2) indicates that this hypothetical substance contracts on freezing. (Note that the boundary between liquid water and ordinary ice, which expands on freezing, slopes towards the pressure axis.)

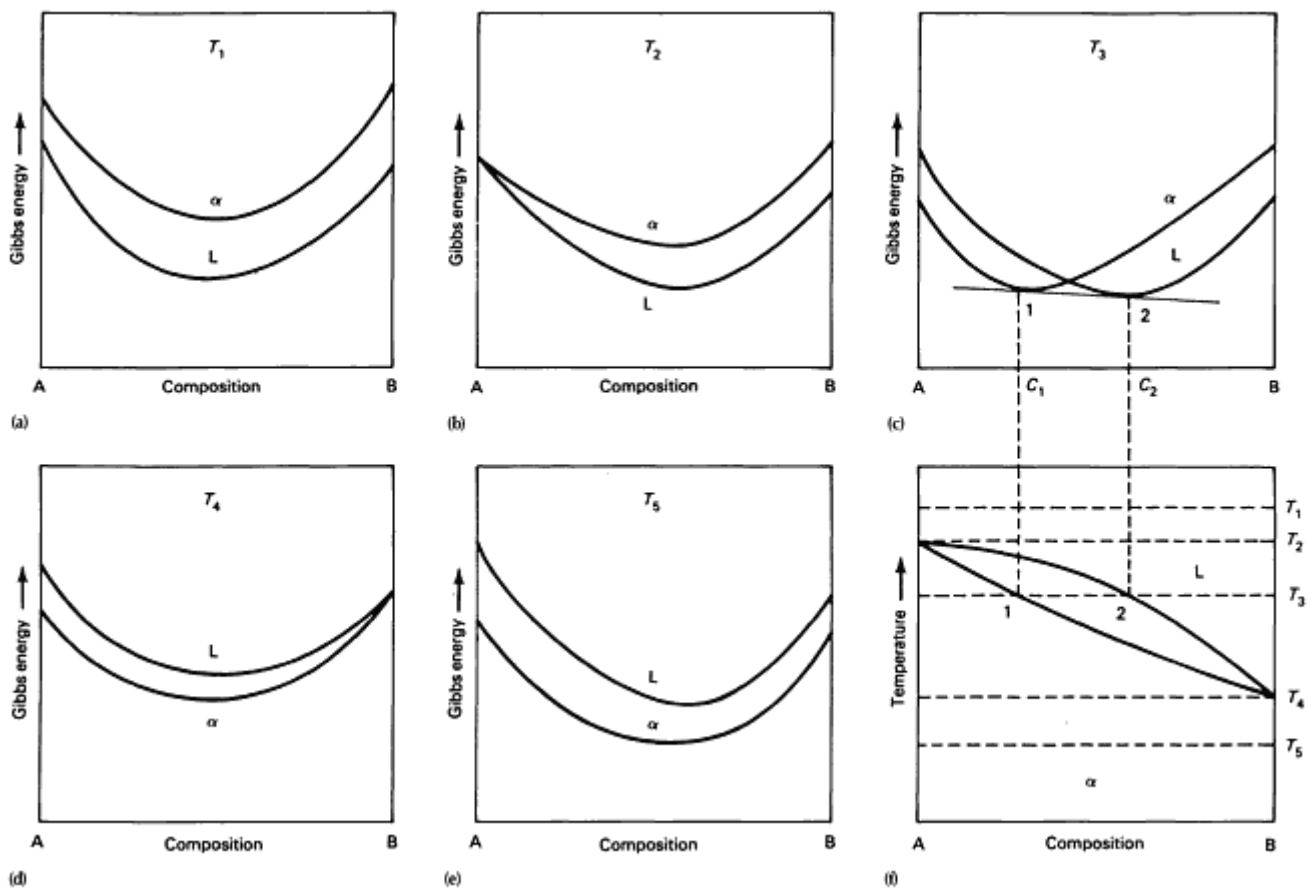

**Clausius-Clapeyron Equation.** The theorem of Le Châtelier was quantified by Benoit Clapeyron and Rudolf Clausius to give the following equation:

$$\frac{dP}{dT} = \frac{\Delta H}{T\Delta V}$$

where  $dP/dT$  is the slope of the univariant lines in a  $PT$  diagram such as those shown in Fig. 2,  $\Delta V$  is the difference in molar volume of the two phases in the reaction, and  $\Delta H$  is difference in molar enthalpy of the two phases (the heat of the reaction).

**Solutions.** The shape of liquidus, solidus, and solvus curves (or surfaces) in a phase diagram are determined by the Gibbs energies of the relevant phases. In this instance, the Gibbs energy must include not only the energy of the constituent components, but also the energy of mixing of these components in the phase.

Consider, for example, the situation of complete miscibility shown in Fig. 3. The two phases, solid  $\alpha$  and liquid, are in stable equilibrium in the two-phase field between the liquidus and solidus lines. The Gibbs energies at various temperatures are calculated as a function of composition for ideal liquid solutions and for ideal solid solutions of the two components, A and B. The result is a series of plots similar to those in Fig. 13(a) to 13(e).

**Fig. 13** Use of Gibbs energy curves to construct a binary phase diagram that shows miscibility in both the liquid and solid states. Source: adapted from Ref 2

At temperature  $T_1$ , the liquid solution has the lower Gibbs energy and, therefore, is the more stable phase. At  $T_2$ , the melting temperature of A, the liquid and solid are equally stable only at a composition of pure A. At temperature  $T_3$ , between the melting temperatures of A and B, the Gibbs energy curves cross. Temperature  $T_4$  is the melting temperature of B, while  $T_5$  is below it.

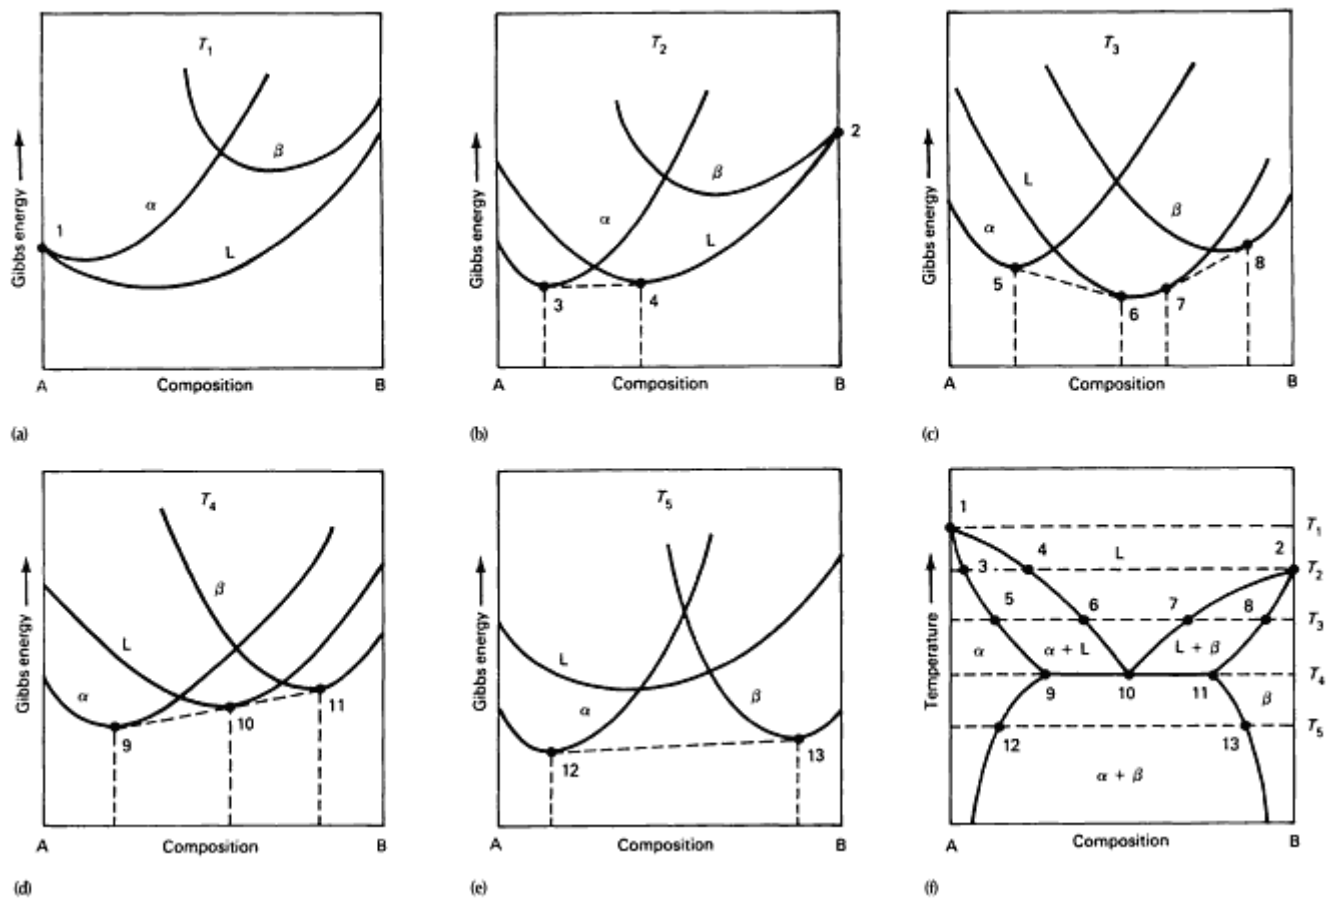

Construction of the two-phase liquid-plus-solid field of the phase diagram in Fig. 13(f) is as follows. According to thermodynamic principles, the compositions of the two phases in equilibrium with each other at temperature  $T_3$  can be determined by constructing a straight line that is tangential to both curves in Fig. 13(c). The points of tangency, 1 and 2, are then transferred to the phase diagram as points on the solidus and liquidus, respectively. This is repeated at sufficient temperatures to determine the curves accurately.

If, at some temperature, the Gibbs energy curves for the liquid and the solid tangentially touch at some point, the resulting phase diagram will be similar to those shown in Fig. 4(a) and 4(b), where a maximum or minimum appears in the liquidus and solidus curves.

**Mixtures.** The two-phase field in Fig. 13(f) consists of a mixture of liquid and solid phases. As stated above, the compositions of the two phases in equilibrium at temperature  $T_3$  are  $C_1$  and  $C_2$ . The horizontal isothermal line connecting points 1 and 2, where these compositions intersect temperature  $T_3$ , is called a *tie line*. Similar tie lines connect the coexisting phases throughout all two-phase fields (areas) in binary and (volumes) in ternary systems, while *tie triangles* connect the coexisting phases throughout all three-phase regions (volumes) in ternary systems.

Eutectic phase diagrams, a feature of which is a field where there is a mixture of two solid phases, also can be constructed from Gibbs energy curves. Consider the temperatures indicated on the phase diagram in Fig. 14(f) and the Gibbs energy curves for these temperatures (Fig. 14a to 14e). When the points of tangency on the energy curves are transferred to the

diagram, the typical shape of a eutectic system results. The mixture of solid  $\alpha$  and  $\beta$  that forms upon cooling through the eutectic point 10 has a special microstructure, as discussed later.

**Fig. 14** Use of Gibbs energy curves to construct a binary phase diagram of the eutectic type. Source: adapted from Ref 3

Binary phase diagrams that have three-phase reactions other than the eutectic reaction, as well as diagrams with multiple three-phase reactions, also can be constructed from appropriate Gibbs energy curves. Likewise, Gibbs energy surfaces and tangential planes can be used to construct ternary phase diagrams.

**Curves and Intersections.** Thermodynamic principles also limit the shape of the various boundary curves (or surfaces) and their intersections. For example, see the  $PT$  diagram shown in Fig. 2. The Clausius-Clapeyron equation requires that at the intersection of the triple curves in such a diagram, the angle between adjacent curves should never exceed  $180^\circ$ , or alternatively, the extension of each triple curve between two phases must lie within the field of third phase.

The angle at which the boundaries of two-phase fields meet also is limited by thermodynamics. That is, the angle must be such that the extension of each beyond the point of intersection projects into a two-phase field, rather than a one-phase field. An example of correct intersections can be seen in Fig. 6(b), where both the solidus and solvus lines are concave. However, the curvature of both boundaries need not be concave.

**Congruent Transformations.** The *congruent point* on a phase diagram is where different phases of same composition are in equilibrium. The *Gibbs-Konovalov Rule* for congruent points, which was developed by Dmitry Konovalov from a thermodynamic expression given by J. Willard Gibbs, states that the slope of phase boundaries at congruent transformations must be zero (horizontal). Examples of correct slope at the maximum and minimum points on liquidus and solidus curves can be seen in Fig. 4.

**Higher-Order Transitions.** The transitions considered in this article up to now have been limited to the common thermodynamic types called *first-order transitions*, that is, changes involving distinct phases having different lattice

parameters, enthalpies, entropies, densities, and so forth. Transitions not involving discontinuities in composition, enthalpy, entropy, or molar volume are called *higher-order transitions* and occur less frequently. The change in the magnetic quality of iron from ferromagnetic to paramagnetic as the temperature is raised above 771 °C (1420 °F) is an example of a second-order transition: no phase change is involved and the Gibbs phase rule does not come into play in the transition.

Another example of a higher-order transition is the continuous change from a random arrangement of the various kinds of atoms in a multicomponent crystal structure (a *disordered structure*) to an arrangement where there is some degree of *crystal ordering* of the atoms (an *ordered structure*, or *superlattice*), or the reverse reaction.

## Reading Phase Diagrams

**Composition Scales.** Phase diagrams to be used by scientists are usually plotted in atomic percentage (or mole fraction), while those to be used by engineers are usually plotted in weight percentage. Conversions between weight and atomic composition also can be made using the equations given in Table 2 and standard atomic weights listed in the periodic table (the periodic table and atomic weights of the elements can be found in the article entitled "The Chemical Elements" in this Section).

**Lines and Labels.** Magnetic transitions (Curie temperature and Néel temperature) and uncertain or speculative boundaries are usually shown in phase diagrams as nonsolid lines of various types.

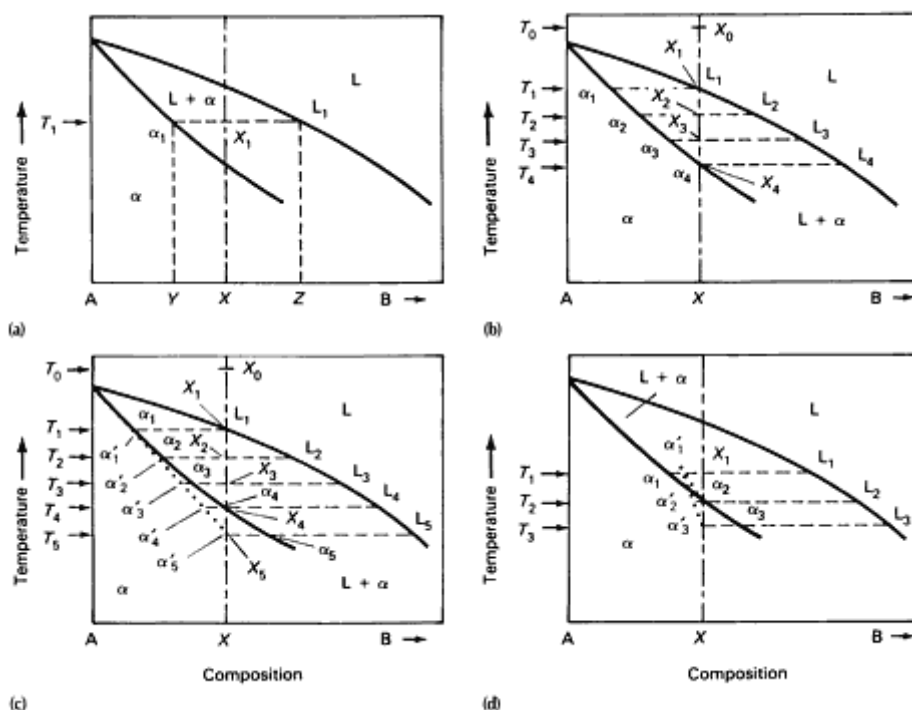

The components of metallic systems, which usually are pure elements, are identified in phase diagrams by their symbols. Allotropes of polymorphic elements are distinguished by small (lower-case) Greek letter prefixes.

Terminal solid phases are normally designated by the symbol (in parentheses) for the allotrope of the component element, such as (Cr) or ( $\alpha$ Ti). Continuous solid solutions are designated by the names of both elements, such as (Cu,Pd) or ( $\beta$ Ti,  $\beta$ Y).

Intermediate phases in phase diagrams are normally labeled with small (lower-case) Greek letters. However, certain Greek letters are conventionally used for certain phases, particularly disordered solutions: for example,  $\beta$  for disordered body-centered cubic (bcc),  $\zeta$  or  $\epsilon$  for disordered close-packed hexagonal (cph),  $\gamma$  for the  $\gamma$ -brass-type structure, and  $\sigma$  for the  $\sigma$ CrFe-type structure.

For line compounds, a stoichiometric phase name is used in preference to a Greek letter (for example,  $A_2B_3$  rather than  $\delta$ ). Greek letter prefixes are used to indicate high- and low-temperature forms of the compound (for example,  $\alpha A_2B_3$  for the low-temperature form and  $\beta A_2B_3$  for the high-temperature form).

**Lever Rule.** As explained in the section on "Thermodynamics and Phase Diagrams," a tie line is an imaginary horizontal line drawn in a two-phase field connecting two points that represent two coexisting phases in equilibrium at the temperature indicated by the line. Tie lines can be used to determine the fractional amounts of the phases in equilibrium by employing the *lever rule*. The lever rule is a mathematical expression derived by the principle of conservation of matter in which the phase amounts can be calculated from the bulk composition of the alloy and compositions of the conjugate phases, as shown in Fig. 15(a).

**Fig. 15** Portion of a binary phase diagram containing a two-phase liquid-plus-solid field illustrating (a) application of the lever rule to (b) equilibrium freezing, (c) nonequilibrium freezing, and (d) heating of a homogenized sample. Source: Ref 1

At the left end of the line between  $\alpha_1$  and  $L_1$ , the bulk composition is  $Y\%$  component B and  $100 - Y\%$  component A, and consists of  $100\%$   $\alpha$  solid solution. As the percentage of component B in the bulk composition moves to the right, some liquid appears along with the solid. With further increases in the amount of B in the alloy, more of the mixture consists of liquid, until the material becomes entirely liquid at the right end of the tie line. At bulk composition  $X$ , which is less than halfway to point  $L_1$ , there is more solid present than liquid. The lever rule says that the percentages of the two phases present can be calculated as follows:

$$\begin{aligned}\% \text{ liquid} &= \frac{\text{Length of line } \alpha_1 X_1}{\text{Length of line } \alpha_1 L_1} \times 100 \\ \% \text{ solid } \alpha &= \frac{\text{Length of line } X_1 L_1}{\text{Length of line } \alpha_1 L_1} \times 100\end{aligned}$$

It should be remembered that the calculated amounts of the phases present are either in weight or atomic percentages, and as shown in Table 3, do not directly indicate the area or volume percentages of the phases observed in microstructures.

**Table 3 Volume fraction**

In order to relate the weight fraction of a phase present in an alloy specimen as determined from a phase diagram to its two-dimensional appearance as observed in a micrograph, it is necessary to be able to convert between weight-fraction values and area-fraction values, both in decimal fractions. This conversion can be developed as follows:
The weight fraction of the phase is determined from the phase diagram, using the lever rule.
Volume portion of the phase = (Weight fraction of the phase)/(Phase density)
Total volume of all phases present = Sum of the volume portions of each phase.
Volume fraction of the phase = (Weight fraction of the phase)/(Phase density $\times$ total volume)
It has been shown by stereology and quantitative metallography that areal fraction is equal to volume fraction (Ref 6). (Areal fraction of a phase is the sum of areas of the phase intercepted by a microscopic traverse of the observed region of the specimen divided by the total area of the observed region.) Therefore:
Areal fraction of the phase = (Weight fraction of the phase)/(Phase density $\times$ total volume)
The phase density value for the preceding equation can be obtained by measurements or calculation. The densities of chemical elements, and some line compounds, can be found in the literature. Alternatively, the density of a unit cell of a phase comprising one or more elements can be calculated from information about its crystal structure and the atomic weights of the elements comprising it as follows:

Total cell weight = Sum of weights of each element

Density = Total cell weight/cell volume

For example, the calculated density of pure copper, which has a fcc structure and a lattice parameter of 0.36146 nm, is:

$$\rho = \frac{4 \text{ atoms/cell} \times 63.546 \text{ g/mol}}{6.0227 \times 10^{23} \text{ atoms/mol} \times (0.36146 \times 10^{-9} \text{ m})^3}$$

$$= 8.937 \text{ Mg/m}^3$$

**Phase-Fraction Lines.** Reading the phase relationships in many ternary diagram sections (and other types of sections) often can be difficult due to the great many lines and areas present. *Phase-fraction lines* are used by some to simplify this task. In this approach, the sets of often nonparallel tie lines in the two-phase fields of isothermal sections (see Fig. 16a) are replaced with sets of curving lines of equal phase fraction (Fig. 16b). Note that the phase-fraction lines extend through the three-phase region where they appear as a triangular network. As with tie lines, the number of phase-fraction lines used is up to the individual using the diagram. While this approach to reading diagrams may not seem helpful for such a simple diagram, it can be a useful aid in more complicated systems. For more information on this topic, see Ref 4 and 5.

**Fig. 16** Alternative systems for showing phase relationships in multiphase regions of ternary-diagram isothermal sections. (a) Tie lines. (b) Phase-fraction lines. Source: Ref 4

**Solidification.** Tie lines and the lever rule can be used to understand the freezing of a solid-solution alloy. Consider the series of tie lines at different temperature shown in Fig. 15(b), all of which intersect the bulk composition X. The first crystals to freeze have the composition  $\alpha_1$ . As the temperature is reduced to  $T_2$  and the solid crystals grow, more A atoms are removed from the liquid than B atoms, thus shifting the composition of the remaining liquid to composition  $L_2$ . Therefore, during freezing, the compositions of both the layer of solid freezing out on the crystals and the remaining liquid continuously shift to higher B contents and become leaner in A. Therefore, for equilibrium to be maintained, the solid crystals must absorb B atoms from the liquid and B atoms must migrate (diffuse) from the previously frozen material into subsequently deposited layers. When this happens, the average composition of the solid material follows the solidus line to temperature  $T_4$  where it equals the bulk composition of the alloy.

**Coring.** If cooling takes place too rapidly for maintenance of equilibrium, the successive layers deposited on the crystals will have a range of local compositions from their centers to their edges (a condition known as *coring*). Development of

this condition is illustrated in Fig. 15(c). Without diffusion of B atoms from the material that solidified at temperature  $T_1$  into the material freezing at  $T_2$ , the average composition of the solid formed up to that point will not follow the solidus line. Instead it will remain to the left of the solidus, following compositions  $\alpha'_1$  through  $\alpha'_3$ . Note that final freezing does not occur until temperature  $T_5$ , which means that nonequilibrium solidification takes place over a greater temperature range than equilibrium freezing. Because most metals freeze by the formation and growth of "treelike" crystals, called *dendrites*, coring is sometimes called *dendritic segregation*. An example of cored dendrites is shown in Fig. 17.

**Fig. 17** Copper alloy 71500 (Cu-30Ni) ingot. Dendritic structure shows coring: light areas are nickel-rich; dark areas are low in nickel. 20 $\times$ . Source: Ref 6

**Liquation.** Because the lowest freezing material in a cored microstructure is segregated to the edges of the solidifying crystals (the grain boundaries), this material can remelt when the alloy sample is heated to temperatures below the equilibrium solidus line. If grain-boundary melting (called *liquation* or "burning") occurs while the sample also is under stress, such as during hot forming, the liquefied grain boundaries will rupture and the sample will lose its ductility and be characterized as *hot short*.

Liquation also can have a deleterious effect on the mechanical properties (and microstructure) of the sample after it returns to room temperature. This is illustrated in Fig. 15(d) for a homogenized sample. If homogenized alloy  $X$  is heated into the liquid-plus-solid region for some reason (inadvertently or during welding, etc.), it will begin to melt when it reaches temperature  $T_2$ ; the first liquid to appear will have the composition  $L_2$ . When the sample is heated at normal rates to temperature  $T_1$ , the liquid formed so far will have a composition  $L_1$ , but the solid will not have time to reach the equilibrium composition  $\alpha_1$ . The average composition will instead lie at some intermediate value such as  $\alpha'_1$ . According to the lever rule, this means that less than the equilibrium amount of liquid will form at this temperature. If the sample is then rapidly cooled from temperature  $T_1$ , solidification will occur in the normal manner, with a layer of material having composition  $\alpha_1$  deposited on existing solid grains. This is followed by layers of increasing B content up to composition  $\alpha_3$  at temperature  $T_3$ , where all of the liquid is converted to solid. This produces coring in the previously melted regions along the grain boundaries and sometimes even voids that decrease the strength of the sample. Homogenization heat treatment will eliminate the coring, but not the voids.

**Eutectic Microstructures.** When an alloy of eutectic composition is cooled from the liquid state, the eutectic reaction occurs at the eutectic temperature, where the two distinct liquidus curves meet. At this temperature, both  $\alpha$  and  $\beta$  solid phases must deposit on the grain nuclei until all of the liquid is converted to solid. This simultaneous deposition results in microstructures made up of distinctively shaped particles of one phase in a matrix of the other phase, or alternate layers of the two phases. Examples of characteristic eutectic microstructures include spheroidal, nodular, or globular; acicular (needles) or rod; and lamellar (platelets, Chinese script or dendritic, or filigreed). Each eutectic alloy has its own characteristic microstructure, when slowly cooled (see Fig. 18). Cooling more rapidly, however, can affect the microstructure obtained (see Fig. 19). Care must be taken in characterizing eutectic structures because elongated particles can appear nodular and flat platelets can appear elongated or needlelike when viewed in cross section.

**Fig. 18** Examples of characteristic eutectic microstructures in slowly cooled alloys. (a) 40Sn-50In alloy showing globules of tin-rich intermetallic phase (light) in a matrix of dark indium-rich intermetallic phase. 150 $\times$ . (b) Al-13Si alloy showing an acicular structure consisting of short, angular particles of silicon (dark) in a matrix of aluminum. 200 $\times$ . (c) Al-33Cu alloy showing a lamellar structure consisting of dark platelets of  $\text{CuAl}_2$  and light platelets of aluminum solid solution. 180 $\times$ . (d) Mg-37Sn alloy showing a lamellar structure consisting of  $\text{Mg}_2\text{Sn}$  "Chinese-script" (dark) in a matrix of magnesium solid solution. 250 $\times$ . Source: Ref 6

**Fig. 19** Effect of cooling rate on the microstructure of Sn-37Pb alloy (eutectic soft solder). (a) Slowly cooled sample shows a lamellar structure consisting of dark platelets of lead-rich solid solution and light platelets of tin. 375 $\times$ . (b) More rapidly cooled sample shows globules of lead-rich solid solution, some of which exhibit a slightly dendritic structure, in a matrix of tin. 375 $\times$ . Source: Ref 6

If the alloy has a composition different than the eutectic composition, the alloy will begin to solidify before the eutectic temperature is reached. If the alloy is hypoeutectic, some dendrites of  $\alpha$  will form in the liquid before the remaining liquid solidifies at the eutectic temperature. If the alloy is hypereutectic, the first (primary) material to solidify will be dendrites of  $\beta$ . The microstructure produced by slow cooling of a hypoeutectic and hypereutectic alloy will consist of relatively large particles of *primary constituent*, consisting of the phase that begins to freeze first surrounded by relatively fine eutectic structure. In many instances, the shape of the particles will show a relationship to their dendritic origin (see Fig. 20a). In other instances, the initial dendrites will have filled out somewhat into *idiomorphic particles* (particles having their own characteristic shape) that reflect the crystal structure of the phase (see Fig. 20b).

**Fig. 20** Examples of primary-particle shape. (a) Sn-30Pb hypoeutectic alloy showing dendritic particles of tin-rich solid solution in a matrix of tin-lead eutectic. 500 $\times$ . (b) Al-19Si hypereutectic alloy, phosphorus-modified, showing idiomorphic particles of silicon in a matrix of aluminum-silicon eutectic. 100 $\times$ . Source: Ref 6

As stated earlier, cooling at a rate that does not allow sufficient time to reach equilibrium conditions will affect the resulting microstructure. For example, it is possible for an alloy in a eutectic system to obtain some eutectic structure in an alloy outside the normal composition range for such a structure. This is illustrated in Fig. 21. With relatively rapid cooling of alloy X, the composition of the solid material that forms will follow line  $\alpha_1 - \alpha'_4$  rather than solidus line to  $\alpha_4$ . As a result, the last liquid to solidify will have the eutectic composition  $L_4$  rather than  $L_3$ , and will form some eutectic structure in the microstructure. The question of what takes place when the temperature reaches  $T_5$  is discussed later.

**Fig. 21** Binary phase diagram, illustrating the effect of cooling rate on an alloy lying outside the equilibrium eutectic-transformation line. Rapid solidification into a terminal phase field can result in some eutectic structure being formed; homogenization at temperatures in the single-phase field will eliminate the eutectic structure; phase will precipitate out of solution upon slow cooling into the  $\alpha$ -plus- $\beta$  field. Source: adapted from Ref 1

**Eutectoid Microstructures.** Because the diffusion rates of atoms are so much lower in solids than liquids, nonequilibrium transformation is even more important in solid/solid reactions (such as the eutectoid reaction) than in liquid/solid reactions (such as the eutectic reaction). With slow cooling through the eutectoid temperature, most alloys of eutectoid composition such as alloy 2 in Fig. 22 transform from a single-phase microstructure to a lamellar structure consisting of alternate platelets of  $\alpha$  and  $\beta$  arranged in groups (or "colonies"). The appearance of this structure is very similar to lamellar eutectic structure (see Fig. 23). When found in cast irons and steels, this structure is called "pearlite"

because of its shiny mother-of-pearl-like appearance under the microscope (especially under oblique illumination); when similar eutectoid structure is found in nonferrous alloys, it often is called "pearlite-like" or "pearlitic."

Fig. 22 Binary phase diagram of a eutectoid system. Source: adapted from Ref 1

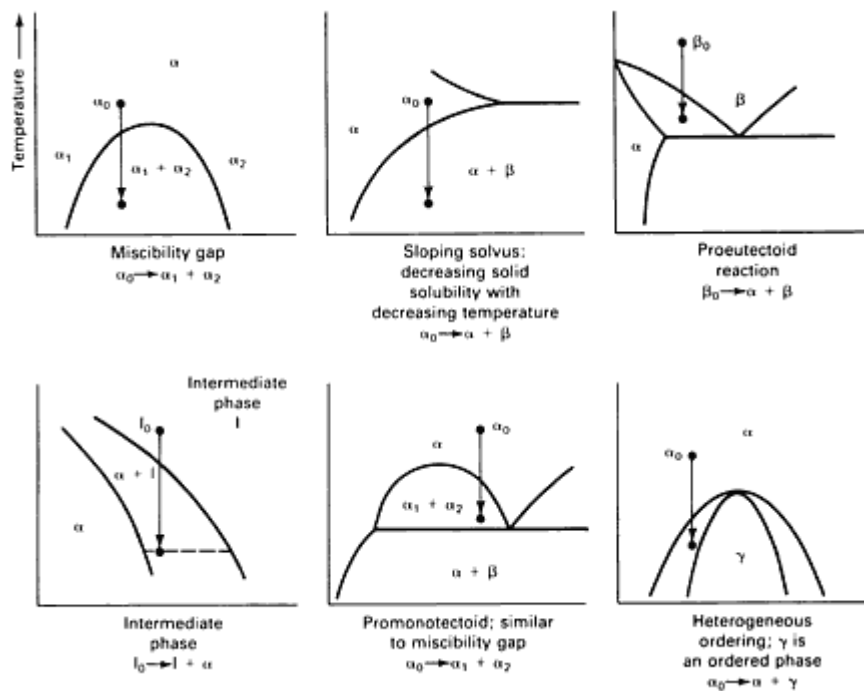

Fig. 23 Fe-0.8C alloy showing a typical pearlite eutectoid structure of alternate layers of light ferrite and dark cementite. 500 $\times$ . Source: Ref 6

The terms, *hypoeutectoid* and *hypereutectoid* have the same relationship to the eutectoid composition as hypoeutectic and hypereutectic do in a eutectic system; alloy 1 in Fig. 22 is a hypoeutectoid alloy, while alloy 3 is hypereutectoid. The solid-state transformation of such alloys takes place in two steps, much like freezing of hypoeutectic and hypereutectic alloys except that the microconstituents that form before the eutectoid temperature is reached are referred to as *proeutectoid constituents* rather than "primary."

**Microstructures of Other Invariant Reactions.** Phase diagrams can be used in a manner similar to that used in the discussion of eutectic and eutectoid reactions to determine the microstructures expected to result from cooling an alloy through any of the other six types of reactions listed in Table 1.

**Solid-State Precipitation.** If alloy X in Fig. 21 is homogenized at a temperature between  $T_3$  and  $T_5$ , it will reach equilibrium condition; that is, the portion of the eutectic constituent will dissolve and the microstructure will consist solely of grains. Upon cooling below temperature  $T_5$ , this microstructure will no longer represent equilibrium conditions, but instead will be supersaturated with B atoms. In order for the sample to return to equilibrium, some of the

B atoms will tend to congregate in various regions of the sample to form colonies of new material. The B atoms in some of these colonies, called *Guinier-Preston zones*, will drift apart, while other colonies will grow large enough to form incipient, but not distinct, particles. The difference in crystal structures and lattice parameters between the two phases causes lattice strain at the boundary between the two materials, thereby raising the total energy level of the sample and hardening and strengthening it. At this stage, the incipient particles are difficult to distinguish in the microstructure. Instead, there usually is only a general darkening of the structure. If sufficient time is allowed, the regions will break away from their host grains of  $\alpha$  and precipitate as distinct particles, thereby relieving the lattice strain and returning the hardness and strength to the former levels. While this process is illustrated for a simple eutectic system, it can occur wherever similar conditions exist in a phase diagram; that is, there is a range of alloy compositions in the system for which there is a transition on cooling from a single-solid region to a region that also contains a second solid phase, and where the boundary between the regions slopes away from the composition line as cooling continues. Several examples of such systems are shown schematically in Fig. 24.

**Fig. 24** Examples of binary phase diagrams that give rise to precipitation reactions. Source: Ref 6

Although this entire process is called *precipitation hardening*, the term normally refers only to the portion before much actual precipitation takes place. Because the process takes a while to be accomplished, the term *age hardening* is often used instead. The rate at which aging occurs depends on the level of supersaturation (how far from equilibrium), the amount of lattice strain originally developed (amount of lattice mismatch), the fraction left to be relieved (how far along the process has progressed), and the aging temperature (the mobility of the atoms to migrate). The precipitate usually takes the form of small idiomorphic particles situated along the grain boundaries and within the grains of  $\alpha$  phase. In most instances, the particles are more or less uniform in size and oriented in a systematic fashion. Examples of precipitation microstructures are shown in Fig. 25.

**Fig. 25** Examples of characteristic precipitation microstructures. (a) General and grain-boundary precipitation of  $\text{Co}_3\text{Ti}$  ( $\epsilon'$  phase) in a Co-12Fe-6Ti alloy aged  $3 \times 10^3$  min at  $800^\circ\text{C}$  ( $1470^\circ\text{F}$ ).  $1260\times$ . (b) General precipitation (intragranular Widmanstätten), localized grain-boundary precipitation in Al-18Ag alloy aged 90 h at  $375^\circ\text{C}$  ( $710^\circ\text{F}$ ), with a distinct precipitation-free zone near the grain boundaries.  $500\times$ . (c) Preferential, or localized, precipitation along grain boundaries in a Ni-20Cr-1Al alloy.  $500\times$ . (d) Cellular, or discontinuous, precipitation growing out uniformly from the grain boundaries in an Fe-24.8Zn alloy aged 6 min at  $600^\circ\text{C}$  ( $1110^\circ\text{F}$ ).  $1000\times$ . ## Examples of Phase Diagrams

The general principles of reading alloy phase diagrams are discussed in the preceding section. The application of these principles to actual diagrams for typical alloy systems is illustrated below.

**The Copper-Zinc System.** The metallurgy of brass alloys has long been of great commercial importance. The copper and zinc contents of five of the most common wrought brasses are:

UNS No.	Common name	Zinc content, %	
		Nominal Range	Range
C23000	Red brass, 85%	15	14.0-16.0
C24000	Low brass, 80%	20	18.5-21.5
C26000	Cartridge brass, 70%	30	28.5-31.5
C27000	Yellow brass, 65%	35	32.5-37.0

As can be seen in Fig. 26, these alloys encompass a wide range of the copper-zinc phase diagram. The alloys on the high-copper end (red brass, low brass, and cartridge brass) lie within the copper solid-solution phase field and are called  $\alpha$  brasses after the old designation for this field. As expected, the microstructure of these brasses consists solely of grains of copper solid solution (see Fig. 27a). The strain on the copper crystals caused by the presence of the zinc atoms, however, produces solution hardening in the alloys. As a result, the strength of the brasses, in both the work-hardened and the annealed condition, increases with increasing zinc content.

**Fig. 26** The copper-zinc phase diagram, showing the composition range for five common brasses. Source: adapted from Ref 7

**Fig. 27** The microstructure of two common brasses. (a) C26000 (cartridge brass, 70Cu-30Zn), hot rolled, annealed, cold rolled 70% and annealed at 638 °C (1180 °F), showing equiaxed grains of copper solid solution. (Some grains are twinned). 75 $\times$ . (b) C28000 (Muntz metal, 60Cu-40Zn) ingot, showing dendrites of copper solid solution in a matrix of  $\beta$ . 200 $\times$ . (c) C28000 (Muntz metal), showing feathery structures of copper solid solution, which formed at  $\beta$  grain boundaries during quenching of all- $\beta$  structure. 100 $\times$ . Source: Ref 6

The composition range for those brasses containing higher amounts of zinc (yellow brass and Muntz metal), however, overlaps into the two-phase (Cu)-plus- $\beta$  field. Therefore, the microstructure of these so-called  $\alpha$ - $\beta$  alloys shows various amounts of  $\beta$  phase (see Fig. 27b and 27c), and their strengths are further increased over those of the  $\alpha$ brasses.

**The Aluminum-Copper System.** Another alloy system of great commercial importance is aluminum-copper. Although the phase diagram of this system is fairly complicated (see Fig. 28), the alloys of concern in this discussion are limited to the region at the aluminum side of the diagram where a simple eutectic is formed between the aluminum solid solution and the  $\theta$ (Al<sub>2</sub>Cu) phase. This family of alloys (designated the 2xxx series) has nominal copper contents ranging from 2.3 to 6.3 wt% Cu, making them hypoeutectic alloys.

**Fig. 28** The aluminum-copper phase diagram, showing the composition range for the 2xxx series of precipitation-hardenable aluminum alloys. Source: Ref 7

A critical feature of this region of the diagram is the shape of the aluminum solvus line. At the eutectic temperature (548.2 °C, or 1018.8 °F), 5.65 wt% Cu will dissolve in aluminum. At lower temperatures, however, the amount of copper that can remain in the aluminum solid solution under equilibrium conditions drastically decreases, reaching less than 1% at room temperature. This is the typical shape of the solvus line for precipitation hardening; if any of these alloys are homogenized at temperatures in or near the solid-solution phase field, they can be strengthened by aging at a substantially lower temperature.

**The Aluminum-Magnesium System.** As can be seen in Fig. 29, both ends of the aluminum-magnesium system have solvus lines that are shaped similarly to the aluminum solvus line in Fig. 28. Therefore, both aluminum-magnesium alloys and magnesium-aluminum alloys are age hardenable and commercially important.

Fig. 29 The aluminum-magnesium phase diagram. Source: Ref 7

**The Aluminum-Silicon System.** Nonferrous alloy systems do not have to be age hardenable to be commercially important. For example, in the aluminum-silicon system (Fig. 30), almost no silicon will dissolve in solid aluminum. Therefore, as-cast hypereutectic aluminum alloy 392 (Al-19% Si) to which phosphorus was added in the melt contains large particles of silicon in a matrix of aluminum-silicon eutectic (see Fig. 20). Aluminum-silicon alloys have good castability (silicon improves castability and fluidity) and good corrosion and wear resistance (because of the hard primary silicon particles). Small additions of magnesium render some aluminum-silicon alloys age hardenable.

Fig. 30 The aluminum-silicon phase diagram. Source: Ref 7

**The Lead-Tin System.** The phase diagram of the lead-tin system (Fig. 31) shows the importance of the low-melting eutectic in this system to the success of lead-tin solders. While solders having tin contents between 18.3 to 61.9% all have the same freezing temperature (183 °C, or 361 °F), the freezing range (and the castability) of the alloys varies widely.

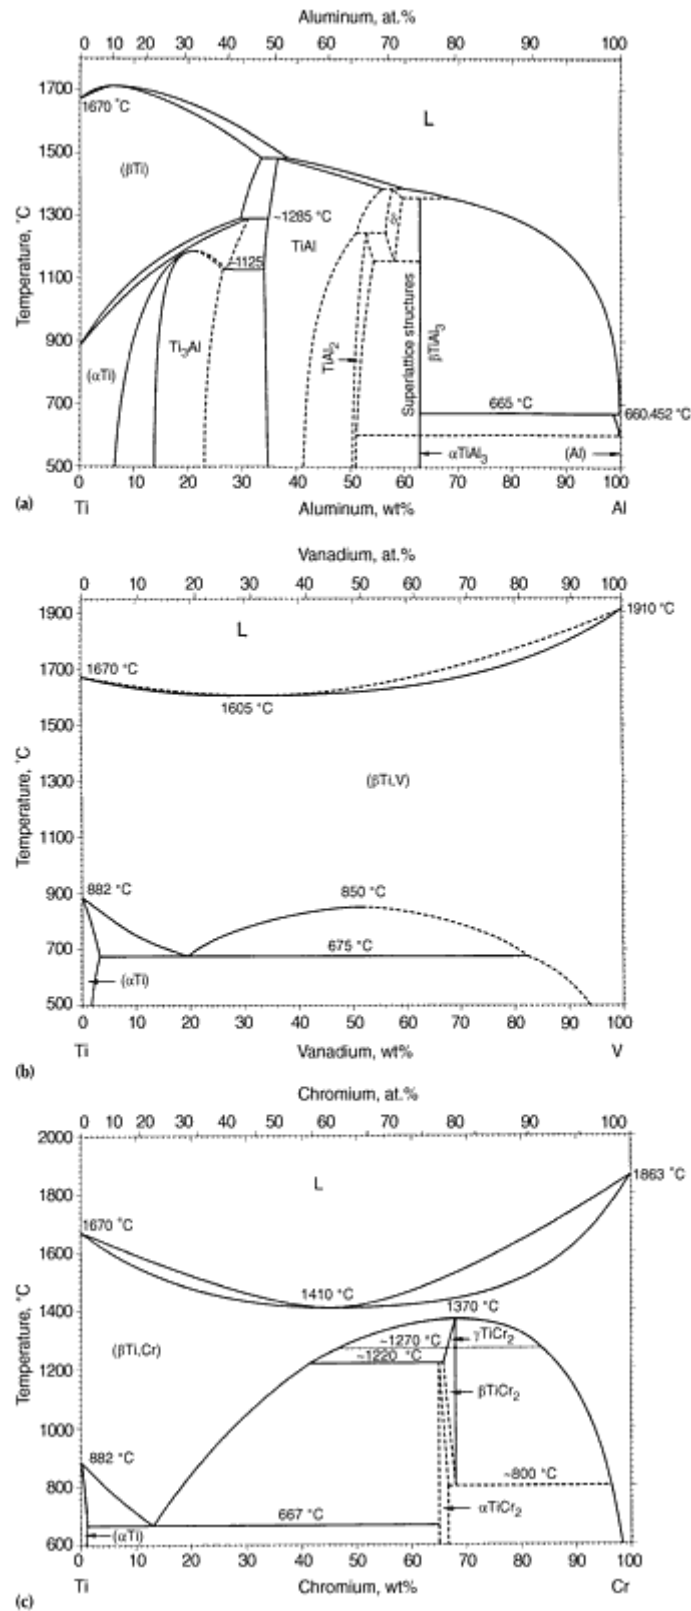

Fig. 31 The lead-tin phase diagram. Source: Ref 7

**The Titanium-Aluminum and Titanium-Vanadium Systems.** The phase diagrams of titanium systems are dominated by the fact that there are two allotropic forms of solid titanium: cph  $\alpha$ Ti is stable at room temperature and up to 882 °C (1620 °F); bcc  $\beta$ Ti is stable from 882 °C to the melting temperature. Most alloying elements used in commercial titanium alloys can be classified as  $\alpha$ stabilizer (such as aluminum) or  $\beta$ stabilizers (such as vanadium and chromium), depending on whether the allotropic transformation temperature is raised or lowered by the alloying addition (see Fig. 32). Beta stabilizers are further classified as those that are completely miscible with  $\beta$ Ti (such as vanadium, molybdenum, tantalum, and niobium) and those that form eutectoid systems with titanium (such as chromium and iron). Tin and zirconium also are often alloyed in titanium, but instead of stabilizing either phase, they have extensive solubilities in both  $\alpha$ Ti and  $\beta$ Ti. The microstructures of commercial titanium alloys are complicated because most contain more than one of these four types of alloying elements.

**Fig. 32** Three representative binary titanium phase diagrams, showing (a)  $\alpha$  stabilization (Ti-Al), (b)  $\beta$  stabilization with complete miscibility (Ti-V), and (c)  $\beta$  stabilization with a eutectoid reaction (Ti-Cr). Source: Ref 7

**The Iron-Carbon System.** The iron-carbon diagram maps out the stable equilibrium conditions between iron and the graphitic form of carbon (see Fig. 33). Note that there are three allotropic forms of solid iron: the low-temperature phase,  $\alpha$ ; the medium-temperature phase,  $\gamma$ ; and the high-temperature phase,  $\delta$ . In addition, ferritic iron undergoes a magnetic

phase transition at 771 °C (1420 °F) between the low-temperature ferromagnetic state and the higher-temperature paramagnetic state. The common name for bcc Fe is "ferrite" (from *ferrum*, Latin for "iron"); the fcc  $\gamma$  phase is called "austenite" after William Roberts-Austen; bcc Fe also is commonly called ferrite because (except for its temperature range) it is the same as  $\alpha$ -Fe. The main features of the iron-carbon diagram are the presence of both a eutectic and a eutectoid reaction, along with the great difference between the solid solubility of carbon in ferrite and austenite. It is these features that allow such a wide variety of microstructures and mechanical properties to be developed in iron-carbon alloys through proper heat treatment.

Fig. 33 The iron-carbon phase diagram. Source: Ref 7

**The Iron-Cementite System.** In the solidification of steels, stable equilibrium conditions do not exist. Instead, any carbon not dissolved in the iron is tied up in the form of the metastable intermetallic compound,  $\text{Fe}_3\text{C}$  (also called cementite because of its hardness), rather than remaining as free graphite (see Fig. 34). It is, therefore, the iron-cementite phase diagram, rather than the iron-carbon diagram, that is important to industrial metallurgy. It should be remembered, however, that while cementite is an extremely enduring phase, given sufficient time, or the presence of a catalyzing substance, it will break down to iron and carbon. In cast irons, silicon is the catalyzing agent that allows free carbon (flakes, nodules, etc.) to appear in the microstructure (see Fig. 35).

**Fig. 34** The iron-cementite phase diagram and details of the ( $\delta$ Fe) and ( $\alpha$ Fe) phase fields. Source: Ref 7

(b) As-cast grade 60-45-12 ductile iron, showing graphite nodules (produced by addition of calcium-silicon compound during pouring) in a ferrite matrix. 100 $\times$ . Source: Ref 6

The boundary lines on the iron-carbon and iron-cementite diagrams that are important to the heat treatment of steel and cast iron have been assigned special designations, which have been found useful in describing the treatments. These lines, where thermal arrest takes place during heating or cooling due to a solid-state reaction, are assigned the letter "A" for *arrêt* (French for "arrest"). These designations are shown in Fig. 34. To further differentiate the lines, an "e" is added to identify those indicating the changes occurring at equilibrium (to give  $A_{e1}$ ,  $A_{e3}$ ,  $A_{e4}$ , and  $A_{e_{cm}}$ ). Also, because the temperatures at which changes actually occur on heating or cooling are displaced somewhat from the equilibrium values, the "e" is replaced with "c" (for *chauffage*, French for "heating") when identifying the slightly higher temperatures associated with changes that occur on heating. Likewise, "e" is replaced with "r" (for *refroidissement*, French for "cooling") when identifying those slightly lower temperatures associated with changes occurring on cooling. These designations are convenient terms because they are not only used for binary alloys of iron and carbon, but also for commercial steels and cast irons, regardless of the other elements present in them. Alloying elements such as manganese, chromium, nickel, and molybdenum, however, do affect these temperatures (mainly  $A_3$ ). For example, nickel lowers  $A_3$  whereas chromium raises it.

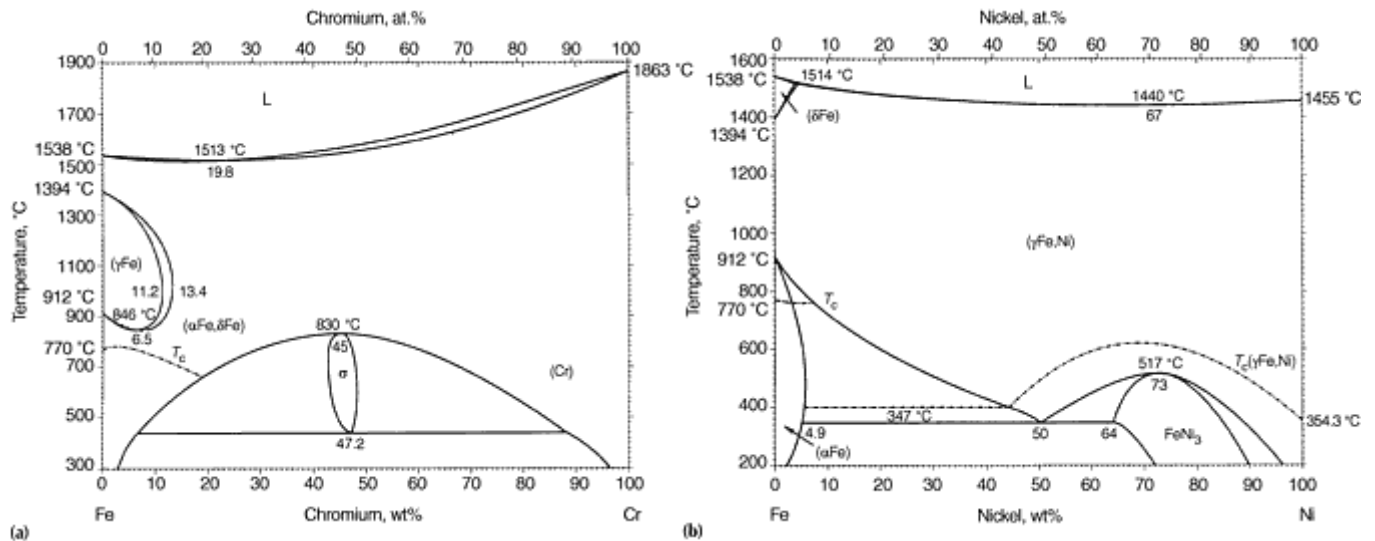

The microstructures obtained in steels by slowly cooling are as follows. At carbon contents from 0.007 to 0.022%, the microstructure consists of ferrite grains with cementite precipitated in from ferrite, usually in too fine a form to be visible by light microscopy. (Because certain other metal atoms that may be present can substitute for some of the iron atoms in  $Fe_3C$ , the more general term, "carbide," is often used instead of "cementite" when describing microstructures). In the hypoeutectoid range (from 0.022 to 0.76% C), ferrite and pearlite grains comprise the microstructure. In the hypereutectoid range (from 0.76 to 2.14% C), pearlite grains plus carbide precipitated from austenite are visible.

Slowly cooled hypoeutectic cast irons (from 2.14 to 4.3% C) have a microstructure consisting of dendritic pearlite grains (transformed from hypoeutectic primary austenite) and grains of iron-cementite eutectic (called "ledeburite" after Adolf Ledebur) consisting of carbide and transformed austenite, plus carbide precipitated from austenite and particles of free carbon. For slowly cooled hypereutectic cast iron (between 4.3 and 6.67% C), the microstructure shows primary particles of carbide and free carbon, plus grains of transformed austenite.

Cast irons and steels, of course, are not used in their slowly cooled as-cast condition. Instead, they are more rapidly cooled from the melt, then subjected to some kind of heat treatment and, for wrought steels, some kind of hot and/or cold work. The great variety of microconstituents and microstructures that result from these treatments is beyond the scope of a discussion of stable and metastable equilibrium phase diagrams. Phase diagrams are, however, invaluable when designing heat treatments. For example, normalizing is usually accomplished by air cooling from about 55  $^{\circ}C$  (100  $^{\circ}F$ ) above the upper transformation temperature ( $A_3$  for hypoeutectoid alloys and  $A_{cm}$  for hypereutectoid alloys). Full annealing is done by controlled cooling from about 28 to 42  $^{\circ}C$  (50 to 75  $^{\circ}F$ ) above  $A_3$  for both hypoeutectoid and hypereutectoid alloys. All tempering and process-annealing operations are done at temperatures below the lower transformation temperature ( $A_1$ ). Austenitizing is done at a temperature sufficiently above  $A_3$  and  $A_{cm}$  to ensure complete transformation to austenite, but low enough to prevent grain growth from being too rapid.

**The Fe-Cr-Ni System.** Many commercial cast irons and steels contain ferrite-stabilizing elements (such as silicon, chromium, molybdenum, and vanadium) and/or austenite stabilizers (such as manganese and nickel). The diagram for the binary iron-chromium system is representative of the effect of a ferrite stabilizer (see Fig. 36a). At temperatures just below the solidus, bcc chromium forms a continuous solid solution with bcc ( $\delta$ ) ferrite. At lower temperatures, the  $\gamma$ -Fe phase appears on the iron side of the diagram and forms a "loop" extending to about 11.2% Cr. Alloys containing up to 11.2% Cr, and sufficient carbon, are hardenable by quenching from temperatures within the loop.

**Fig. 36** Two representative binary iron phase diagrams, (a) showing ferrite stabilization (Fe-Cr) and (b) austenite stabilization (Fe-Ni). Source: Ref 7

At still lower temperatures, the bcc solid solution is again continuous bcc ferrite, but this time with  $\alpha$  Fe. This continuous bcc phase field confirms that  $\delta$  ferrite is the same as  $\alpha$  ferrite. The nonexistence of  $\gamma$ -Fe in Fe-Cr alloys having more than about 13% Cr, in the absence of carbon, is an important factor in both the hardenable and nonhardenable grades of iron-chromium stainless steels. Also at these lower temperatures, a material known as  $\sigma$  phase appears in different amounts from about 14 to 90% Cr. Sigma is a hard, brittle phase and usually should be avoided in commercial stainless steels. Formation of  $\alpha$ , however, is time dependent; long periods at elevated temperatures are usually required.

The diagram for the binary iron-nickel system is representative of the effect of an austenite stabilizer (see Fig. 36b). The fcc nickel forms a continuous solid solution with fcc ( $\gamma$ ) austenite that dominates the diagram, although the  $\alpha$  ferrite phase field extends to about 6% Ni. The diagram for the ternary Fe-Cr-Ni system shows how the addition of ferrite-stabilizing chromium affects the iron-nickel system (see Fig. 37). As can be seen, the popular 18-8 stainless steel, which contains about 8% Ni, is an all-austenite alloy at 900 °C (1652 °F), even though it also contains about 18% Cr.

**Fig. 37** The isothermal section at 900 °C (1652 °F) of the Fe-Cr-Ni ternary phase diagram, showing the nominal composition of 18-8 stainless steel. Source: Ref 8

**The Cr-Mo-Ni System.** In addition to its use in alloy and stainless steels and in cobalt- and copper-base alloys, nickel is also used as the basis of a family of alloys. Many of these nickel-base alloys are alloyed with chromium and molybdenum (and other elements) to improve corrosion and heat resistance. As the chromium and the molybdenum contents in most commercial Ni-Cr-Mo alloys range from 0 to about 30%, the phase diagram shown in Fig. 38 indicates that their microstructures normally consist of a matrix of  $\gamma$  solid solution, although this matrix is usually strengthened by a dispersion of second-phase materials such as carbides. For example, precipitated fcc  $\gamma'$  ( $\text{Ni}_3\text{Al,Ti}$ ) improves high-temperature strength and creep resistance.

# Properties of Metals

Hugh Baker, Consulting Editor, ASM International

## Introduction

THE PROPERTIES of materials determine their usefulness. In the context in which it is frequently used, the term "property" connotes something that a material inherently possesses. More properly, a property should be regarded as the response of a material to a given set of imposed conditions (e.g., temperature and/or pressure). Material properties are the link between the basic structure and composition of the material and the service performance of a part or component.

A wide variety of properties must be considered when choosing a material and a combination of properties is usually required for a given application. The properties of greatest importance for metals include:

- Physical properties, such as mass characteristics, thermal, electrical, magnetic, and optical properties
- Chemical properties, such as corrosion and oxidation resistance
- Mechanical properties, such as tensile and yield strength, elongation (ductility), toughness, and hardness

Many of these are discussed in this article. More detailed information can be found in the extensive data compilation on pure metals presented in Volume 2 of the *ASM Handbook*.

## Physical Properties of Metals

### Mass Characteristics

Mass characteristics include atomic weight and density. The *atomic weight* (or *relative atomic mass*) is the ratio of the average mass per atom of an element to  $\frac{1}{12}$  of the mass of the atom of the nuclide  $^{12}\text{C}$ . Atomic weights of the metallic elements are given in the periodic table in the introductory article in this Section entitled "The Chemical Elements." The term *density* refers to the mass per unit volume of a solid material and is usually expressed in  $\text{g/cm}^3$  and abbreviated by the Greek letter rho,  $\rho$ . For solid materials, density decreases with increasing temperature. Examples of room-temperature density values for various metals can be found in Table 1.

Table 1 Some physical properties of metals at room temperature

Metal	Density $\rho_d$ , $\text{g/cm}^3$	Specific heat capacity ( $C_p$ ), $\text{kJ/kg} \cdot \text{K}$	Coefficient of linear thermal expansion ( $\alpha$ ), $\mu\text{m/m} \cdot \text{K}$	Thermal conductivity ( $k$ ), $\text{W/m} \cdot \text{K}$	Electrical resistivity ( $\rho$ ), $\text{n}\Omega \cdot \text{m}$

(a) The electrical resistivity of carbon in diamond form is > 107 nΩ · m.

### Thermal Properties

**Melting and Boiling Points.** The *melting point* is the temperature at which the solid and liquid phases of a pure material are in equilibrium. The *boiling point* is the temperature at which the vapor pressure of a liquid equals the pressure of the surroundings: normally this pressure is taken to be 1 atm (760 torr). The melting and boiling points of the chemical elements and the temperatures at which allotropic phase transformations occur are given in Appendices 1 and 2 in the article "Alloy Phase Diagrams and Microstructure" in this Section.

**Vapor Pressure.** The *vapor pressure* of an element at a given temperature is related to the ratio of that temperature on the absolute scale to the boiling point of the element, also on the absolute scale. Vapor pressure values for various elements can be found in Table 2.

**Table 2 Vapor pressures of the elements up to 1 atm (760 mm Hg)**

Element	Pressure, atm											
	0.0001		0.001		0.01		0.1		0.5		1.0

(d)  $\gamma$ .

**Thermal Expansion.** Most solid materials expand upon heating and contract when cooled. The change in length with temperature for a solid material can be expressed as follows:

$$(l_f - l_o)/l_o = \alpha_1(T_f - T_o)$$

or

$$\Delta l/l_o = \alpha_1 \Delta T$$

where  $l_o$  and  $l_f$  represent, respectively, the original and final lengths with the temperature change from  $T_o$  to  $T_f$ . The parameter  $\alpha_1$  is called the *linear coefficient of thermal expansion* (CTE); it is a material property that is indicative of the extent to which a material expands upon heating and has units of reciprocal temperature ( $K^{-1}$ ) or  $\mu m/m \cdot K$ . Table 1 lists room-temperature linear CTE values for various metals. With respect to temperature, the magnitude of the CTE increases with rising temperature. In general, CTE values for metals fall between those of ceramics (lower values) and polymers (higher values).

Of course, heating or cooling affects all the dimensions of a body, with a resultant change in volume. Volume changes may be determined from:

$$\Delta V/V_o = \alpha_v \Delta T$$

where  $\Delta V$  and  $V_o$  are the volume change and original volume, respectively, and  $\alpha_v$  represents the volume coefficient of thermal expansion. In many materials, the value of  $\alpha_v$  is anisotropic; that is, it depends on the crystallographic direction along which it is measured. For materials in which the thermal expansion is isotropic,  $\alpha_v$  is approximately  $3\alpha_1$ .

**Heat Capacity.** A solid material, when heated, experiences an increase in temperature indicating that some energy has been absorbed. *Heat capacity* is the property that represents the ability of a material to absorb heat from external surroundings; it is the amount of energy required to produce a unit temperature rise. Heat capacity,  $C$ , is expressed as follows:

$$C = dQ/dT$$

where  $dQ$  is the energy required to produce a  $dT$  temperature change. Heat capacity is ordinarily specified per mole of material (e.g., J/mol · K). For most practical purposes the quantity used is the *specific heat capacity*, or *specific heat*, which is the quantity of heat required to change by one degree the temperature of a body of material of unit mass, expressed as J/kg · K. Lower and higher specific heat values correspond with lower and higher temperatures, respectively.

There are really two ways in which the specific heat can be measured according to the environmental conditions accompanying the transfer of heat. One is the specific heat capacity while maintaining the specimen volume constant,  $C_v$ ; the other is for constant external pressure,  $C_p$ . The magnitude of  $C_p$  is always greater than  $C_v$ ; however, this difference is very slight for most solid materials at room temperature and below. Table 1 lists  $C_p$  values for various metallic elements.

**Thermal Conductivity.** Thermal conduction is the phenomenon by which heat is transported/transferred from high- to low-temperature regions of a substance. The property that characterizes the ability of a material to transfer heat is the *thermal conductivity*, which is defined as:

$$q = -k(dT/dx)$$

where  $q$  denotes the heat flux, or heat flow, per unit time per unit area (area being taken as that perpendicular to the flow direction),  $k$  is the thermal conductivity, and  $dT/dx$  is the temperature gradient through the conducting medium. The units for  $q$  and  $k$  are W/m<sup>2</sup> and W/m × K, respectively. (Room-temperature  $k$  values for various metals are given in Table 1.) It should be noted that the above equation is valid for only steady-state heat flow, that is, for situations in which the heat flux does not change with time. The minus sign in the equation indicates that the direction of heat flow is from hot to cold, or down the temperature gradient.

Because the thermal vibration of the free electrons in metallic crystals is a major contributor to the high thermal conductivity of solid metals (along with ionic vibration), the values of the thermal and electrical conductivities of a metal at any given temperature are related. The ratio between the two is called the Wiedemann-Franz ratio ( $k/\sigma$ ), which was developed by Gustav Heinrich Wiedemann and Rudolf Franz and is about  $1.6 \times 10^{-6}$  at 20 °C. Further, because electrical resistivity is nearly proportional to the absolute temperature, the value  $k/\sigma T$ , called the Lorentz number (after Henrick Anton Lorentz), is approximately constant. A more exact relation between the two conductivities, however, is defined by the Bungardt and Kallenbach equation:

$$k = A \times \sigma T + B \times T$$

where  $A$  and  $B$  are the constants for the free-electron and ionic contributions, respectively, for a given metal. Because of the difficulty involved in measuring thermal conductivity compared to electrical resistivity, this relation is useful in estimating the thermal conductivities of alloys as well as metals.

It should be noted that because both electrical and thermal conductivities rely on the migration of free electrons, temperature is not the only factor that affects these properties. Anything that distorts the crystal structure, such as thermal vibrations of the ions, crystal vacancies and dislocations, grain boundaries, interstitial and solute ions, and elastic and plastic strain, will increase resistance to conduction.

**Thermal diffusivity** is a useful measure of the speed at which heat spreads throughout a metal object, and this property can be calculated by dividing the thermal conductivity by the product of the specific heat capacity and the density of the metal. The units of thermal diffusivity are  $\text{m}^2/\text{s}$ , and the value describes the rate at which the spherical area within the object that is at a given temperature expands from a point heating source.

### ***Electrical Properties***

One of the most important electrical characteristics of a solid material is the ease with which it transmits an electric current. *Ohm's law* (after Georg Simon Ohm) relates the current,  $I$ , to the applied voltage,  $V$ , as follows:

$$V = IR$$

where  $R$  is the resistance of the material through which the current is passing. The units for  $V$ ,  $I$ , and  $R$  are volts (V), amperes (A), and ohms ( $\Omega = \text{V/A}$ ). The value of  $R$  is influenced by specimen configuration, and for many materials is independent of current. The *resistivity*, designated  $\rho$ , is independent of specimen shape, but related to  $R$  through the expression:

$$\rho = RA/l$$

where  $l$  is the distance between the two points at which the voltage is measured, and  $A$  is the cross-sectional area perpendicular to the direction of the current. The units for  $\rho$  are  $\Omega \times \text{m}$  (often given as  $\mu\text{m}\Omega \times \text{m}$  or  $\text{n}\Omega \times \text{m}$ ). From the expression for Ohm's law and the previous equation:

$$\rho = VA/I$$

Sometimes, *electrical conductivity*,  $\sigma$ , is used to specify the electrical character of a material. It is simply the reciprocal of the resistivity, or  $\sigma = 1/\rho$ .

As shown in Table 1, metals exhibit a wide range of resistivities--from the low resistivity (high conductivity) of silver and copper to the high resistivity (low conductivity) of manganese and bismuth. Resistivity values of metals increase with increasing temperature.

Also as shown in Table 1, the semimetals boron, carbon, silicon, white phosphorus, sulfur, germanium, and tellurium have electrical resistivities that are intermediate between those of metal conductors and nonmetal insulators. Therefore, they are called *semiconductors*. Their resistivities range from about  $10^3$  to  $10^{13} \Omega \cdot \text{m}$ , and they decrease with increasing temperature over some temperature range.

### ***Magnetic Properties***

All metals have magnetic properties, and these properties are important in many industrial applications. The *magnetic moments* are generated by the movements of the electrically charged electrons that orbit the atomic nuclei making up the crystal structure of the metal. Each electron generates magnetic moments from two sources, as shown in Fig. 1; one source is its orbiting and the other is its spinning as it orbits. Because these moments have specific directions, the orbital moments of some electron pairs in each individual atom can cancel each other. This also applies to spin moments. The resulting magnetic moment for each atom, then, is the net sum (rather than the total) of the individual moments of its electrons. Therefore, for atoms having completely filled electron shells, there is complete cancellation of electron moments, and the material is not capable of being permanently magnetized.

**Fig. 1** Sources of magnetic moments. (a) Orbiting electron. (b) Spinning electron

One measure of the magnetism of a material is its *magnetic permeability*. Magnetic permeability is a measure of the tendency of magnetic lines of force to pass through a metal in comparison to empty space. Another measure of the magnetism of a material is its *magnetic susceptibility*. Magnetic susceptibility is the ratio of the intensity of magnetization in a metal to the magnetizing force to which the metal is subjected. Relative permeability and susceptibility are both unitless, but the values of susceptibility in SI units (referred to as meter-kilogram-second or mks units) are  $4\pi$  greater than the values in cgs-emu (centimeter-gram-second electromagnetic unit) units. (The values of relative permeability are identical in SI and cgs-emu units.)

The magnetic susceptibility,  $\mu$ , of a material is defined by the equation:

$$B = \mu H$$

where  $H$  is the strength of a magnetic field applied to a material and  $B$  is the density of magnetic flux induced in the material. As the applied field is increased, the magnetic flux density also increases until a saturation level for the material is reached (see Fig. 2).

**Fig. 2** Magnetization curve for polycrystalline iron

Another property of magnetic materials is its *saturation magnetic moment* (see Table 3). The value of the saturation magnetic moment of a material is the ratio of the magnetic moment per atom of the material at magnetic saturation to the spin magnetic moment per electron in the material.

Source: J.J. Rhyne, *Bull. Alloy Phase Diagrams*, Vol 3 (No. 3), 1982, p 402

- (a) FM, transition from paramagnetic to ferromagnetic state; AC, transition to periodic (antiferromagnetic) state that is commensurate with the lattice periodicity (e.g., spins on three atom layers directed up followed by three layers down, etc.); AI, transition to periodic (antiferromagnetic) state that is generally not commensurate with lattice periodicity (e.g., helical spin ordering); CF, transition to conical ferromagnetic state (combination of planar helical antiferromagnetic plus ferromagnetic component); and FI, transition to ferromagnetic periodic structure (unequal number of up and down spin layers).
- (b) Ce exists in five crystal structures, two of which are magnetic ( $\gamma$ -fcc; and  $\beta$ -dcph).  $\gamma$ Ce is estimated to be antiferromagnetic below 14.4 K by extrapolation from fcc Ce-La alloys. ( $\alpha$ Ce does not exist in pure form below  $\approx 100$  K.)  $\beta$ Ce is thought to exhibit antiferromagnetism on the hexagonal lattice sites below 13.7 K and on the cubic sites below 12.5 K.
- (c) Magnetic measurements quoted in table for  $\gamma$ Fe are for fcc Fe precipitated in copper.
- (d) The magnetic moment assignments of Mn are complex.
- (e) h, A; c, A; indicate that sites of hexagonal and cubic point symmetry order antiferromagnetically, but at different temperatures.

The magnetic properties of some metallic elements are listed in Tables 3 and 4. It should be noted that there are several types of magnetism found in metals, and the temperatures at which they change from one type to another are also given in Table 3. As seen in the table, iron is not the only metal to exhibit ferromagnetism. Cobalt, nickel, and possibly promethium also exhibit ferromagnetism at room temperature. Gadolinium and a few other rare earth metals are ferromagnetic at very low temperatures. *Ferromagnetic materials* are those in which, at temperatures below a characteristic temperature called the *Curie point* (after Pierre Curie), the magnetic moments of atoms or ions tend to be aligned parallel to one another without the presence of an applied field, thereby producing a "permanent" magnetic moment. Above the Curie point, these materials become paramagnetic. *Paramagnetic materials* are those within which the permanent-magnetic dipole moments of atoms or ions are only partially aligned and the magnetic induction (magnetic flux density) is only slightly greater than the applied magnetic-field strength. The permeability of a ferromagnetic metal can reach values of the order of  $10^6$  times that of empty space, while the permeability of a paramagnetic metal is only slightly greater than that of empty space.

**Table 4 Room-temperature magnetic susceptibilities for paramagnetic and diamagnetic materials**

Paramagnetics		Diamagnetics	
Material	Susceptibility $X_m$ (volume) (SI units)	Material	Susceptibility $X_m$ (volume) (SI units)
Aluminum	$2.07 \times 10^{-5}$	Copper	$-0.96 \times 10^{-5}$
Chromium	$3.13 \times 10^{-4}$	Gold	$-3.44 \times 10^{-5}$
Molybdenum	$1.19 \times 10^{-4}$	Mercury	$-2.85 \times 10^{-5}$
Sodium	$8.48 \times 10^{-6}$	Silicon	$-0.41 \times 10^{-5}$
Titanium	$1.81 \times 10^{-4}$	Silver	$-2.38 \times 10^{-5}$
Zirconium	$1.09 \times 10^{-4}$	Zinc	$-1.56 \times 10^{-5}$

There are three other types of magnetic materials. *Ferrimagnetic materials* are those in which the magnetic moments of atoms or ions tend to assume an ordered but nonparallel arrangement in a zero applied field below a characteristic temperature called the Néel point (after Louis E.F. Néel). *Antiferromagnetic materials* are those in which the magnetic moments of atoms or ions tend to assume an ordered arrangement in a zero applied field, such that the vector sum of the moments is zero below the Néel point. The permeability of antiferromagnetic materials is comparable to that of paramagnetic materials. Above the Néel point, both these materials become paramagnetic. *Diamagnetic materials* are those within which the magnetic induction is slightly less than the applied magnetic field. For diamagnetic materials, the permeability is slightly less than that of empty space, and the magnetic susceptibility is negative and small.

The response of ferromagnetic, paramagnetic, and diamagnetic materials is compared in Fig. 3. Additional information on the magnetic characteristics of metals and alloys can be found in the Section "Special-Purpose Materials" in this Handbook.

**Fig. 3 Schematic of the flux density,  $B$ , versus magnetic field strength,  $H$ , for diamagnetic, paramagnetic, and**

ferromagnetic materials

## ***Optical Properties***

Several optical properties of smooth, bare, unoxidized metal surfaces are important in some applications. Four of these are *solar reflectivity* (shininess in sunlight), *solar absorptivity* (warming by sunlight), *thermal emissivity* (radiation cooling from a warm body), and color. (The word ending "ance" is substituted for "ivity" when the properties are measured on a rough surface.) The reflectivities of metals are high, but their emissivities are low. It should be remembered, however, that the values of these properties apply only to smooth, clean, unoxidized bare surfaces, which are seldom found on metals and alloys in practical applications. Instead, the surfaces of metals are almost always covered with some kind of an oxide layer or paint, both of which have the relatively low reflectance, but high *emittance* of nonmetallics. Exceptions are the noble metals (see below), which are normally bare.

The surface of clean, bare, unoxidized metals is lustrous. The color in all but two instances ranges from silvery gray to various shades of white. The exceptions are the reddish color of copper and the red-yellow of gold, which is the result of their electron configurations. Because of their chemical activities, thin oxides rapidly form on freshly bare surfaces of most metals, and these oxides can affect their appearance (see below).

## ***Radiation Properties***

The properties that describe the transparency or opaqueness of metals to radiation are important in some industries. The transparency to x-rays of light metals is required for the holders of x-ray films, while absorption of x-rays by lead makes possible its use as a shielding material. The thermal-neutron cross section of a metal defines the extent to which that metal absorbs thermal (slow) neutrons from a nuclear reactor, and the low thermal-neutron cross section of zirconium makes it a good canning material for nuclear fuel.

## **Chemical Properties of Metals**

The chemical property most important to structural use of a metal is its corrosion behavior. Most metals are basic in chemical behavior (will react with acids). But as stated above, because of the chemical activities of the metallic elements, thin oxides rapidly form on freshly bare surfaces of most metals. Ruthenium, rhodium, palladium, silver, osmium, iridium, platinum, and gold are the exceptions. These eight metals have such low chemical activity that they are called *noble metals*.

The physical and chemical properties of the oxides that form on the nonnoble metals, however, differ from metal to metal. Physically, some oxides cohere tightly to their base metal, while others readily spall or flake off and expose fresh base metal to the air. Also, some oxides are very dense and impervious to diffusion and allow very little oxygen to penetrate to the base metal, while others are quite porous and allow oxidation of the base metal to readily continue.

The oxides also differ in their chemical behavior, and this affects their compatibility with various environments (including paints). Many of these oxides are also basic in chemical behavior. The oxides of the alkali metals are strong bases, while those of the alkaline earth metals are moderately strong bases. The oxides of the metals in group 13 of the periodic table, such as aluminum, are amphoteric (react with both strong acids and bases). The oxides of most transition elements are weak bases, but many of these are amphoteric. This includes ferric oxide ( $\text{Fe}_2\text{O}_3$ ), which may react with strong bases. In general, the metals farther to the right of the periodic table form oxides that are increasingly weaker bases. While the metal oxides are protective in many situations, it also should be noted that most bare structural metals are very chemically active, and whenever their protective oxide film breaks down, the reaction to the environment can be quite rapid.

## ***General Corrosion Behavior of Metals***

The general corrosion behaviors of several metals used in construction are discussed below. More detailed information on corrosion characteristics can be found in the Sections of this Handbook that deal with these metals and their alloys.

**Tin** also is protected by a very thin layer of oxide ( $\text{SnO}_2$ ) that is relatively impervious, adherent, and quite transparent. This oxide layer has the good thermal emittance of nonmetallics, but because it is very thin and quite transparent, the surface has almost the same good reflectivity of bare tin.

**Copper.** The corrosion product predominantly responsible for the protection of copper in aqueous environments is  $\text{Cu}_2\text{O}$ . This oxide layer is not impervious, but is adherent and provides excellent protection against further corrosion. In marine environments, an attractive and protective green patina forms, which consists of a film of copper chloride or carbonate, sometimes with a inner layer of  $\text{Cu}_2\text{O}$ .

**Aluminum.** The oxide that first forms on aluminum is also both quite impervious to diffusion and quite coherent (although some of the gray oxide will rub off). Therefore, oxidation of the base metal slows almost to a stop while the oxide film is still so thin that it is quite transparent (about 1 nm thick). The corrosion product that forms on the surface of bare metals exposed to air, however, is seldom a simple oxide such as the thin barrier layer of  $\text{Al}_2\text{O}_3$  that forms aluminum. In moist air, a more permeable layer of hydrated oxide,  $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ , forms over the oxide layer on aluminum, and it is the chemical properties of these two corrosion products that controls the chemical behavior of aluminum.

**Titanium.** The oxide that typically forms on titanium in aqueous environments is  $\text{TiO}_2$ , but can consist of mixtures of other oxides, such as  $\text{Ti}_2\text{O}_3$  and  $\text{TiO}$ . The  $\text{TiO}_2$  film is typically less than 10 nm thick and, therefore, also invisible. Like tin, copper, and aluminum, the oxide surface has both good emittance and good reflectivity. In addition, it is impervious to oxygen (and hydrogen) and is highly chemical resistant and attacked by very few substances.

**Iron.** In contrast to the metals described above, the oxide that forms on iron is much less dense. Therefore, the layer of iron-oxide rust is rather permeable and builds up fairly rapidly to a thickness that is easily seen (and its reddish color enhances its visibility), and the layer will continue to thicken until all the base metal is converted. The rust also readily flakes and rubs off. This rust, however, consists of hydrated oxides rather than simple oxides, but these hydrated oxides can lose water due to drying and revert to the anhydrous  $\text{FeO}$  and  $\text{Fe}_2\text{O}_3$ . In addition, a layer of  $\text{Fe}_3\text{O}_4$  ( $\text{FeO} \cdot \text{Fe}_2\text{O}_3$ ) often forms between the  $\text{FeO}$  and  $\text{Fe}_2\text{O}_3$ , and various crystal forms of  $\text{FeOOH}$  have also been found to exist in the complicated system of compounds that form on iron (and steel). The composition of this rust film and its corrosion behavior depends on oxygen availability, humidity, temperature, and the levels of atmospheric pollutants present. In aqueous environments, pH affects corrosion of iron and steel. While the rust film offers some protection to iron and steel in alkaline environments, the evolution of hydrogen at low pH tends to diminish this protection.

**Magnesium.** The film that first forms on magnesium is the hydroxide,  $\text{Mg}(\text{OH})_2$ . This hydroxide then reacts with any carbonic acid in the environment to form various hydrated carbonates, including  $\text{MgCO}_3 \cdot \text{H}_2\text{O}$ ,  $\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$ , and  $3\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 3\text{H}_2\text{O}$ . In atmospheres contaminated with sulfur compounds, magnesium sulfites or sulfates such as  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  may also be present in the film. This gray film is permeable, but also is fairly adhesive and does not readily rub off.

**Zinc** is highly resistant to atmospheric corrosion due to the formation of insoluble basic carbonate films that protect the metal surface.

## Mechanical Properties

**Elasticity.** When a crystal is stressed by an internal or external load, the lattice responds by relative movement of the atoms (ions) in it in a manner that tends to relieve that stress. The measure of the change in size of the crystal or multicrystalline object caused by the stress is strain. When the load is removed, the crystal or object will return to its original size provided that all the atoms in the crystal or object keep their original neighbors. When this provision is met, the strain is elastic (the crystal or object has sustained *elastic deformation*) and amount of strain is directly proportional to the amount of stress placed on the crystal or object. This proportionality is called *Hooke's law* (after Robert Hooke).

The relation between *applied stress* and *elastic strain* is called the *modulus of elasticity* of the material. The modulus obtained under unidimensional tension or compression loading is called *Young's modulus*,  $E$  (after Thomas Young), while torsion or shear loading gives the *modulus of rigidity* or *shear modulus*,  $G$ . Young's modulus and the shear modulus are related by the formula below, which involves the *Poisson's ratio*,  $\nu$  (after Siméon Denis Poisson), which is the ratio of lateral strain to axial strain in a stressed material:

$$\nu = (E - 2G)/2G$$

Hydrostatic compression causes materials to contract in volume. The ratio of the unit change in volume to the mean normal (perpendicular) compressive stress is called the *compressibility*,  $\beta$ , of the material. The inverse of compressibility

(the ratio of the mean normal pressure on the material to its unit contraction) is called the *bulk modulus*,  $K$ , of the material. The values of elastic moduli of several metals are listed in Table 5.

**Table 5 Mechanical properties of selected metals at room temperature**

Metal	Young's modulus ( $E$ ), GPa	Shear modulus ( $G$ ), GPa	Poisson's ratio, $\nu$	Yield strength, MPa	Tensile strength, MPa	Elongation, %
Aluminum	67	25	0.345	15-20	40-50	50-70
Beryllium	303	142	0.07	262-269	380-413	2-5
Cadmium	55	19.2	0.43	...	69-83	50
Chromium	248	104	0.210	...	83	0
Cobalt	211	80	0.32	758	945	22
Copper	128	46.8	0.308	33.3	209	33.3
Gold	78	27	0.4498	...	103	30
Iron	208.2	80.65	0.291	130	265	43-48
Lead	26.1	5.6	0.44	9	15	48

Tungsten	345	134	0.283	350	150	40
Zinc	69-138	...	...	...	...	...

Zirconium	49.3	18.3	0.35	230	...	32
-----------	------	------	------	-----	-----	----

**Plasticity.** When the *elastic limit* of the bulk material is exceeded and not all of the atoms in a crystal or object under stress keep their original neighbors (due to slip and/or twinning), a *plastic strain* increment is added to the elastic strain to make up the *total strain* on the crystal or object. At this point, the material is said to have begun yielding. Then when the load is removed, the plastic strain remains and the crystal or object has sustained *permanent deformation*, producing a *permanent set*.

**Stress-Strain Curves.** Plots of the relation between applied *nominal stress* (load divided by original cross section) and resulting strain (unit deformation) that are determined for a material specimen reveal much information about the mechanical properties of that material. Figure 4 shows a tensile stress-strain curve typical of a pure metal. A specimen having a reduced-cross-section "gage" section is prepared, the area of that section is measured, and a standard gage length (often 50 mm, or 2 in.) is marked on the section. Upon initial loading, the metal specimen elongates and laterally contracts (or laterally expands if the load is in compression), and the curve of strain versus stress follows the modulus line until it reaches the *proportional limit*, which is essentially the same point as the elastic limit. This limit is so low in most metals that it is difficult to determine an accurate value for the modulus of elasticity of the metal from a stress-strain curve. Therefore, this value for metals is often determined instead by a sonic vibrational test.

**Fig. 4** Typical tension stress-strain curve for a nonferrous metal

Brittle metals, such as chromium, will fracture upon loading to the elastic limit rather than sustain plastic deformation. Upon loading of ductile metals beyond the elastic limit, the addition of plastic deformation to the elastic strain causes the total strain to increase at a faster rate than before and the plot curves off from the modulus line. Because it also is difficult to determine on a stress-strain curve where yielding begins, an arbitrary definition of "yielding" is used. In many testing standards, the *yield strength* of most metals is defined as the stress at which a line parallel to the modulus line, but offset from it by 0.2% strain, intersects the curve (see Fig. 4).

It should be remembered that the stress applied to the specimen is normally the nominal stress rather than *true stress*. In the initial portion of the plot, the amount of lateral contraction (thinning) of the specimen is distributed along the entire test length of the specimen and is therefore so small that the nominal and true stress are almost identical. But in the latter portion of the test, *necking* of a tensile specimen occurs. That is, thinning begins to concentrate near the region where fracture will eventually occur. This necking can often become so pronounced that the nominal stress will decrease upon additional loading, as shown in Fig. 4, even though the true stress continues to increase until fracture occurs.

A plot of nominal tension stress versus strain such as shown in Fig. 4 is sometimes called an *engineering stress-strain curve* to distinguish it from a *true stress-strain curve* (see also Fig. 5). The high point on an engineering stress-strain curve is defined in test standards as the *ultimate tensile strength* of the specimen, or simply the *tensile strength*. The point

of fracture is called the *fracture strength* or *breaking strength*. Upon fracture, the elastic energy in the specimen is released and the elastic strain is recovered. The plastic strain remaining in specimen, called the *total elongation*, is then determined by fitting the broken pieces together and measuring the new distance between the gage marks. The *reduction in area* of the broken specimen is determined by measuring the dimensions of the necked-down region at the fracture and comparing that cross-sectional area to the original cross section. Besides tensile and compressive stress-strain curves, occasionally torsion and/or bearing curves are determined. Table 5 lists typical strengths and total elongations of several annealed metals.

**Fig. 5** True stress-strain curve versus engineering stress-strain curve

Modern design concepts sometimes require better descriptions of stress-strain behavior than afforded by tabular values of modulus, strength, and elongation. Therefore, stress-strain curves themselves are sometimes reproduced, but usually only the portion covering the first few percent of elongation. Other times, strain is not shown on the final plot. Instead, the slope of the stress-strain curve is described by plotting the secant modulus or the tangent modulus. As shown in Fig. 6, the *tangent modulus* is defined as the slope of a stress-strain curve at a specified point on that curve; the *secant modulus* is the slope of a line connecting the origin of a stress-strain curve with a specified point on that curve.

**Fig. 6** Three types of modulus ratios that can be derived from a stress-strain curve

The stress-strain curves of iron containing even a small amount of carbon are different from those of pure metals. As seen in Fig. 7, the point at which yielding begins, called the *yield point* or *upper yield point*, is quite sharply defined. This is because as soon as the stress corresponding to this point is exceeded, the stress required for plastic deformation noticeably drops to a level called the *lower yield point*. The plot then begins to rise in a curve similar to that for pure metals. The stress at the upper yield point, rather than the lower yield point, is usually reported as the yield strength of these materials.

Fig. 7 Typical tension stress-strain curve for iron containing 0.15% C

**Creep** is the term used to describe the time-dependent plastic deformation, *creep strain*, that occurs when a material is subjected to constant nominal stress. When the non-time-dependent strain that results from the initial loading is added to the creep strain, the result is called *total strain*. (The thermal expansion that occurs upon heating to the test temperature, however, is not included.) Most creep testing is done under tension and at temperatures that are relatively high for the material being tested, and the terms *creep extension* and *total extension* are used. As shown in Fig. 8, the rate of creep strain upon initial loading is fairly rapid, but decreases with time; this is called *primary creep*. The creep rate then reaches a minimum and a fairly constant rate for a period of time, which is called *secondary creep*. In *third-stage creep* or *tertiary creep*, the creep rate begins to increase again and continues to increase until the specimen breaks (if the test is continued to this point). The relative portions of the total time to rupture taken by these three stages depends on several factors, and in some tests, the secondary stage becomes a point on the graph where it changes from decreasing to increasing curvature.

Fig. 8 The three stages of a creep curve

The results of creep tests are reported in a variety of ways. Sometimes, the results for a given temperature (especially short-time, high-temperature tests) are reported in the form of *isochronous stress-strain curves*, which are curves constructed from equal-time points on the stress-strain relationships determined in the creep test (see Fig. 9). The elastic portion of such isochronous stress-strain curves is added by using the modulus value for the test temperature determined independently. The stress that causes a specified strain at that temperature is then called the *creep strength* of the material for those conditions. (The term creep strength is sometimes also used to describe the stress that will cause a specified rate of secondary creep at that temperature.) Other times, equal-strain results for a given temperature are plotted on stress-time graphs.

**Fig. 9** Isochronous stress-strain curves for specimens of a material creep tested at a given temperature

When a creep test is continued until the specimen ruptures, the test is often called a *creep-rupture* or *stress-rupture* test, and the results are reported on a plot of stress versus time to rupture.

**Fatigue.** The tendency of a material to break under conditions of repeated cyclic stresses is called *fatigue*. Fatigue fractures are different from the ductile fractures that usually result from regular tension and creep loading of most metals. Instead, fatigue fracture is caused by the propagation of cracks that initiate at a single point or at a few points in the material, and fatigue fractures are always brittle fractures. Most parts and fatigue specimens contain points of *stress concentration*, such as surface roughness or changes in part or specimen section, at which stress is concentrated and where fatigue cracking initiates. The amount of concentration can be determined (based on purely elastic behavior) and is reported as the *theoretical stress-concentration factor* or simply the *stress-concentration factor*,  $K_t$ . The *fatigue-strength reduction factor* or *fatigue-notch factor* can be determined by dividing the fatigue strength of smooth (unnotched) specimens by the fatigue strength of notched specimens. Comparing the fatigue-strength reduction factor to the theoretical stress-concentration factor gives a measure of the sensitivity of the material to notches when under cyclic loading; *notch sensitivity* is the fatigue factor divided by  $K_t - 1$  and often is expressed as a percentage.

Several different fatigue tests have been developed, each designed to replicate the loading conditions found in specific industrial applications. The rotating-beam test replicates the loading of a railroad axial; the plate-bending test, a leaf spring; the axial test, connecting rods and chain links. Some tests run under constant load, while others run under constant strain. Therefore, tabular values of fatigue strength or fatigue limit are of value mainly in material selection, rather than useful in actual design calculations.

The stress in a fatigue test usually is cycled between a maximum tensile stress and a minimum tensile stress or between a maximum tensile stress and a maximum compression stress. The ratio of these extremes (where compression is considered a negative stress) is called the *stress ratio*,  $R$ . The ratio for fully reversed stress then becomes  $-1$ . Other terms used to describe a fatigue stress include mean *stress* (the stress midway between the extremes), the *stress range* (the stress variation between the extremes), and the *stress amplitude* (the stress variation between the mean stress and one of the maximums).

The results of fatigue test are usually reported in the form of plots of stress versus number of cycles to fracture, called *S-N* curves. In these plots, the number of cycles is usually plotted on a logarithmic scale (and sometimes stress is also). Most metals have *S-N* curves that continually show longer lives at lower stresses, and the *fatigue strength* of the material must be reported for a given number of cycles (as well as the stress ratio for the test and the stress-concentration factor if the specimen contains a notch). For steels, however, the curve breaks off and becomes essentially horizontal at some stress level called the *fatigue limit* (see Fig. 10).

Fig. 10 Comparative fatigue curves

Some fatigue tests are conducted using a fracture-mechanics approach. This is described in the Section "Failure Analysis" in this Handbook.

**Toughness.** Generally speaking, *toughness* is a measure of the amount of energy a material absorbs during straining to fracture. Specimen shape as well as the manner of load application are important in toughness determination. For dynamic (high-strain-rate) loading conditions and when a notch (or point of stress concentration) is present, notch toughness is assessed by using an impact test (see the Section on "Mechanical Testing" in this Handbook). A special measure of toughness is used in *linear fracture mechanics* called *fracture toughness* (the ability of a material to resist fracture when a crack is present). This is a scaling factor, also called the *critical stress-intensity factor*,  $K$ , that describes the intensification of applied stress at the tip of a crack of known size and shape at the onset of rapid crack propagation. Details on fracture toughness and fracture mechanics can be found in the Sections "Mechanical Testing" and "Failure Analysis" in this Handbook.

For the static (low-strain-rate) situation, toughness can be determined from the results of a tensile stress-strain test. It is the area under the stress-strain curve up to the point of fracture.

Hardness is the resistance of a material to plastic indentation. While the measurement of hardness can involve only a simple scratch test or bounce test, it usually involves the amount of indentation caused by the application of a hard indenter of some standard shape and material. Hardness values are roughly proportional to the strength of a metal (see, for example, the hardness conversion tables for steels in the Section "Glossary of Terms and Engineering Data") and can give an indication of its wear properties (abrasion resistance). Therefore, hardness values can be useful during selection of a suitable material for an application. They also are very useful during quality-control operations, but the values cannot be applied directly during the design of a part. Hardness tests are described in the Section "Mechanical Testing" in this Handbook.

# Introduction and Overview of Design Considerations and Materials Selection

## Introduction

ENGINEERING DESIGN can be defined as the creation of a product that satisfies a certain need. A good design should result in a product that performs its function efficiently and economically within the prevailing legal, social, safety, and reliability requirements. To satisfy such requirements, the design engineer has to take into consideration many diverse factors:

- *Function and consumer requirements*, such as capacity, size, weight, safety, design codes, expected service life, reliability, maintenance, ease of operation, ease of repair, frequency of failure, initial cost, operating cost, styling, human factors, noise level, pollution, intended service environment, and possibility of use after retirement
- *Material-related factors*, such as strength, ductility, toughness, stiffness, density, corrosion resistance, wear

resistance, friction coefficient, melting point, thermal and electrical conductivity, processability, possibility of recycling, cost, available stock size, and delivery time

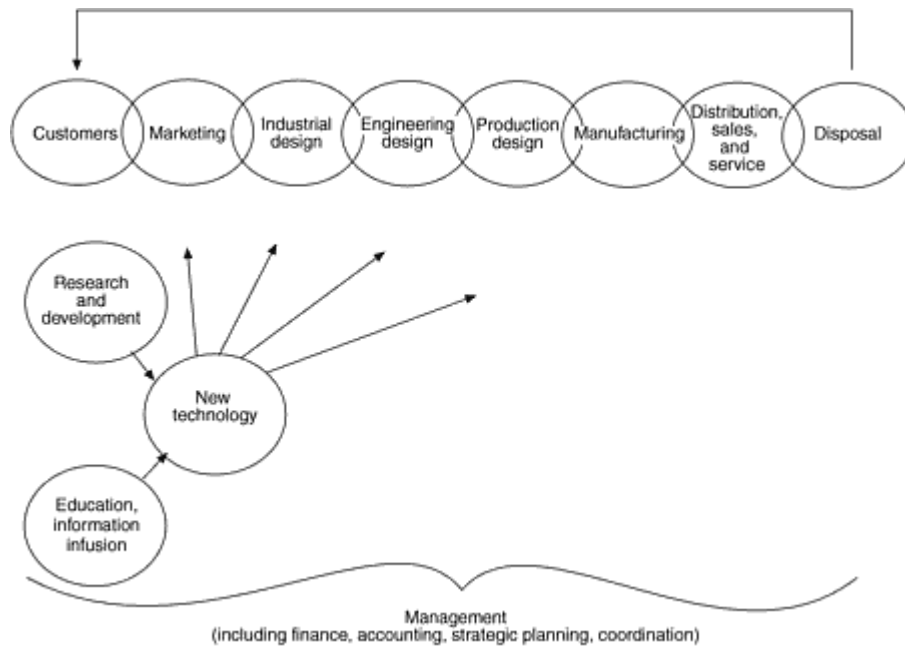

- *Manufacturing-related factors*, such as available fabrication processes, accuracy, surface finish, shape, size, required quantity, delivery time, cost, and required quality

Figure 1 illustrates the relationship among the previously mentioned groups. The figure also shows that there are other secondary relationships between material properties and manufacturing processes, between function and manufacturing processes, and between function and material properties.

**Fig. 1** Factors to consider in component design. Source: Ref 1

Figure 2 shows that engineering design is actually part of a much larger process of bringing new products to market. The name that has been coined for the complete process is the product realization process (PRP). As indicated in Fig. 2, engineering design takes place approximately between marketing and manufacturing within the total PRP of a firm. Engineering design, however, is not an isolated activity. It influences, and is influenced by, all other parts of a manufacturing business. Unfortunately, the relationship between design and other sectors of a manufacturing business has not been sufficiently recognized in the past. Recently, however, mostly in response to the pressures of international competitiveness, new approaches to product design and development have arisen to improve quality, drive down cost, and reduce product cycle time. Generally called *concurrent engineering*, the product uses product development teams of experts from all functions--design, manufacturing, marketing, and so forth--to work together from the start of the product design project. This opens new opportunities for better materials selection and has resulted in the development of new computer-based design tools.

**Fig. 2 Engineering design as a part of the product realization process**

This introductory article, as well as the other articles that follow on "Design Factors" and "Factors in Materials Selection," discuss the various roles and responsibilities of materials engineers in a product realization organization and suggest new and different ways in which materials engineers can benefit their organizations. The integration of material, process, and product design relies on individuals who are trained in materials selection and can work in a team environment. Often it is the materials engineer/specialist, familiar with the conflicting needs of design, production, and marketing, who can assume the role of mediator to focus on the final product.

## Key Considerations for Design

**The Design Process.** The role of the materials engineer during the design process can take many paths. The task may simply be to design a "new" part that is nearly identical to an existing part and is expected to be used in similar ways. In this case, it may be possible to use the same material and processing used for the existing part. Alternatively, the task may be to design and select material for a new part. Obviously, this is a much more complex task and requires knowledge of loads, load distributions, environmental conditions, and a host of other performance factors (including customer expectations) and manufacturing-related factors.

In addition to a knowledge of the required performance characteristics, the materials selector is responsible for defining and accounting for manufacturing-induced changes in material properties. Different production methods, as well as controlled and uncontrolled thermal and mechanical treatments, will have varying effects on the performance properties and the cost of the final part or assembly. Often, it is by relating the varying effects of manufacturing processes to customer needs that one manufacturer develops an advantage over another product, using essentially the same material and process combinations.

It is critical to understand and accept that the choice of manufacturing processes is frequently not under the direct control of the materials selection expert. In fact, by the time the concept and initial configuration of a design is committed to paper, or to a computer-aided design (CAD) system, the manufacturing processes and sequence of processes required to produce a product cost effectively are normally fixed. They are no longer variables that can be controlled without redesign.

**Criteria and Concepts in Design.** Material selection involves more than meeting minimum property requirements for strength, fatigue, toughness, corrosion resistance, or wear resistance. There are numerous options for product design and materials selection, and frequently they cannot be quantified. This precludes the use of mathematical optimization routines and shifts the emphasis to experience. Experience is essential in dealing with these "soft issues" related to qualitative non-property considerations.

The design must be producible. This means robust processes must be selected that have known statistical variation and will yield features or complete parts that lie well within the specification limits. This design for manufacturability approach is becoming popular, is an integral part of an integrated product development team's tool box, and has been demonstrated to be effective in improving quality and reducing cost.

Designing to minimize the total costs to the consumer during the expected product life (the life cycle cost) is yet another challenge. These costs include raw material, production, use, maintenance (scheduled or otherwise), and disposal or recycling costs. Some of these cost elements are unknown. This is where the combination of the art and skill of engineering faces its most severe test.

Similar issues arise when the safety, product liability, and warranty cost exposure aspects of product design and material selection are concerned. In many cases, alternate designs or materials could be chosen with no measurable difference. However, there are also many cases where a particular design and/or material choice could prevent an undesirable product failure mode. An understanding of how a part, assembly, or entire structure can fail and the ramifications of that failure are essential in providing a safe and reliable design.

The growing environmental and regulatory demand to consider the entire life cycle of a product could require the manufacturer to recover and recycle the product and process waste materials. This places renewed emphasis on considering all options. Changing the materials or the manufacture of a component involves designing an environmentally friendly product. Changing from chromium plating appears to be environmentally friendly, but today's chrome plating units are being constructed to operate in a zero discharge mode, so there is no obvious gain from eliminating the chrome. The anodizing process can be just as clean. Paint, on the other hand, is suffering severe scrutiny over both emissions during the painting process as well as subsequent mishandling by the consumer. And, changing a part body from metal to plastic is not necessarily a good solution because the recycling infrastructure is not yet adequate on a global level to effectively reclaim the material.

Another design factor is the repairability of a product. Automobiles are not intended to have accidents, but they do. Design and material selection only for initial cost and performance factors has led to the widespread use of one-piece plastic parts that are not repairable in many cases. Any product that costs more to repair than the owner finds acceptable will eventually suffer in the marketplace.

## **Key Considerations for Materials Selection**

The selection of the correct material for a design is a key step in the process because it is the crucial decision that links computer calculations and lines on an engineering drawing with a working design. Materials and the manufacturing processes that convert the material into a useful part underpin all of engineering design. The enormity of the decision task in materials selection is given by the fact that there are well over 100,000 engineering materials from which to choose. On a more practical level, the typical design engineer should have ready access to information on 50 to 80 materials, depending on the range of applications.

The importance of materials selection in design has increased in recent years. The adoption of concurrent engineering methods (see following discussion) has brought materials engineers into the design process at an earlier stage, and the importance given to manufacturing in present day product design has reinforced the fact that materials and manufacturing are closely linked in determining final properties. Moreover, world pressures of competitiveness have increased the general level of automation in manufacturing to the point where cost of materials comprise 50% or more of the cost for most products.

**Relation of Materials Selection to Design.** An incorrectly chosen material can lead not only to failure of the part but also to unnecessary cost. Selecting the best material for a part involves more than selecting a material that has the properties to provide the necessary performance in service; it is also intimately connected with the processing of the material into the finished part (Fig. 2). A poorly chosen material can add to manufacturing cost and unnecessarily increase

the part cost. Also, the properties of the material can be changed by processing (beneficially or detrimentally), and that may affect the service performance of the part.

With the enormous combination of materials and processes to choose from, the task can be done only by introducing simplification and systemization. Design proceeds from concept design, to embodiment (configuration) design, to detail (parametric) design, and the material and process selection then becomes more detailed as the design progresses through this sequence.

At the concept level of design, essentially all materials and processes are considered rather broadly. The materials selection methodology and charts developed by Ashby (Ref 2) are highly appropriate at this stage. The decision is to determine whether each design concept will be made from metal, plastics, ceramic, composite, or wood, and to narrow it to a group of materials. The precision of property data needed is rather low. If an innovative material is chosen, it must be done at the conceptual design step because later in the design process too many decisions have been made to allow radical change.

At the embodiment or configuration level of design, the emphasis is on determining the shape and approximate size of a part using engineering methods of analysis. Now the designer will have decided on a class of materials and processes, for example a range of aluminum alloys, wrought and cast. The material properties must be known to a greater level of precision.

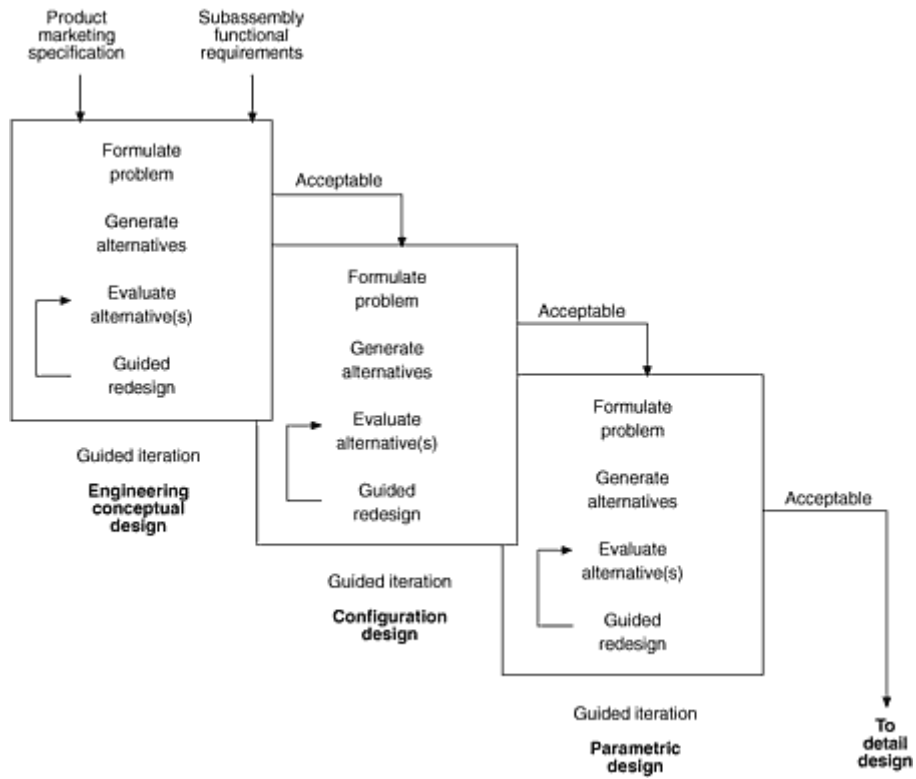

At the detail or parametric design level, the decision will have narrowed to a single material and only a few manufacturing processes. Here the emphasis will be on deciding on critical tolerances, optimizing for robust design, and selecting the best manufacturing process using quality engineering and cost modeling methodologies. Depending on the criticality of the part, materials properties may need to be known to a high level of precision. At the extreme, this requires the development of a detailed data base from an extensive materials testing program.

In a more detailed approach to engineering design, Dixon and Poli (Ref 3) suggest a four-level approach to materials selection:

- *Level I.* Based on critical properties, determine whether the part will be made from metal, plastic, ceramic, or composite.
- *Level II.* Determine whether metal parts will be produced by a deformation process (wrought) or a casting process; for plastics determine whether they will be thermoplastic or thermosetting setting polymers.
- *Level III.* Narrow options to a broad category of material. Metals can be subdivided into categories such as carbon steel, stainless steel, and copper alloys. Plastics can be subdivided into specific classes of thermoplastics and thermosets such as polycarbonates and polyesters.
- *Level IV.* Select a specific material according to a specific grade or specification.

Thus material and process selection is a progressive process of narrowing from a large universe of possibilities to a specific material and process selection. Levels I and II are often sufficient for conceptual design. Level III is needed for embodiment (configuration) design and sometimes for conceptual design Level IV usually can be postponed until the detail (parametric) design.

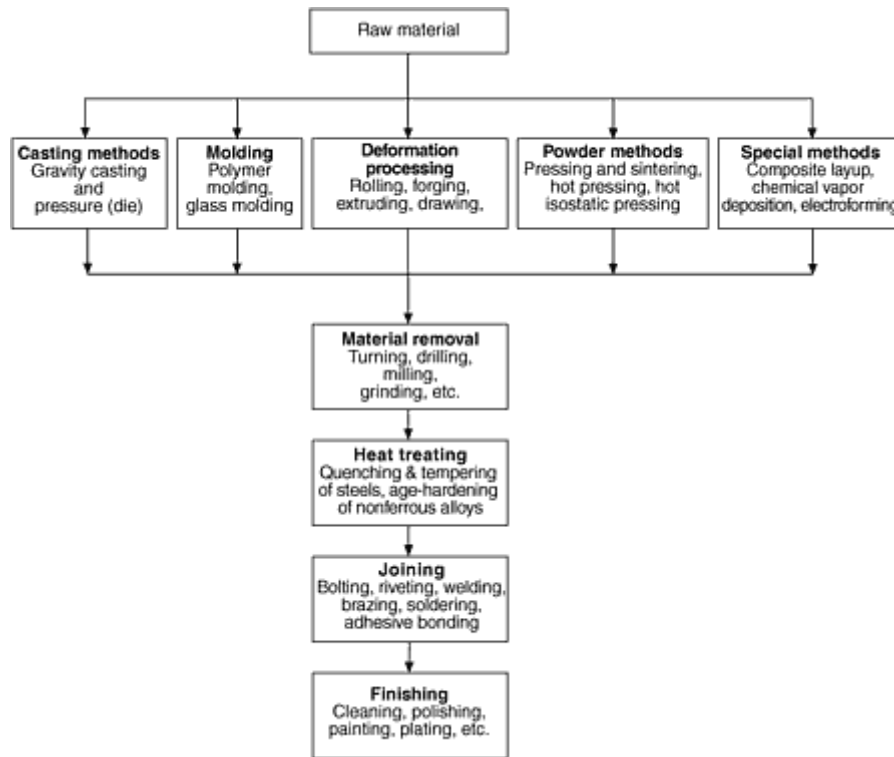

For all the stages of engineering design, the problem solving methodology employed is called *guided iteration* (Ref 3). The steps in the guided iteration process are formulation of the problem, generation of alternative solutions; evaluation of the alternatives; and if these steps are unacceptable, redesign guided by the results of the evaluations. This methodology is fundamental to design processes. It is repeated hundreds or thousands of times during product design. It is used again and again in recursive fashion for the conceptual stage to select materials and processes, to configure parts and to assign numerical values to dimensions and tolerances (i.e., parametric design). Figure 3 summarizes the guided iteration methodology.

**Fig. 3** Guided iteration used for conceptual, configuration, and parametric design

**Relation of Materials Selection to Manufacturing.** The selection of a material must be closely coupled with the selection of a manufacturing process. This is not an easy task because there are many processes that can produce the same part.

The goal is to select the material and process that maximizes quality and minimizes the cost of the part. Figure 4 gives a breakdown of manufacturing processes into nine broad classes.

**Fig. 4** The nine classes of manufacturing processes. The first row contains the primary forming (shaping) processes. The processes in the lower vertical column are the secondary forming and finishing processes. Source: Ref 2

In a very general sense, the selection of the material determines a range of processes that can be used to process parts from the material. Table 1 shows the manufacturing methods used most frequently with different metals and plastics (Ref 4). The material melting point and general level of deformation resistance (hardness) and ductility determine these relationships. The next aspect to consider is the minimum and maximum overall size of the part, often expressed by volume, projected area, or weight. Maximum size often is controlled by equipment considerations. Shape is the next factor to consider. The overall guide should be to select a primary process that makes the part as near to final shape as possible (near-net shape forming) without requiring expensive secondary machining or grinding processes. Sometimes the form of the starting material is important. For example, a hollow shaft can be made best by starting with a tube rather than a solid bar. Shape is often characterized by aspect ratio, the surface-to-volume ratio, or the web thickness-to-depth ratio. Closely related to shape is complexity. Complexity is correlated with lack of symmetry. It also can be measured by the information content of the part, that is, the number of independent dimensions that must be specified to describe the shape. Tolerance is the degree of deviation from ideal that is permitted in the dimensions of a part. Closely related to tolerance is surface finish. Surface finish is measured by the root-mean-square amplitude of the irregularities of the surface. Each manufacturing process has the capability of producing a part with a certain range of tolerance and surface finish (Fig. 5).

## Concurrent Engineering

The selection of the material and its processing, product design, cost, availability, recyclability, and performance in final product form have become inseparable. As a result, more and more companies are forming multidisciplinary project teams to ensure that all needed input is obtained concurrently. This is reflected by the increasing use of "concurrent" or "simultaneous" engineering methods (Ref 6, 7).

**Definition.** As defined by the 1986 Institute for Defense Analysis Report R-338 (Ref 6), "concurrent engineering" is a "systematic approach to the integrated, concurrent design of products and their processes, including manufacture and support. This approach is intended to cause the developers, from the outset, to consider all elements of the product life cycle from concept through disposal, including quality, cost, schedule, and user requirements." Thus, concurrent engineering refers to the philosophic constructs needed to create a synergistic engineering environment that optimizes quality and productivity at a minimum cost.

**Cross-Functional Design Teams.** Today concurrent design proceeds through well-connected cross-functional integrated product development teams with a common purpose. Information exchange is critical to minimizing error and reducing the development time and costs. Given sufficient priority among a group of projects, an ideal team might be formed with individuals possessing historical, experimental, and fundamental knowledge in the candidate materials, processes, and products. The most effective design teams involve a clearly delineated group of individuals who work full time on the specified product from creation through market introduction. The team comprises not only research and development professionals, but also manufacturing and marketing members, and often members from quality, finance, or

field service. When a team discovers holes in collective knowledge, it may need to rely in part on external sources of information and knowledge (e.g., from key suppliers), as well as to develop new information on its own. Consequently, information transfer both within the team and external to the team are important. References 8, 9, and 10 provide more detailed information on staffing cross-functional design teams and their effectiveness in the implementation of modern design practices and methods.

**Concurrent Engineering Approach to Materials Processing (Ref 7).** Figure 6 shows some of the concepts that must be addressed for successful concurrent material, process, and product engineering (in this case, for aluminum alloy manufacturing). Typical customer needs are indicated at the left and some typical processes are considered along the top of the figure. It is instructional to locate on this chart the specific types of processing efforts that are often pursued. Process refinement and process control both refer to improvements in a limited set of capabilities of a specific process. Unit process optimization refers to a more comprehensive improvement of the many facets of a particular processing operation. Alloy-process design refers to examining a range of sequential processes but limiting attention to a specific set of evolving product attributes, those with a microstructural origin in this case. Near-net-shape processing is one example of the more general case of eliminating process steps in order to reduce cost. Cost estimation deals with a specific process sequence and assumes that the desired product attributes are achievable.

Customer needs		Process history												
		Alloy	Cast	Stress relief	Homogenize	Hot work	Anneal	Cold work	Heat treat	Surface	Trim	Form	In-service	
Form														
	Dimensions	Net shape				Process control								
	Tolerance													
Structure	Grains													
	Texture				Alloy-process design									
	Dislocations													
	Particles													
	Porosity							Unit process optimization						
Residual stress	Macro													
	Micro													
Surface	Chemistry													
	Roughness					Process refinement								
	Directionality													
	Defects													
Cost		Cost estimation												

**Fig. 6** Concurrent engineering matrix for aluminum alloy manufacturing. Source: Ref 7

Some of these activities may require historical data (e.g., cost estimation), some may be experimental (e.g., alloy-process design), and some may be model based (e.g., process control). Different forms of information must, therefore, be dealt with in concurrent engineering to maximize knowledge transfer between individuals or subgroups. Improving the quantity, quality, and speed of knowledge transfer is essential because it can improve the effectiveness of the team in understanding and maneuvering within the design space outlined in Fig. 6. However, data transfer itself does not provide an increase in the team's design, optimization, or inverse engineering capabilities. Process modeling and computer simulations can provide such flexibility.

## Introduction

DESIGN FACTORS described in this article have been somewhat arbitrarily grouped into three categories: functional requirements, analysis of total life cycle, and other major factors; the factors are listed in Tables 1, 2, and 3, respectively. These categories intersect and overlap, which constitutes a major challenge in engineering design.

## Functional Requirements in Design

### *Performance Specifications*

It is obvious that any design must necessarily meet performance specifications (Table 1). These specifications must reflect a full and complete analysis of the functions required of the product. An important distinction needs to be made between performance specifications, which enumerate the basic functional requirements of the product, and product specifications, which list requirements for configurations, tolerances, materials, manufacturing methods, and so forth. Performance specifications represent the basic parameters from which the design can be formulated; product specifications are codifications of designs, used for purchase or manufacture of the product. Excellence in design or product specification is not possible without complete and adequate performance specifications.

Performance specifications must reflect thorough consideration of the factors listed in Tables 2 and 3. Consequences and risks involved in possible product failures caused by predictable misuse or overload or by imperfections in workmanship or material must be considered in establishing performance specifications (see the discussion on "Risk and Hazard Analysis"). Situations in which the consequences of product failure would be dire or in which only the very lowest risks of failure can be tolerated dictate the use of stringent performance specifications. When product failure does not involve a risk of personal injury and is not likely to result in great financial loss to the user, economic considerations usually imply that performance specifications be no more stringent than necessary to meet functional requirements. Realistic performance specifications result in design and manufacture of products that perform their required functions with little risk of failure, and that at the same time can be produced at the lowest possible cost.

As an example of setting performance specifications to suit the application, resistance to corrosion can be specified at any of three levels: (a) avoiding contamination by corrosion products, (b) preventing leaks into or out of closed containers, and (c) maintaining structural integrity and other mechanical and physical properties in spite of corrosive attack. For food-processing equipment, the first of these considerations has paramount importance. For a bridge, the third factor is critical; furthermore, a bridge must retain its structural integrity for many years. In a petrochemical plant, all three considerations are important; chemical process equipment can be designed for continuous operation for two or three years, and any breakdown between scheduled maintenance periods would be extremely expensive. Furthermore, leakage of dangerous chemicals from process equipment is unacceptable. In this case, the cost of a breakdown and the damage caused by leakage can justify use of expensive materials if their performance reduces the probability of leaks or breakdown to very low levels. On an automobile body, low-carbon steel with a corrosion-resistant surface treatment and coating provides corrosion resistance consistent with the anticipated lifetime of the vehicle. Thus, for these various applications, the appropriate criteria for corrosion resistance depend on one or more of the following factors: the degree of contamination permitted by the application, the intended lifetime of the object, the corrosion characteristics of the environment, and the consequences and risks associated with corrosion failure.

### ***Example 1: Functional Requirements for an Automotive Exhaust System.***

The product design specification for the exhaust system must include the following functions:

- Conducting engine exhaust gases away from the engine

- Preventing noxious fumes from entering the automobile
- Cooling the exhaust gases
- Reducing the engine noise
- Reducing the exposure of automobile body parts to exhaust gases
- Affecting engine performance as little as possible
- Helping control undesirable exhaust emissions Having a service life that is acceptably long
- Having a reasonable cost, both as original equipment and as a replacement part

In its basic form, the exhaust system consists of a series of tubes that collect the gases at the engine and convey them to the rear of the automobile. The size of the tube is determined by the volume of the exhaust gases to be carried away and the extent to which the exhaust system can be permitted to impede the flow of gases from the engine. An additional device, the muffler, is required for noise reduction, and a catalytic converter is required to convert polluting gases to less-harmful emissions. The basic lifetime requirement is that the system must resist the attack of hot, moist exhaust gases for some specified period. In addition, the system must resist attack by the atmosphere, water, mud, and road salt. The location of the exhaust system under the car requires that it be designed as a complex shape that will not interfere with the running gear of the car, road clearance, or the passenger compartment. The large number of automobiles produced each year requires that the material used in exhaust systems be readily available at minimum cost.

This system requires numerous material property requirements. The mechanical property requirements are not overly severe: suitable rigidity to prevent excessive vibration and fatigue plus enough creep resistance to provide adequate service life. Corrosion is the limiting factor on life, especially in the cold end, which includes the resonator, muffler, and tail pipe. Several properties of unique interest, that is, where one or two properties dominate the selection of the material, are found in this system. These pertain to the platinum-base catalyst and the ceramic carrier that supports the catalyst. The majority of the tubes and containers that comprise the exhaust system were for years made of readily formed and welded low-carbon steel, with suitable coatings for corrosion resistance. With the advent of greater emphasis on automotive quality and longer life, the material selection has moved to specially developed stainless steels with improved corrosion and creep properties. Ferritic 11% Cr alloys are used in the cold-end components, with 17 to 20% Cr ferritic alloys and austenitic Cr-Ni alloys in the hot end of the system.

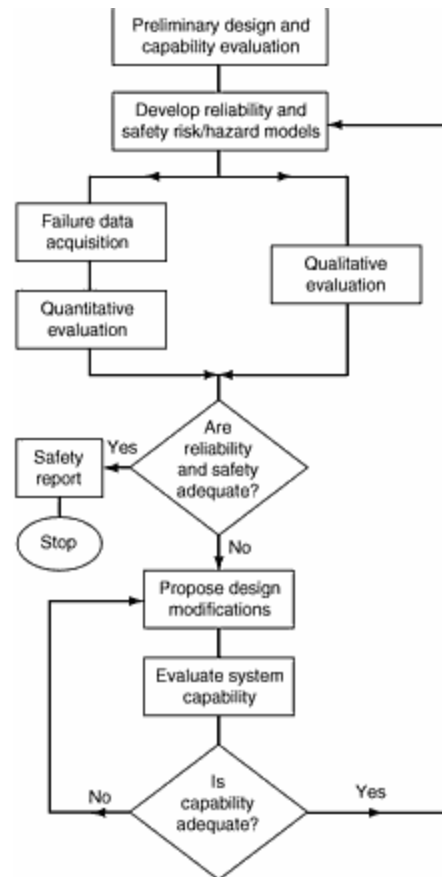

### ***Risk and Hazard Analysis***

As described briefly above, product failure and the associated risk of personal injury are critical considerations of the engineering design process. No engineering system/component devised or used can be 100% safe or error free. The objective of risk and hazard analysis is to identify the level of risk and to pinpoint the parts of the system that represent the greatest risk for failure. Then, if the analysis is used properly, steps can be taken to eliminate the cause or reduce the risk to an acceptable minimum. It has been demonstrated that hardware systems approaching a "failure-free" condition can be produced when actions are taken at all levels that are based on:

- Attention to past experiences with similar systems
- Availability of risk information for all project personnel
- A sound, aggressive risk and hazard analysis during all phases
- Development of suitable corrective action and safety programs based on the analysis
- A continuous and searching review of all phases of the program efforts

The various analysis techniques have developed from the search for system reliability. Consequently the approach is hardware oriented, with the emphasis on ensuring that hardware is able to perform its intended function.

Figure 1 is a flow chart that shows the integration of risk and hazard analysis in the overall design process. Even if designers or design managers are not directly responsible for implementing these analyses, they must be familiar with the methodology so that they understand how they are carried out and how they can respond in terms of design or system changes. Most efforts are best completed during early design phases, and they can be effectively used during design reviews to provide valuable feedback to the design to avoid failures.

**Fig. 1** Flow chart showing the integration of risk and hazard analysis into the design process. Source: adapted from Ref 1

**Defining Risk.** To clarify acceptable risk, Starr et al. (Ref 2) suggest it is useful to recognize the existence of four different definitions of "risk":

- *Real risk* is determined by actual circumstances as the future unfolds.
- *Statistical risk* is determined from currently available data, based on assumptions that a large number of future systems will, on the average, act the same way as a large number of similar past systems.
- *Predicted risk* is based on analysis of system, models, and historical data.
- *Perceived risk* is risk seen intuitively by individuals or society.

It should be noted that only "real risk" is a property of hardware. The other three risks represent the concept of risk represented by the system.

An important factor in the perception of risk is the probable severity of the consequences if an accident were to occur. A complete assessment of risk requires that the potential effects of an accident be integrated with a probability of its occurrence.

Linked closely to severity of consequences in the perception of risk is the episodic nature of consequences. It seems that the size of a potential accident is more important than the probability of occurrence. This truly represents society's value system to a great degree. Activities capable of producing catastrophic accidents, therefore, are seen as a great risk and must be more stringently controlled than high-frequency individual risks.

The two methodologies described later in this article can identify possible hazards and possibly identify the resources that are necessary to avoid or reduce the risks; however, whether the resources should be expended to alleviate the perceived risk remains a political-humanistic-management decision. The justification for undertaking these risk and hazard

technological studies is that they give a clearer picture of decisions that must be made to ensure that the functional requirements of a design can be met. More detailed information on quantitative and qualitative risk and hazard analyses is found in Ref 3 and in the section "Human Factors and Safety in Design" in this article.

**Failure mode and effect analysis (FMEA)** was originally developed as a tool to review the reliability of systems and components. It has been modified over the years to include criticality analysis (CrA) and failure hazard analysis (FHA) to help determine equipment safety requirements. Its intent is still to ensure reliable system function. The objective of FMEA is to expose all potential element failure modes to scrutiny, to classify and quantify their possible causes with their associated probability of occurrence, and to evaluate their impact on the overall system performance.

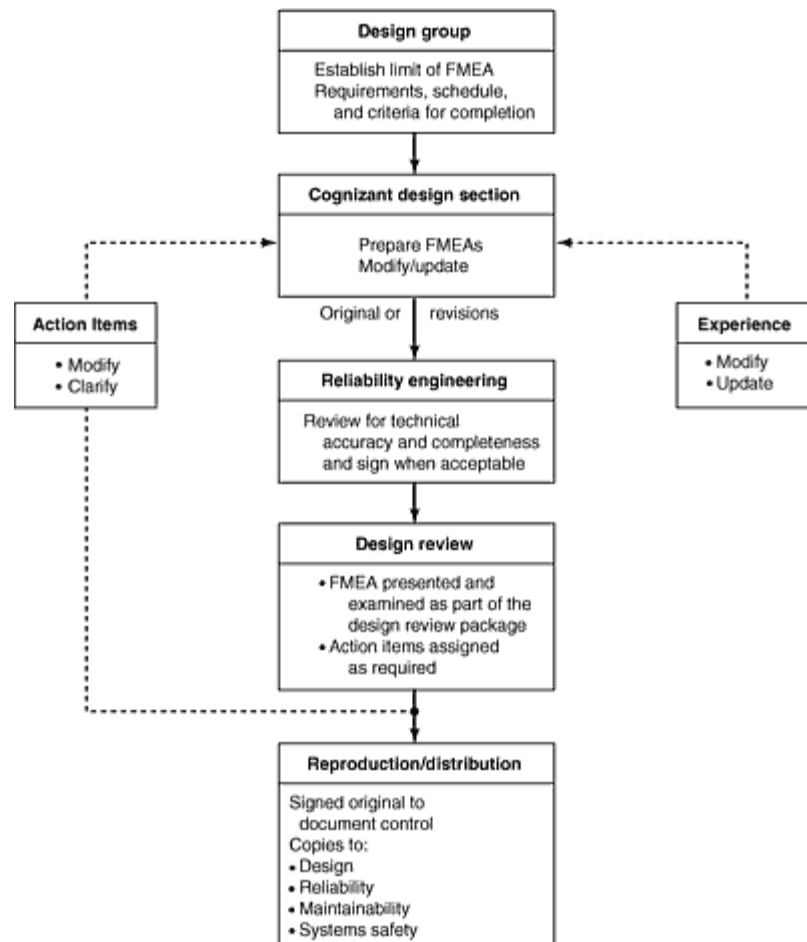

Failure mode and effect analysis normally is implemented as part of a comprehensive reliability program. The analysis is performed at increasing levels of complexity as the design progresses, so that the recommendations resulting from the analysis can be implemented early at minimum cost. The results are used to guide other activities such as design, purchasing, manufacturing, and quality control.

Failure mode and effect analysis is a systematic, organized procedure for determining, evaluating, and analyzing all potential failures in an operating system; it is used to supplement and support other reliability or safety activities. The FMEA process involves examining each potential failure mode to assess if the system elements support reliability and to ascertain the consequences of the failure on the entire system. The general process involves the following steps:

1. The probable failure modes of the system are identified, evaluated, assessed, and documented.
2. The documentation of possible failure modes is used to check and verify the safety of the design.
3. Corrective actions are formulated to eliminate or reduce to an acceptable level the consequences of the failure.

The formal procedure (Fig. 2) for preparing an FMEA constitutes the following steps:

1. A functional block diagram or logic diagrams are developed for the system or subsystem. Copies of these diagrams become part of the FMEA documentation. Individual items to be considered are identified by number.
2. All realistic probable failure modes of each element on the diagram are postulated and entered on the FMEA documentation item by item.
3. The probable causes associated with each failure mode are listed beside each failure mode.
4. The immediate consequences of each assumed failure are described and listed beside the failure mode. Symptoms that would affect the function are also listed.
5. Any internal compensating provisions, within the system that either circumvent or mitigate the effect of the failure, are evaluated and noted.
6. The effect of the failure on other components or systems is evaluated and documented.
7. The level of severity of each mode of failure is evaluated in terms of importance and documented as critical, major, or minor.
8. A quantitative probability of occurrence of the failure mode is made. The probability should be expressed numerically (Ref 5), where possible. In some cases, categorizing may be more meaningful if commonly defined categories are used.
9. Finally, remarks and recommendations are documented. Here the analyst provides any additional meaningful data.

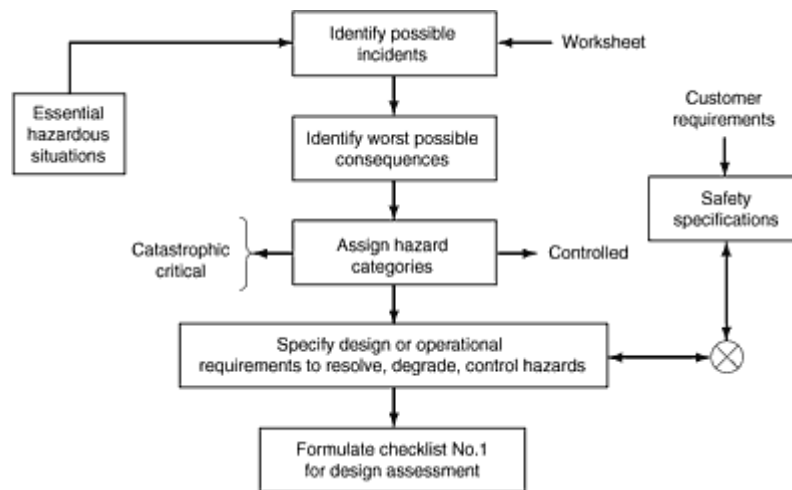

**Fig. 2** Failure mode and effect analysis flow chart. Source: Ref 4

**Safety analysis** is the synthesis of other risk/hazard analysis techniques to produce a qualitative systematic analysis throughout all phases of the project design, development, and implementation, with the objective of preventing accidents. This includes preventing personnel injuries, damage to equipment, and so forth. The techniques are simple but rigorous and time consuming, and to be effective must be continued throughout the life of the system from conception to shutdown and disposal. The method can be applied to any system but from a different point of view than system analysis. The focus of safety analysis is the prevention of hazardous failure.

The primary tools of safety analysis are worksheets, a hazard log book, a checklist of hazards, and a system description. A basic requirement is that the practitioners have a willingness to challenge the status quo; they cannot be the same as those committed to the design and implementation of the hardware system.

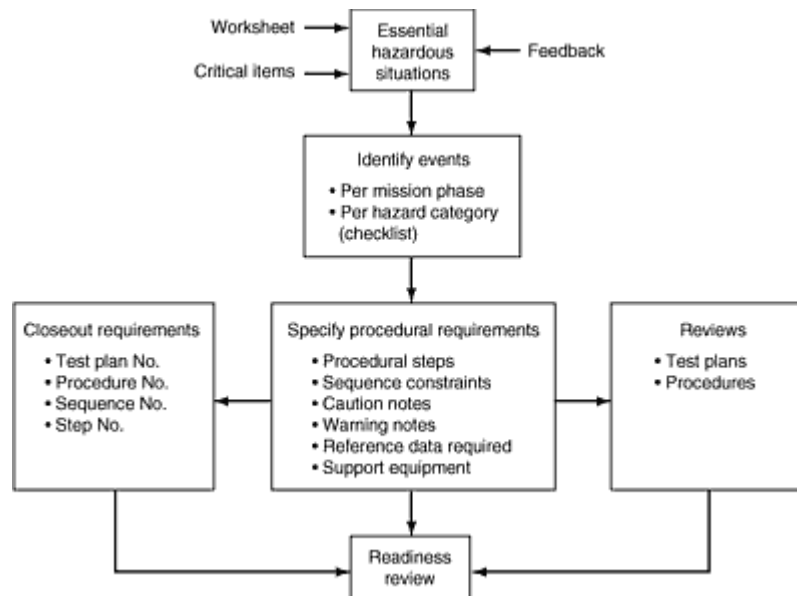

The identification of the hazards is an initial and continuous activity. Identification initiates an iterative process--the preliminary hazard analysis (Fig. 3) that undertakes elimination or reduction of the essential hazardous situations to an acceptable minimum. Design changes, safety devices, warning systems, crew procedures, emergency measures, and so forth, are all recommended. These are carried out to control or resolve the hazard situation. This often requires compromises between the designer and the safety analyst, or even changes in the specification governing the functions and use of the system. At the completion of the preliminary hazard analysis:

- The general hazards of concern are identified.
- Additional design and operation requirements have been established to forestall or alleviate anticipated hazards.
- Areas where further improvements with respect to safety are necessary have been identified.
- A databank has been started that can be used to follow and document potentially hazardous situations.

**Fig. 3** Safety analysis flow chart for preliminary hazard analysis. Source: Ref 6

Because no system is perfect, safety analysis cannot stop with the design and production of hardware. The safety analysis evolves into the next stage, operating hazard analysis (OHA) (Fig. 4). This serves to identify solutions where failure that is attributable to operator performance is likely to occur. The techniques of carrying out OHA are the same as for system hazard analysis except that the human operator and his limitations must be considered. The outputs from OHA are operational requirements that compensate for or correct a human limitation. The procedures have to either prevent the hazard or confine and minimize its impact.

**Fig. 4** Safety analysis flow chart for operating hazard analysis. Source: Ref 6

The outputs from OHA can be in the form of procedural steps, sequence constraints, caution or warning notes, reference data, or support or standby equipment.

### ***The Design Process***

The design process includes determination of the configuration of the product and various component parts and selection of materials and processes to be used. In its early stages, the process consists of evaluating various combinations of

preliminary configuration, candidate material and potential method of manufacture, and comparing these with previously established performance specifications. The relationship between configuration and material (processed in some specific way) is that every configuration places certain demands on the material, which has certain capabilities to meet these demands. A common specific relationship is a relationship between the stress imposed by the configuration and the strength of the material. Of course, there are other relationships as well. Changes in processing can change the properties of a material, and certain combinations of configuration and material cannot be made by some manufacturing processes.

**Probabilistic or Deterministic Approach.** Quantitative relationships between configurational demands and material capabilities can be established by deterministic methods--the more well known approach--or probabilistic methods. In the former, nominal or average values of stress, dimension, and strength are used in design calculations; appropriate safety factors are used to compensate for expected variations in these parameters and for discontinuities in the material. In the probabilistic approach, each design parameter is accorded a statistical distribution of values. From these distributions and from an allowable limit on probability of failure, minimum acceptable dimensions in critical areas (or minimum strength levels for critical components) can be calculated. Compared with deterministic methods, the probabilistic approach requires greater sophistication on the part of the designer and more elaborate calculations, but offers the potential for more compact parts that use less material. A significant handicap to use of probabilistic methods is the fact that statistical distributions of properties are not widely available and often must be determined before these methods can be applied to a specific design problem.

In either approach to design, the effects of notches and stress concentrations must be considered, because these features increase the vulnerability of all types of parts to failure. However, studies in fracture mechanics have shown that, under some circumstances, notches and discontinuities in the material may be benign, and therefore of little consequence in some design applications. A more detailed description on the use of statistical methods for the prediction of such factors as operating stress, strain, deflection, deformation, wear rate, fatigue strength, creep strength, or service life is found in the Section "Statistical Aspects of Design."

**Effect of Service Hazards.** Cyclic loading, use at extreme temperatures, and the presence of agents that cause either general corrosion or stress-corrosion cracking are special hazards that must be considered during the materials-selection process. Table 4 lists some common failure modes and the mechanical properties most related to particular modes. Cyclic loading, in particular, is a very common factor in the design of anything that has moving parts; it is also widely recognized that fatigue is responsible for a large portion of all service failures. In 1943, Almen (Ref 7) made an observation that is still valid about fatigue:

"Fully 90 percent of all fatigue failures occurring in service or during laboratory and road tests are traceable to design and production defects, and only the remaining 10 percent are primarily the responsibility of the metallurgist as defects in material, material specification, or heat treatment.

"Study of fatigue of materials is the joint duty of metallurgical, engineering, and production departments. There is no definite line between mechanical and metallurgical factors that contribute to fatigue. This overlapping of responsibility is not sufficiently understood.

"Hence, the engineers are constantly demanding new metallurgical miracles instead of correcting their own faults. Until metallurgists are less willing to look for metallurgical causes of fatigue and insist that equally competent examination for mechanical causes be made, we cannot hope to make full use of our engineering material."

Table 4 Relationships between failure modes and material properties

Failure mode	Material property														
	Ultimate tensile strength	Yield strength	Compressive yield strength	Shear yield strength	Fatigue properties	Ductility	Impact energy	Transition temperature	Modulus of elasticity	Creep rate	$K_{Ic}^{(a)}$	$K_{Isc}^{(b)}$	Electrochemical potential	Hardness	Coefficient of expansion
Gross yielding		X		X											
Buckling			X						X						
Creep										X					
Brittle fracture							X	X			X				
Fatigue, low cycle					X	X									
Fatigue, high cycle	X				X										
Contact fatigue			X												
Fretting			X										X		
Corrosion													X		
Stress-corrosion	X											X	X		

cracking															
Galvanic corrosion													X		
Hydrogen embrittlement	X														
Wear														X	
Thermal fatigue										X					X
Corrosion fatigue					X								X		

An "X" at the intersection of material property and failure mode indicates that a particular material property is influential in controlling a particular failure mode.

(a) Plane-strain fracture toughness.

(b) Threshold stress intensity to produce stress-corrosion cracking

Although Almen spoke specifically about fatigue, his comments can be applied to engineering design on a far broader basis. His comments must not be construed to excuse materials engineers from a proper share of the overall design responsibility, nor to allow them to slacken their efforts to find better materials for specific applications.

Almen's comments do imply that all aspects of design must be considered, because even apparently insignificant factors can have far reaching effects. (For example, there is at least one known instance in which fatigue failure of an aircraft in flight was traced to an inspection stamp that was imprinted on a component using too heavy a hammer blow.)

**Failure Anticipation.** Even parts for which loading in service is known accurately and stress analysis is straightforward, gross design deficiencies can arise from reliance on static load-carrying capacity based solely on tensile and yield strengths. The possibility of failure in other modes, such as fatigue, stress-corrosion cracking, and brittle fracture caused by impact loading, must be considered in the design process.

Any discussion of potential failures in service should include careful consideration of the possible consequences of failure. Those failure modes that might endanger life or limb, or destroy other components of the apparatus, should be avoided. Sometimes, a piece of equipment is designed so that one component will fail in a relatively harmless fashion and thus avoid the potentially more serious consequences of the failure of another. For example, a piece of earth-moving equipment might be designed so that the engine will stall if the operator attempts to lift a load so heavy that it might upset the equipment or damage any of the structural components. A blowout plug in a pressure vessel is another example. Conformance to codes and standards, such as those listed in Table 3, can preclude serious consequences of service failure, but designers still must exercise careful judgment in studying (and designing against) the consequences of possible modes of failure.

**Restrictions on Size, Weight, or Volume.** The size and weight of a part can affect the choice of both material and manufacturing process. Small parts often can be economically machined from solid bar stock, even in fairly large quantities. The material cost of a small part may be far less than the cost of manufacturing it, perhaps making relatively expensive materials feasible. Large parts can be difficult or impossible to heat treat to high-strength levels. There are also limits on size for parts that can be formed by various manufacturing processes. Die castings, investment castings, and powder metallurgy parts are generally limited to a few kilograms. When weight is a critical factor, parts often are made from materials having high strength-to-weight ratios.

The quantity of parts to be made can affect all aspects of the engineering design process. Low-quantity production runs can seldom justify the investment in tooling required by production processes, such as forging or die casting, and may limit the choice of materials to those already in the designer's factory or those stocked by service centers. High-quantity production runs may be affected by the capability of materials producers to supply the required quantity. Mass-produced parts sometimes are designed and redesigned, requiring a large expenditure for engineering and evaluation, but providing enough savings, considering the large quantity involved, to make the effort worthwhile. Design for small-quantity parts may be limited to finding the first design and material that serve the required purpose.

**Other Relationships Influencing the Design Process.** Products that can be manufactured in several locations can present additional problems for designers because the cost and availability of materials can vary from place to place. If the product is to be made in different countries, the nearest equivalent grades of steel, for example, might be different enough to affect service performance. In some areas that have low prevailing labor costs, it may be desirable to design a labor-intensive product; in a high-cost labor market, the designer often attempts to design the product to fit the capabilities of automated manufacturing equipment.

It is relatively late in the design process before designers, materials engineers, and manufacturing engineers, by working together, can establish those factors described in "Factors in Material Selection" (for example, Table 1 in the previously mentioned article). Only then can the field of candidate materials and manufacturing processes be narrowed to a manageable number of alternatives. The implications of each of these alternative materials and manufacturing processes can then be evaluated, and any required changes in configuration can be made.

One of the complicating factors in materials selection is that virtually all materials properties, including fabricability, are interrelated. Substituting one material for another, or changing some aspect of processing in order to effect a change in one particular property, generally affects other properties simultaneously. Similar interrelations that are more difficult to characterize exist among the various mechanical and physical properties and variables associated with manufacturing processes. For example, cold drawing a wire to increase its strength also increases its electrical resistivity. Steels that have high carbon and alloy contents for high hardenability and strength generally are difficult to machine and weld. Additions

of alloying elements such as lead to enhance machinability generally lower long-life fatigue strength and make welding and cold forming difficult. The list of these relationships is nearly limitless.

**Value analysis** also known as value engineering, is a problem-solving methodology that focuses on identifying the key function(s) of a design so that unnecessary costs can be removed without compromising the quality of the design. Key concepts that must be examined during value analysis include:

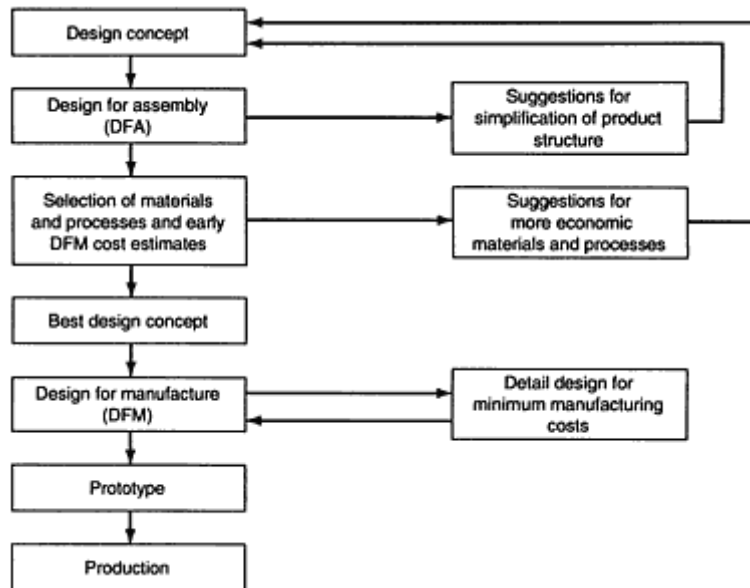

- Is it necessary?
- Does it do more than is required?
- Does it cost more than it is worth?
- Is there something that does the job better?
- Can it be made by a less-costly method?
- Can a standard item be used?
- Considering the quantities used, could a less-costly tooling method be used?
- Does it cost more than the total of reasonable labor, overhead, material, and profit?
- Can another manufacturer provide it at less cost without affecting dependability?
- If it was a personal purchase, would the item be too expensive to purchase?

Value analysis using such criteria can provide both designers and managers with assurance that the final combination of configuration, material, and manufacturing process is a good combination. More detailed information on this topic is found in Ref 8.

### ***Design for Manufacture and Assembly***

With increased awareness of the importance of the interaction between design and manufacture, a new field aimed at formalizing this relationship is evolving, called "design manufacture and assembly" (DFMA) (Ref 9). The DFMA approach examines the product design in all aspects for methods of integrating the product and its processing so that the best match is made between product and process requirements and that the integrated product/process ensures inherent ease of manufacture. A major objective of DFMA is to ensure that the product (including material selection) and the process are designed together.

Figure 5 summarizes the steps taken when using DFMA analysis during design. The design-for-assembly (DFA) analysis is conducted first, leading to a simplification of the product structure. Then, early cost estimates for the parts are obtained for both the original design and the new design to make trade-off decisions. During this process, the best materials and processes to be used for the various parts are considered. For example, would it be better to manufacture a cover from plastic or sheet metal? Once the materials and processes have been finally selected, a more thorough analysis for design for manufacture (DFM) can be carried out for the detail design of the parts.

**Fig. 5** Typical steps taken when using design for manufacture and assembly (DFMA) analysis during design

Reducing the number of separate parts, thereby simplifying the product, is the greatest improvement provided by DFA (Ref 10). To give guidance in reducing the part count, the DFA software asks the following questions as each part is added to the product during assembly:

- Is the part or subassembly used only for fastening or securing other items?
- Is the part or subassembly used only for connecting other items?

If the answer is "yes" to either question, the part or subassembly is not considered theoretically necessary. If the answer is "no" to both questions, the following criteria questions are considered:

- During operation of the product, does the part move relative to all other parts already assembled?
- Must the part be made from a different material than, or be isolated from, all other parts already assembled? Only fundamental reasons concerned with material properties are acceptable.
- Must the part be separate from all other parts already assembled because the necessary assembly or disassembly of other separate parts would otherwise be impossible?

If the answer to all three criteria questions is "no," the part cannot be considered theoretically necessary.

Implementation of DFM analysis helps to quantify cost of parts and allow trade-off decisions to be made for design proposals and material and process selection. Major cost savings are achieved when:

- The design of products, subassemblies, components, modules, and individual parts are standardized
- Readily processed materials are used
- The product design is developed for the particular manufacturing process that will be used to make the part
- Each part is designed for ease of manufacture
- Inherently expensive machining operations are eliminated

Of course, engineering designers must design products that not only can be economically manufactured and assembled, but they also must function as intended. This requires selecting and understanding the physical principles by which the product will operate. Moreover, proper function requires special attention to tolerances. These two considerations are called designing for function and fit. However, designers must consider a myriad of other issues as well: installation, maintenance, service, environment, disposal, product life, reliability, safety, and other issues. The phrase "design for X" (DFX) refers to these other issues (Ref 11).

Designing for DFM, DFA, minimum parts, function, fit, and DFX is still not all that is required of the engineering designer. Products also must be designed for marketing and profit, that is, for the customer and for the nature of the marketplace. Designers, therefore, need to be aware of what features customers want, and what customers consider to be quality in a product. In addition, marketing considerations should include cost, quality, and, increasingly important, time--that is, when the product will reach the marketplace.

Designers also should recognize that the processes by which parts and products are made, and the conditions under which they are used, are variable. As described in the section on "Design for Quality," designing so that products are robust under these variabilities is another design requirement.

### ***Design for Quality***

**Robust Design.** Variability is the enemy of manufacturing. It is a major cause of poor quality resulting in unnecessary manufacturing cost, product unreliability, and ultimately, customer dissatisfaction and loss of market share. Variability reduction and robustness against variation of hard-to-control factors are therefore recognized as being of paramount importance in the quest for high-quality products. In a design for quality approach, the design team seeks to design the product and process in such a way that variation in hard-to-control manufacturing and operational parameters is minimal. The ideas behind this approach are largely attributable to the efforts of Genichi Taguchi and the cost-saving approaches to quality control pioneered in Japan. The Taguchi method(s), also known as *robust design*, is an integrated system of tools and techniques that allow engineers and scientists to reduce product or process performance variability while simultaneously guiding that performance toward the best possible level. Major robust design techniques, tools, and concepts include the quality loss function, parameter design, tolerance design, signal-to-noise ratio, technology development, and orthogonal arrays. Each of these are treated extensively in the literature (see, for example, Ref 12 and 13).

**Statistical Process Control.** Another important tool for quality improvement, advocated by W.E. Deming (Ref 14, 16), and Scherkenbach (Ref 15), is *statistical process control* (SPC). This is a procedure, using statistical mathematics, which signals that some extraneous factor is affecting the output of a production process. The signal alerts production and quality personnel that a process fault should be looked for and eliminated. In this way, the procedure aids in identifying and correcting the causes of product component defects. Because there are natural random variations in the results of any manufacturing process, the ability to differentiate between these random variations and those caused by some change in process conditions is a critical part of maintaining good control over specified characteristics and dimensions. Broken or worn cutting tools, slipped adjustments, leaks in a pressurized system, and an accidental change to a less-active solder flux are some examples of the kinds of process changes that might otherwise not be noticed, but which may cause a quality deterioration that would be detected by *SPC* analyses. Additional information about SPC is provided throughout this Handbook.

**Total Quality Management.** Deming also states that 85% of quality problems are caused by systems, procedures, or management, and only 15% of quality problems are caused by bad workmanship (Ref 16). Blaming workers is not the way to cure quality problems. Incidentally, the 85% of quality problems attributable to management includes problems traceable to weaknesses or errors in the product design.

Current thinking on the best managerial approaches to control quality improvement involve heavy worker participation in both the monitoring of quality and the corrective actions taken to solve quality problems. One approach that encompasses worker involvement is *total quality management* (TQM). Total quality management is more a broad management philosophy and strategy than a particular technique. Referred to earlier as total quality control, it originated in Japan. It involves:

- A strong orientation toward the customer in matters of quality.
- Emphasis on quality as a total commitment for all employees and all functions including research, development, design, manufacturing, materials, administration, and service. Employee participation in

quality matters is standard at all levels. Suppliers also participate.

- A striving for error-free production. Perfection is the goal.
- Use of statistical quality control data and other factual methods rather than intuition to control quality.
- Prevention of defects rather than reaction after they occur.
- Continuous improvement.

Total quality management programs usually stress that quality must be designed into the product rather than tested for at the end of the production process. Reference 17 provides additional information.

## ***Reliability in Design***

**Definition.** Reliability is a measure of the capacity of equipment or systems to operate without failure in the service environment. The National Aeronautics and Space Administration (NASA) defines reliability as the probability of a device performing adequately for the period of time intended under the operating conditions encountered. Reliability is always a probability, thus its calculation is one form of applied mathematics. Probabilistical and statistical methods, however, like any other forms of mathematics, are aids to, not substitutes for, logical reasoning.

Reliability is identified with a state of knowledge, not a state of things. Reliability cannot be used to predict discrete, or individually specific, events; only probabilities, that is averages, are predicted. Probability is a measure of what is expected to happen on the average if the given event is repeated a large number of times under identical conditions. Probability serves as a substitute for certainty. A generalization is made from samples, and the conclusions reached cannot be considered to be absolutely correct.

The NASA definition of reliability (and any other definition) includes "adequate performance" of the specific device. There is no general definition of adequate performance. Criteria for adequate performance must be carefully and exactly detailed or specified in advance for each device or system considered.

A reliability of 0.99 implies a probability of 1 failure per 100. A reliability of 0.999 does not imply greater accuracy (one more significant figure) but an order of magnitude difference, that is, a probability of failure of 1 per 1000.

**Reliability Tasks.** All general definitions, like the NASA definition, are qualitative. A quantitative definition of reliability for operating time  $t$  is:

$$R(t) = P(T > t) \quad (\text{Eq 1})$$

where  $R$  is reliability,  $P$  is probability, and  $T$  is the time to failure of the device. ( $T$  itself is a variable.)

The first task in ensuring reliability is to derive and investigate Eq 1. This is first done for a single component. The reliability of an entire system is then determined in keeping with the functions and configuration of the units composing the system. This, in turn, can be a subsystem of a more complex system. The building process continues until the entire system has been treated. The complete system can be so complex that it includes entire organizations, such as maintenance and repair groups with their personnel.

The second task, after the system and its reliability are truly understood, is to find the best way of increasing the reliability. The most important methods for doing this are:

- Reduce the complexity to the minimum necessary for the required functions. Nonessential components and unnecessary complexity increase the probability of system failure, that is, they decrease reliability.
- Increase the reliability of components in the system.
- Use parallel redundancy, one or more "hot" spares operate in parallel. If one fails, others still function.
- Use standby redundancy. One or more "cold" spares is switched to perform the function of a failed component or subsystem.
- Employ repair maintenance. Failed components are replaced by a technician rather than switched in as with standby redundancy. Replacement is neither automatic nor necessarily immediate.

- Employ preventive maintenance. Components are replaced periodically by new components even though they may not have failed prior to the time of replacement.

The third task is to maximize system reliability for a given weight, size, or cost. Conversely, the task may be to minimize weight, size, cost or other constraints for a given reliability.

**Graphic Representation of Reliability.** Consider a population of homogeneous components from which a very large sample is taken and placed in operation at time  $T = 0$ . ( $T$  is age, in contrast with  $t$ , commonly used for operational life or mission time.) The population will initially show a high failure rate. This decreases rapidly as shown in Fig. 6. This period of decreasing failure rate is called various names, such as early life period, infant mortality period, and shakedown period. Failure occurs due to design or manufacturing weaknesses, that is, weak or substandard components.

**Fig. 6 Mortality curve; failure rate versus age (schematic). Source: Ref 18**

When the substandard components have all failed at age  $T_E$ , the failure rate stabilizes at an essentially constant rate. This is known as useful life because the components can be used to greatest advantage. Failures during useful life are known as random, chance, or catastrophic because they occur randomly and unpredictably.

When components reach age  $T_W$ , the failure rate again increases. Failures begin to occur from degradation due to aging or wear as the components are approaching their rated life.

Early life can be made as short as desired (even eliminated) by proper design, fabrication and assembly, and/or deliberate burn-in periods. For systems that must operate satisfactorily over extended periods, incidence of wear out can be postponed almost indefinitely by replacing units as they fail during useful life and replacing each unit (even if it has not failed or given any indication of imminent failure) no later than at the end of useful life. Reference 19 provides more detailed information on estimating useful life, mean time to failure, and mean time between failures.

**Reliability Testing.** Reliability tests measure or demonstrate the ability of equipment to operate satisfactorily for a prescribed time period under specified operating conditions. Assuming a system with ten components in series, which must operate for 1000 h with a reliability of 0.99, the characteristic life of a component must be  $\sim 10^6$  h, or about 115 years. To obtain a state of knowledge to determine this requires more than 115 years of failure-free testing (115 components for 1 year or 1150 components for 6 weeks) for each of 10 components. If the number of parts is several hundred and the desired reliability is 0.999 (not at all uncommon), it is obvious that the required number of tests becomes absurdly impossible. Yet, such products are designed, built, and meet guaranteed performance.

Although maximum use is made of past performance data and engineering judgment, it is essential for the designer to know as soon as possible if a design objective for reliability and/or life will be met. To meet a production schedule, it is rarely realistic to test under normal operating conditions. Thus accelerated testing is desired. Three factors control the degree of acceleration: environment, sample size, and testing time. Environment includes any operating condition to which the part is subjected and that may affect its performance and/or durability. Two broad categories of testing are implied: (a) tests to determine which aspects of the environment are truly significant and (b) accelerated tests to determine performance as quickly as possible.

Univariate testing (one parameter at a time) for environmental factors is not always useful because there is no indication of any effect of interaction between two or more factors.

Factorial experiments can be used to estimate the main (direct) effect of each "stress," interactions between two (or more) stresses, and experimental error (Ref 20, 21, 22, 23, 24). Related information is contained in the Section "Statistical Aspects of Design," which is contained below.

To run a complete factorial experiment, especially for replication, may require a very large number of individual tests or runs. Fortunately, in such a situation, most of the desired information can be obtained by performing only a fraction of the full factorial. In one unusual (and outstanding) situation with 19 variables, a complete full factorial study would have required more than 500,000 samples. A judiciously selected fractional factorial design provided the desired information from a study of only 20 samples (Ref 20, 21, 22, 23, 24, 25).

Accelerated testing, which is reducing the time required for testing, can be accomplished by: (a) taking a large sample and testing only part of the sample to failure, (b) magnifying the stress, or (c) sudden-death testing. Alternatives (a) and (c) are especially useful in testing a large number of relatively inexpensive components. Sequential testing is more useful when there are only a few relatively expensive units.

If a number of identical units are tested simultaneously, failure will occur in an ordered sequence with the weakest units failing first, and so forth. Such ordering is unique with life testing (Ref 26). The choice of a test involving failure of  $r$  units out of  $n$  ( $n > r$ ) rather than the choice of a test involving failure of  $r$  out of  $r$  units will, in general, permit determination of an estimate of characteristic life in a relatively shorter time. For example, if 20 units have to be operated for 200 h to induce all 20 failures, then on the average, only 46 h are needed to observe the first 10 failures in a sample of 20.

Use of magnified loading does reduce testing time and possibly the number of items required for the test. Correlation is a major problem because "normal" needs to be defined and enough overload data must exist to correlate with normal. Rabinowicz et al. (Ref 27) suggested a technique based on cumulative damage. An example of acceleration in fatigue testing was developed by Conover et al. (Ref 28). Intensified loading of programmed fatigue tests developed from field data was used to reduce time to failure in steels for automotive components by a factor of ten. These results were applicable for unnotched specimens, notched specimens, and automotive components.

Other useful reliability tests include sudden-death testing (Ref 18, 21), which is especially useful with a large number of relatively inexpensive units, and sequential testing (Ref 18, 21) which is especially useful for tests of a small number of relatively expensive units.

## **Redesign**

Redesign often can improve performance and reduce cost, and can occur informally during the early stages of design. It may also result from formal design-review procedures. Failure-mode analysis is particularly useful in redesign to reduce the likelihood of further failures. These techniques often have resulted in greatly improved product performance.

Standardization and simplification of design can lead to substantial savings without loss of performance. Retaining only the most efficient sizes, types, grades and models of a product is an example; during World War II, the number of "standard" types of steel, brass, and bronze valves in the United States was reduced from 4080 to 2500. Utilization of standard off-the-shelf components can also lead to significant savings. It might be less costly, for example, to use a  $\frac{1}{4}$ -20 bolt 2 in. (50 mm) long, which is a widely stocked size, even though design requirements could be satisfied by a bolt  $1\frac{7}{8}$  in. (48 mm) long, which would probably be a special order item.

Further savings could be realized if the assembly were to be redesigned to allow use of  $1\frac{1}{2}$  in. (38 mm) or  $1\frac{3}{4}$  in. (44 mm) bolts.

Functional substitution offers great opportunity for improvement and cost reduction through redesign. The goal of functional substitution is to find a new and different way to meet a design requirement. For example, a bolted assembly might be redesigned for assembly by welding, by pressing mating parts together, or by adhesive bonding. The scope of a

functional redesign program might be rather modest, as in the example just mentioned, or it might entail complete redesign of the product.

## **Statistical Aspects of Design**

For many years engineers have designed components and structures using best available estimates of material properties, operating loads, and other design parameters. Once established, most of these estimated values have commonly been treated as fixed quantities or constants. This approach is called deterministic, in that each set of input parameters allows the determination of one or more output parameters, where those output parameters may include a prediction of factors such as operating stress, strain, deflection, deformation, wear rate, fatigue strength, creep strength, or service life. In reality, virtually all material properties and design parameters exhibit some statistical variability and uncertainty that influence the adequacy of a design.

Fundamentally, designing to prevent service failures is a statistical problem. In simplistic terms, an engineered component fails when the resistance to failure is less than the imposed service condition. Depending on the structure and performance requirements, the definition of failure varies; it could be buckling; permanent deformation; tensile failure; fatigue cracking; loss of cross section due to wear, corrosion; erosion; or fracture due to unstable crack growth. In any of these cases, the failure resistance of a large number of components of a particular design is a random variable, and the nature of this random variable often changes with time. The imposed service condition for these components is also a random variable; it too can change with time. The intersection of these two random variables at any point in time represents the expected failure percentage and provides a measure of component reliability.

This section presents some of the statistical aspects of design from an engineer's perspective. Some statistical terms are clarified first because many engineers have not worked in the field of statistics enough to put these terms into day-to-day engineering practice. More detailed information pertaining to the statistical aspects of design is found in Ref 29, 30, 31, 32, 33 and in Volume 8, *Mechanical Testing*, of the *ASM Handbook*.

### ***Classification of Statistical Terms***

**Random Variables.** Any collection of test coupons, parts, components, or structures designed to the same set of specifications or standards will exhibit some variability in performance between units. Performance can be measured by a wide variety of parameters, or some combination of those parameters, as discussed earlier. In any case, these measures of performance are not controlled, although there is often an attempt to optimize them to maximize performance, within prescribed cost constraints. Because these measures of performance are not controlled and subject to inherent random variability, they are commonly called random variables.

The tensile strength of a structural material is a practical example of a random variable. Given a single heat and lot of a material manufactured to a public specification, such as an ASTM, SAE/AMS, or Department of Defense (DoD) specification, repeated tests to determine the tensile strength of that material will produce varied results. This will be true even if the individual tests are performed identically, within the limits of engineering accuracy. Table 5 illustrates that even apparently similar tensile samples tested under identical conditions generally do not produce the same results, producing data scatter or variability. Each observation was based on randomly selected samples from each heat of material.

**Table 5 Results of a hypothetical test series to determine the ultimate tensile strength of two heats of material**

Sample No.	Tensile strength			
	Heat 1		Heat 2	
	MPa	ksi	MPa	ksi
1	522	75.7	517	75.0
2	511	74.1	490	71.1
3	489	70.9	499	72.4
4	554	80.3	514	74.6
5	500	72.5	503	72.9

**Density Functions.** In statistical terms, a density function is simply a function that shows the probability that a random variable will have any one of its possible values. Consider, for example, the distribution of fatigue lives for a material as shown in Table 6. Assume that these 23 observations were generated from a series of replicate tests, that is, repeated tests under the same simulated service conditions. A substantial range in fatigue lives resulted from these tests, with the greatest fatigue life being more than ten times the lowest observation.

**Table 6 Representative fatigue data showing variability in cycles to failure**

Life interval, $10^6$ cycles	Number of failures	Cycles to failure, $10^6$ cycles
0.0-0.5	1	0.425
0.5-1.0	5	0.583, 0.645, 0.77, 0.815, 0.94
1.0-1.5	7	1.01, 1.09, 1.11, 1.21, 1.30, 1.41, 1.49
1.5-2.0	4	1.61, 1.70, 1.85, 1.97
2.0-2.5	2	2.19, 2.32
2.5-3.0	2	2.65, 2.99

3.0-3.5	1	3.42
3.5-4.0	0	...
4.0-4.5	0	...
4.5-5.0	1	4.66
<b>Total observations</b>	<b>23</b>	

The resulting approximate density function for these data is shown in Fig. 7. This figure shows the number of fatigue life observations within uniform cycles-to-failure intervals. Each interval of the histogram shows the frequency of occurrence of fatigue failures within the interval. It is evident that the probability of occurrence of a fatigue failure for this material and test condition is not constant over the range of possible fatigue lives. If 300 observations were available, instead of 23, the shape of the histogram would tend to stabilize. As the number of observations increase, "bumps" in the frequency diagram (as in Fig. 7) caused by random variations in fatigue life would tend to disappear, and the shape will begin to resemble that of a continuous function. A mathematical representation of such a distribution is called a density function.

**Fig. 7** Histogram of fatigue data from Table 6 showing approximate density function

**Cumulative Distribution Functions.** Plots of experimental data as density functions, as shown in Fig. 7, provide some useful statistical information. Inferences can be made regarding the central tendencies of the data and the overall variability in the data. However, additional information can be obtained from a data sample like the sample summarized in Table 6, by representing the data cumulatively, as in Table 7, and plotting these data on probability paper, as shown in Fig. 8(a). This is done by ranking the observations from lowest to highest and assigning a probability of failure to each ranked value. These so-called median ranks can be obtained from tables of these values from a statistical test (see, for example, Ref 21).

**Table 7 Cumulative distribution of fatigue failures from Table 6**

	Cycle interval $\times 10^6$									
	0.0-0.5	0.5-1.0	1.0-1.5	1.5-2.0	2.0-2.5	2.5-3.0	3.0-3.5	3.5-4.0	4.0-4.5	4.5-5.0
No. of failures	1	5	7	4	2	2	1	0	0	1

(a)

(b)

**Fig. 8 Cumulative distribution function for fatigue data from Table 6 based on (a) assumed normal distribution and (b) assumed log-normal distribution**

**Sample versus Population Parameters.** When performing a deterministic analysis, the input parameters are defined to represent the material in some specific way. For example, the input parameter may be the average or typical yield strength of a material or a specification minimum value. The implicit assumption is that, given an infinite number of observations of the strength of this material, the assumed average or minimum values would match the "real" values for this infinite population. Of course, the best that can be done is to generate a finite number of observations to characterize the performance of this material (in this case, yield strength); these observations are considered a statistical sample of this never-attainable, infinite population. Intuitively, an increase in the number of observations (the sample size), should increase the accuracy of the sample estimate of the real, or population material properties.

**Variability versus Uncertainty.** Variability and uncertainty are terms sometimes used interchangeably. However, it is useful when talking about statistical aspects of design to draw a distinction between them. Uncertainty is defined in most dictionaries as "the condition of being in doubt" or something similar to this. In the context of this discussion, uncertainty can be considered the bounds within which the "true" engineering result, such as the average fatigue life of a component, can be expected to fall. To establish this uncertainty in quantitative terms, it is necessary to identify and quantify all factors that contribute to that uncertainty. Generally speaking, the uncertainty in an engineering result is broad in the early stages of a design, and this uncertainty decreases significantly as more experimentation and analysis work is done. This uncertainty is commonly described in terms of confidence limits, tolerance limits, or prediction limits.

Variability is an important element of an uncertainty calculation. The meaning of the term can be drawn directly from its root word, variable. Virtually all elements of a design process can be described as random variables, with some measure of central tendency or average performance and some measure of scatter or variability. For continuous variables, this

variability is generally quantified in terms of a sample standard deviation, or sample variance, which is simply the standard deviation squared,  $\sigma^2$ , where  $\sigma$  equals the population standard deviation.

Another commonly used measure of variability is the coefficient of variation, which is defined as the sample mean divided by the sample standard deviation and generally is expressed as a percentage. This normalized parameter allows direct comparisons of relative variability of materials or products that display significantly different mean properties. For example, two different aluminum alloys might have tensile strengths that are described statistically as follows:

Aluminum alloy	Average tensile strength, ksi	Standard deviation, ksi
No. 1	70	2.5
No. 2	75	4.0

Alloy No. 1 displays a coefficient of variation (COV) of approximately 3.6%, while alloy No. 2 displays a COV of approximately 5.3%. The higher variability of alloy No. 2, as represented by a COV nearly 50% higher than alloy No. 1, could lead to a higher level of uncertainty in the performance of a structure made from the second alloy in comparison to the first alloy.

**Precision versus Bias.** Precision and bias are statistical terms that are important when considering the suitability of an engineering test method or making a comparison of the relative merits between two or more procedures or processes (Ref 33). A statement concerning the precision of a test method provides a measure of the variability that can be expected between test results when the method is followed appropriately by a competent laboratory. Precision can be defined as the reciprocal of the sample standard deviation, which means that a decrease in the scatter of a test method as represented by a smaller standard deviation of the test results leads directly to an increase in the precision. Conversely, the greater the variability or scatter of the test results, the lower the precision.

The test results of two different processes (e.g.; heat treatments and their effect on tensile strength) can also be statistically compared, and a statement made regarding the precision of one process compared to another. Such a statement of relative precision is only valid if no other potentially significant variables, such as different test machines, laboratories, or machining practices are involved in the comparison.

The bias of a set of measurements quantifies the difference in those test results from an accepted reference value or standard. The concept of a bias can also be used to describe the consistent difference between two operators, test machines, testing periods, or laboratories. The term accuracy is sometimes used as a synonym for bias, but it is possible to identify a bias between two sets of measurements or procedures without necessarily having any awareness of which set is most accurate. In order to make quantitative statements about absolute bias or accuracy, it is necessary to have a known baseline or reference point; such fixed points are seldom available in the real world of an engineer.

**Independent versus Dependent Variables.** Many engineering analyses involve the prediction of some outcome based on a set of predefined input conditions. A very simple example is the prediction of stress in the elastic range for a metal, based on a measured strain and an estimated or measured value for elastic modulus. Another more complex example is the prediction of the fatigue resistance of a part based on estimated local stress or strain amplitudes and experimentally determined fatigue parameters. In general, relationships such as these are developed through a regression analysis, in which the predicted outcome,  $y$ , is estimated from a series of terms written as a function of one or more input quantities,  $x_i$ , and regression parameters,  $A_i$ , as follows:

$$y = A_0 + A_1 f_1(x) + A_2 f_2(x) \dots \quad (\text{Eq 2})$$

In this expression, the predicted result,  $y$ , is the dependent variable, while the defined quantity,  $x$ , is the independent variable. In some cases, multiple independent variables are needed in combination to realistically estimate the independent variable(s).

**Why Not Just Assume Normality and Forget the Complications?** The first assumption that most engineers will make when applying statistics to an engineering problem is that the property in question is normally distributed. The normal distribution is relatively simple mathematically, is well understood, and is well characterized. The engineering statistics applications where nonnormal statistical distributions and nonparametric (distribution-free) approaches are used probably do not total the number of applications based on normal statistics.

The assumption of normality is reasonable in many cases where only mean trends or average properties are of interest. The importance of verifying this assumption increases when properties removed from the mean or average are being addressed, such as an estimated first percentile value of a design factor or a value 2 or 3 standard deviations below the mean. The assumptions that are made regarding underlying statistical distributions can have a significant impact on the meaningfulness of the answers that result.

## ***Statistical Distributions***

Statistical distributions model various physical, mechanical, electrical, and chemical properties, as well as the number of occurrences of events. There are seven well-known and widely used statistical distributions: normal, log normal, Weibull, and exponential, which are continuous in nature and binomial Poisson and hypergeometric, which are discrete functions. Each of these statistical distributions are briefly described below. References 34, 35, and 36 provide a comprehensive collection of information about numerous statistical distributions used in the development of statistical theory and practice. Reference 21 is a useful layman's source on statistical distributions and their practical application.

**The normal distribution** is the most widely used and best understood statistical distribution. In addition to its widespread use as an approximation to the distributions of many computed statistics, the normal distribution is frequently used to model various physical, mechanical, electrical, and chemical properties—for example, tensile strength, hardness, conductivity, and elastic modulus. Many properties that scatter randomly about a well-defined mean value, without either positive or negative bias, also tend to follow a normal distribution.

The primary limitation associated with the modeling of physical measurements with the normal distribution is its symmetry of average value. Thus, skewed or asymmetric populations are not modeled well by the normal distribution. The main advantage of the normal distribution is the large body of literature available describing procedures for the analysis of normally distributed data.

Figure 9 illustrates a histogram that describes the distribution of tensile yield strengths for a particular material. The number of observations in each interval is recorded. Continuous probability density functions are superimposed over the histogram to indicate the conformity of these data to a normal distribution as compared with either a two-parameter or a three-parameter Weibull distribution.

**Fig. 9** Histogram of tensile yield strength values with superimposed probability density functions

**Log-Normal Distribution.** Probably the second most often assumed distribution for engineering random variables is the log-normal distribution. Of course, the log-normal distribution is really just a special case of the normal distribution, where the quantities that are assumed to be normally distributed are the logarithms of the original observations. For example, when the logarithms of the fatigue lives of the material listed in Table 6 were completed and the computed values were ranked and plotted on normal probability paper, a nearly straight line resulted (Fig. 8b). The data trends deviate from linearity only at the very low- and high-fatigue lives.

**Weibull distribution** is used frequently in representing engineering random variables because it is very flexible. It was originally proposed (Ref 37) to represent fatigue data, but it is now used to represent many other types of engineering data. For the modeling of fatigue strength at a given life, it has been argued that only the Weibull distribution is appropriate (Ref 38). One of the reasons that the Weibull distribution is popular is that data can be plotted on Weibull paper and the conformance of these data to the Weibull distribution can be evaluated by the linearity of the cumulative distribution function in the same way as normal distribution (Fig. 9).

**Exponential distribution**, which is a special case of the Weibull distribution, has been found to be useful in the analysis of failure rates of complete systems or assemblies, such as light bulbs, water heaters, and automobile transmissions, or where their failures result from chance occurrence alone, such as a wheel hitting a large pothole.

**Binomial distribution** may be applicable where the random variable is discrete and takes on non-negative integer values. It is used commonly in developing sampling plans for periodic inspections of manufacturing or material quality. For example, it is used to model the number of defective items in samples drawn from large lots of items (such as electrical parts) submitted to inspection.

**Other Discrete Distributions.** Two other common variations of the binomial distribution are the hypergeometric and the Poisson distributions. The hypergeometric distribution is used for the same kinds of applications as the binomial distribution, except that for the binomial, the percentage of defective items is assumed to be constant throughout the experiment.

The Poisson distribution differs from the binomial and hypergeometric distributions in that the number of times that an event occurs is not known, but the probability of occurrence of the event is known.

## ***Statistical Procedures***

Many different statistical techniques can be useful in analysis of mechanical-property data. This section presents brief descriptions of procedures that are used frequently (Ref 39). More detailed descriptions of these and other statistical techniques and tables in their various forms can be found in a number of workbooks and texts (for example, Ref 40).

**Goodness-of-fit tests** can be used to establish whether a sample can realistically be assumed to follow a normal distribution. The Anderson-Darling goodness-of-fit test for normality can be used to determine whether the density function that fits a given set of data can be approximated by a normal curve. The test involves a numerical comparison of the cumulative distribution function for observed data with that for the fitted normal curve over the entire range of the property being measured. Arithmetic normal probability paper is recommended for graphic illustration of the degree to which a normal distribution fits a set of data. Logarithmic normal probability paper can be used to determine whether the distribution of data could be normalized by a logarithmic transformation. One axis is scaled in units of the property measured, and the other axis is a nonlinear scale of probability. For further information on goodness-of-fit tests, refer to Ref 41 and 42.

**Tests of significance**, which include the *F* test and *t* test, are used in determining whether the populations from which two samples are drawn are identical. The *F* test is used to determine whether two products differ with regard to their variability. The *t* test is used to determine whether two products differ with regard to their average properties. If they do, it can be concluded that the two products do not belong to the same population.

In making the *t* test, it is assumed that the variances of two products are nearly equal, as first determined from the *F* test. If the *F* test shows that the variances are significantly different, there is no need to conduct the *t* test.

**Data Regression Techniques.** When it is suspected that the average of one measured value varies linearly or curvilinearly with some other measured value, a regression analysis is often used to investigate and describe the relationship between the two quantities. Examples are effect of product thickness on tensile strength, effect of temperature on yield strength, and effect of stress on cycles to failure or time to rupture. Reference 43 describes mathematical techniques for performing linear regression computations.

***Related ASTM Engineering Statistics Standards***

Table 8 lists standards published by the American Society for Testing and Materials (ASTM) that address statistical issues relevant to engineering design. These standards are maintained by ASTM Committee E11 on Statistical Methods. A primary purpose of this group is to advise other ASTM committees in the area of statistics, and to provide information for general application.

## Total Life Cycle in Design

It is an accepted principle of engineering to design a product for minimum cost, consistent with fulfilling the functional requirements of the product. It is tempting to define the cost of a product strictly on the basis of component and labor costs (plus allowances for overhead, selling cost, and profit). However, such accounting neglects several important items in the total cost of the product to the user, such as cost of energy to operate the product, cost of maintaining the product, depreciation, and cost of disposal. In addition to the cost of a product to its producer and user, there is the cost to society at large; some of the components of this cost are consumption of raw materials and energy and the impact of the product on the environment. The relative importance of considering the cost to the user and to society during design depends in part on the nature of the product. An automobile, for instance, has considerable user and societal costs; for a bolt, these costs are smaller, harder to identify, and easier to neglect.

To a materials engineer, the concept of total life cycle must include the total life of the product, as discussed above and in Table 2, but should also include the total life cycle of the components and materials in the product. Whenever possible, a product should be designed so that components that do not wear out can be reused, or so that the materials in the product can be recycled.

**Life-cycle analysis (LCA)** refers to the "cradle to grave" assessment of the energy requirements and environmental impacts of a given product design. All aspects of the total life cycle of the product are considered, including raw-material extraction from the earth and product manufacture, use, recycling (including design for recycling), and disposal. Key factors considered in the life-cycle engineering approach are examined in the Section on "Recycling and Life-Cycle Analysis" in this Handbook.

**Energy Requirements.** Reuse of components and materials obviously conserves raw materials, such as the ore from which a metal is made, but it also conserves the energy required to extract the metal from the ore. Basic metal-production operations are highly energy intensive. It has been estimated that 95% of the energy required to manufacture aluminum beverage cans from ore can be saved if metal in the cans is recycled. It may be possible to conserve energy by choosing materials that do not require heat treatment but still have adequate strength. Heavily drafted cold-drawn and stress-relieved steel bars can have yield strengths of 690 MPa (100 ksi); for many purposes, such bars can be used in place of hardened-and-tempered bars. The potential for conservation of scarce resources, particularly those that might be subject to manipulation for economic or political gain, is apparent in these two examples.

As suggested above, the energy required to operate a mechanical device can represent a significant portion of its total life-cycle cost. For example, the cost of electricity used to operate an air conditioner for the duration of the warranty period may be greater than its purchase price.

**Producibility.** The question of producibility affects engineering design at several levels. The most basic question is whether the technology required to economically produce the desired quantity of the item exists. A product should be designed in accordance with established technological practice whenever possible; working at the limit of technology leads to higher scrap levels and difficulties in production, and advancing the limit of technology requires a developmental program before production can begin. A second question concerns the capability of the factory (or entire industry) to produce the desired number of parts. The third question concerns utilization of existing equipment and personnel. Some of the answers to these questions are managerial prerogatives, but it is usually desirable for designers to analyze the various possibilities and present a set of alternatives, together with possible consequences, advantages, and disadvantages of each, to management.

**Durability,** or intended service lifetime, is one of the parameters on which a design must be based. In general, basic goals for service lifetime are established for, rather than by, designers. As in the case of producibility, it may be desirable for a designer to develop alternative combinations of material and design that could significantly affect the anticipated service life of the product.

**Quality assurance** should be an integral part of the manufacturing process of any product, especially because the possible consequences of permitting deficient products to reach the marketplace can be dire. This article does not attempt to describe a quality assurance program, or how to develop such a program; rather, it emphasizes the importance of such a program and points out how design and quality assurance are interrelated.

A designer must know the types and severity of discontinuities that can be detected in a quality assurance program and have an appropriate level of confidence in the detection methods. By knowing what can be expected from the quality assurance program, the designer can then provide a margin of safety to compensate for the existence of discontinuities that cannot be detected. This is part of the basic philosophy of fracture mechanics. A similar approach is applicable to design of redundant systems in the product. In either case, the product should be designed with the capabilities and limitations of the quality assurance program in mind.

**Handling** requirements of various products are too frequently neglected in engineering design. Almost without exception, a product is made in one location and used in another. Thus, it is essential to provide means for transporting it from the manufacturer to the seller to the user; the means of transportation can affect the design of the product in several ways. The most obvious concern is to ensure that the product will not be degraded in handling, transit, or storage. Whenever feasible, a product should be designed against the possibility of damage caused by normal handling. A product that can be easily damaged in handling must be carefully (and expensively) protected by packaging or special shipping procedures. It is also important to design a product to minimize shipping and storage space requirements. For example, wastebaskets are usually designed to be nested during handling; many wastebaskets have lugs or other design features that limit nesting in order to permit easy separation. Particularly for consumer products, the design of packages may not be considered a part of product design, but it is still appropriate for a product designer to consider packaging requirements that might result from various design alternatives.

## Other Major Factors in Design

Besides the functional factors listed in Table 1 and the total life-cycle considerations described in Table 2, several other major factors affect design and materials selection; some of them are listed in Table 3.

### *State of the Art*

Most of the time, the state of the art in a particular field can be inferred from an engineering evaluation of products currently on the market. Existing products may lack capabilities that could be provided by a new product. The extent of improvement might range from purely cosmetic (which might be the case for a new product intended to capitalize on the market acceptance of an established product) to complete redesign resulting in an entirely new product unlike anything previously produced. The state of the art can be defined not only by existing products but also by industrial and societal standards, technical publications, and patents. Patent infringement is often considered a matter for legal departments, but technical personnel are often able to analyze technological aspects of patents on devices and processes that might be applicable to new products.

## ***Designing to Codes and Standards***

Many products are subject to either mandatory or voluntary standards. By definition, a "code" is any set of standards set forth and enforced by a local government for the protection of public safety, health, etc., as in the structural safety of buildings (building code), health requirements for plumbing, ventilation, etc. (sanitary or health code), and the specifications for fire escapes or exits (fire code)." "Standard" is defined as "something considered by an authority or by general consent as a basis of comparison; an approved model."

As a practical matter, codes tell the user *what* to do and *when* and under what circumstances to do it. Codes are often legal requirements that are adopted by local jurisdictions that then enforce their provisions. Standards tell the user *how* to do it and are usually regarded only as recommendations that do not have the force of law. As noted in the definition for code, standards are frequently collected as reference information when codes are being prepared. It is common for sections of a local code to refer to nationally recognized standards. In many instances, entire sections of the standards are adopted into the code by reference, and then become legally enforceable. A list of such standards is usually given in an appendix to the code.

**The Need for Codes and Standards.** The information contained in codes and standards is of major importance to designers in all disciplines. As soon as a design problem has been defined, a key component in the formulation of a solution to the problem should be the collection of available reference materials; codes and standards are an indispensable part of that effort. Use of codes and standards can provide guidance to the designer about what constitutes good practice in that field and ensures that the product conforms to applicable legal requirements.

The fundamental need for codes and standards in design is based on two concepts: part/component interchangeability and compatibility. Standardization of parts within a particular manufacturing company to ensure interchangeability is only one part of the industrial production problem. The other part is compatibility. What happens when parts from one company, working to their standards, have to be combined with parts from another company, working to their standards? Will parts from company A fit with parts from company B? Yes, but only if the parts are compatible. In other words, the standards of the two companies must be the same.

**Common Examples of Codes and Standards.** Most materials engineers are familiar with the many professional society codes that have been developed. The American Society of Mechanical Engineers (ASME) publishes the Boiler and Pressure Vessel Code, which has been used as a design standard for many decades. The Society of Automotive Engineers (SAE) publishes hundreds of standards relating to the design and safety requirements for vehicles and their appurtenances. ASTM publishes thousands of standards relating to materials and the methods of testing. These standards are published in a set of 70 volumes divided into 15 separate sections. The standards are developed on a consensus basis with several steps in the review process. Initial publication of a standard is on a tentative basis; such standards are marked with a T until finally accepted. Periodic reviews keep the requirements and methods current. Because designers frequently call out ASTM testing requirements in their materials specifications, the designer should routinely check ASTM listings to make certain the applicable version is being called for.

Coordination, approval, and distribution of many domestic standards fall under the auspices of the American National Standards Institute (ANSI), New York, NY. A sponsoring trade association will request that ANSI review its standard. A review group is then formed that includes members of many groups other than the industry. This expands the area of consensus and is an essential feature of the ANSI process. Table 9 gives a partial list of the many organizations that act as sponsors for the standards that ANSI prepares under their consensus format.

**Table 9 Sponsoring organizations for standards published by the American National Standards Institute**

<b>Acronym</b>	<b>Organization</b>
AAMA	American Apparel Manufacturers Association 2500 Wilson Blvd., Arlington, VA 22201 (703) 524-1864

ANSI circulates copies of the proposed standard to all interested parties seeking comments. A time frame is setup for receipt of comments, after which a Board of Standards Review considers the comments and makes what it considers necessary changes. After more reviews, the standard is finally issued and published by ANSI, listed in their catalog, and made available to anyone who wishes to purchase a copy. A similar process is used by the International Standards Organization (ISO), which began to prepare an extensive set of worldwide standards in 1996. Standards published by ISO members are also listed in ANSI catalogs.

**Standards Information Services.** Copies of standards and information about documents published by the more than 350 code- and standard-generating organizations in the United States and several other countries can be obtained from resellers such as Global Engineering Documents, Englewood, CO. They provide information on CD-ROM, magnetic tape, microfilm, or microfiche formats. Similar services exist in many countries throughout the world.

### ***Human Factors and Safety in Design***

**Human factors in design** describe the interactions between a device and anyone who uses or maintains it. Examples of human factors in design include designing the handle of a portable electric drill to fit comfortably into either hand of the user, arranging gages and controls on an automobile dashboard to be easily seen or reached, and designing an ejector to remove the beaters of an electric mixer. Human factors also include operational methods and procedures, testing and evaluating these methods and procedures, job design, development of job aids and training materials, and selection and training of people who will be users.

One branch of industrial engineering that deals specifically with human factors is referred to as "ergonomics"; contact with persons involved in such research would be useful to designers. References 44, 45, and 46 include examples of useful references describing human factors in design.

**Safety in Design.** The designer/manufacturer of any product (e.g., consumer product, industrial machinery, tool, system, etc.) has a major obligation to make the product safe (i.e., reduce the risks associated with the product to an acceptable level). In this context, "safe" means a product with an irreducible minimum of danger (as defined in the legal sense), that is, safe not only with regard to intended use (or uses) but also all unintended, but foreseeable, uses. For example, consider the common flat-tang screw driver. Its intended use is well known. Can anyone say that they have never used such a screwdriver for any other purpose? It must be designed and manufactured to be safe in all these uses.

There are three aspects, or stages, in designing for safety:

1. Make the product safe (i.e., design all hazards out of the product).
2. If it is impossible to eliminate all hazards in design, provide guards that eliminate the danger.
3. If it is impossible to provide proper and complete guarding, provide appropriate directions and warnings.

Although the principles or specific guidelines for carrying out these stages in designing for safety are beyond the scope of this article, there is an abundance of literature on safe practices in design (see, for example, Ref 47, 48, 49, 50).

Documents pertaining to safety and control or elimination of workplace hazards can also be obtained from ANSI and the National Safety Council.

## ***Aesthetics***

Aesthetics is an important aspect of the design of almost any product, but it is an aspect that should not be allowed to compromise functional requirements. Some consumer products are sold almost exclusively by aesthetic appeal; design of such products is usually assigned to artists. However, aesthetic appeal is important even for industrial products. A smooth or shiny finish, an artistically pleasing shape, or an appearance of ruggedness and durability may have little or no influence on the ability of the product to perform its function but may, nevertheless, have a considerable effect on the attitude of a potential buyer or on worker acceptance when the item is put into service.

## ***Cost***

Assuming that a product meets the basic functional requirements established for it, the most important single factor in its design and manufacture is cost. The cost of any product must be competitive with the cost of comparable products already on the market. Whether there is a directly comparable product or not, the cost must be low enough to convince a prospective purchaser that the benefits to be derived from the product exceed its cost. Cost-benefit studies almost always precede the purchase of major pieces of manufacturing equipment.

Cost generally enters the design process as one of several criteria against which the merit of a design is judged. Whenever a choice exists between different materials, designs, or manufacturing processes, the least costly alternative will be chosen, provided that the basic functional requirements for the product can still be met. In some instances, the possibility of significant cost reduction will justify re-evaluation of basic functional requirements and performance specifications; it may be possible to modify the design goals slightly and thereby significantly reduce costs. However, it is important to remember that any modification of functional requirements and performance specifications can adversely affect utility and marketability.

# Factors in Materials Selection

---

## Introduction

THE SELECTION OF ENGINEERED MATERIALS is an integral process that requires an understanding of the interaction between such factors as materials properties, manufacturing and fabrication characteristics, and the design considerations described in the previous article. Two often cited reasons for selecting a certain material for a particular application are (a) the material has always been used in that application and (b) the material has the right properties. Neither reason is evidence of original thinking or even careful analysis of the application. The collective experience gained from common usage of a material in a particular application is useful information, but not justification in itself for selecting a material. The time has passed when each application has its preferred material and a particular material its secure market. In the context in which it is frequently mentioned, the term "property" connotes something that a material inherently possesses. On the contrary, a property should be regarded as the response of the material to a given set of imposed conditions. It must also be recognized that this property should be that of the material in its final available and processed form. Tabulated properties data, such as those available from handbooks, standards organizations, computerized databases, and other sources of materials information summarized in Ref 1 are helpful, but such information must be used judiciously and must be relevant to a particular application.

Regardless of specific expertise, every engineer concerned with hardware of any description (and this includes essentially all engineers) must deal constantly with selecting an appropriate material (or combination of materials) for the design. Except in trivial applications, it certainly is not sufficient to indicate that the components should be "steel" or "aluminum" or "plastic". Rather, the engineer must focus attention, knowledge, and skill on the general factors in materials selection listed in Table 1. It is obvious that these are inseparable and interwoven with the factors described in Tables 1 to 3 in the article "Design Factors" in this Section.

**Table 1 General factors in materials selection**

Functional requirements and constraints
Material properties (see Table 2)
Manufacturing process considerations
Fabricability (see Table 2)
Design configuration
Available and alternative materials
Corrosion and degradation in service
Thermal stability
Properties of unique interest
High density
High stiffness-to-weight ratio
Low melting point
Special thermal expansion properties
Electrical conductivity/superconductivity
Wear resistance
Biocompatibility
Cost

In principle, a mathematical expression describing the merit of an engineering design as a function of all these variables, differentiating it with respect to each of the criteria for evaluation, and solving the resulting differential equations to obtain the ideal solution could be written. This is not a reality, however, the principle is valid and should provide a basis for action by the designer. In some instances, a standard, readily available component can be much less costly than, and yet nearly as effective as, a component of optimized, nonstandard design.

## Materials Properties

The performance or functional characteristics of a material are expressed chiefly by physical, mechanical, thermal, electrical, magnetic, and optical properties. Material properties are the link between the basic structure and composition of the material and the service performance of the part (Fig. 1).

Fig. 1 The role played by material properties in the selection of materials

An important role of the materials engineer is to assist the designer in making meaningful connections between materials properties and the performance of the part or system being designed. For most mechanical systems, performance is limited, not by a single property, but by a combination of them.

## Mechanical Properties

One question usually asked in selecting materials is whether strength is adequate to withstand the stresses imposed by service loading. Although the primary selection criterion is often strength, it also may be toughness, corrosion resistance, electrical conductivity, magnetic characteristics, thermal conductivity, specific gravity, strength-to-weight ratio, or some other property listed in Table 2. For example, in residential water service, where the water pressure is relatively low, weaker and more expensive copper tubing might be a better choice than stronger steel pipe. Steel pipe comes in sections and is joined by threaded connections with elbows at corners, whereas soft copper can be obtained in coils and can be easily bent around corners. Thus, the lower installation cost of copper can overcome the higher material cost. Also, because of the relatively low water pressure, the strength of copper would be adequate, and the greater strength of steel unnecessary. Furthermore, in the event of freezing, copper usually yields instead of bursting; in many regions of the country, it is more resistant to corrosion by the local water than steel. In general, the usual criterion for selection is not just one property, such as strength, but some combination of properties, manufacturing characteristics, and cost.

Weldability

**Ultimate tensile strength** is a commonly measured and widely reported indication of the ability of a material to withstand loads. However, the direct application of tensile-strength data to design problems is extremely difficult. First of all, the definition of "ultimate tensile strength" is the maximum stress (based on initial cross-sectional area) that a specimen can withstand before failure; it occurs at the onset of plastic instability. Thus, any component loaded to its ultimate tensile strength is likely to fracture immediately. Secondly, if the design is based on a fraction of the ultimate strength, there is the question of what fraction provides adequate strength and safety, together with efficient use of the material. Finally, there seems to be only a rough correlation between tensile strength and material properties such as hardness and fatigue strength at a specified number of cycles, and no correlation whatsoever between tensile strength and properties such as resistance to crack propagation, impact resistance, or proportional limit.

**Yield strength** indicates the lowest measurable stress at which permanent deformation occurs. This information is necessary to estimate the forces required for forming operations. Yield strength is also useful in considering the effects of a single-application overload; most structures must be designed so that a foreseeable overload will not exceed the yield strength.

**Hardness** is another widely measured material property and is useful for estimating the wear resistance of materials and estimating approximate strength of steels. Its most widespread application is for quality assurance in heat treating. However, only rough correlation can be made between hardness and other mechanical properties or between hardness and behavior of materials in service.

**Ductility** of a metal, usually measured as the percent reduction in area or elongation that occurs during a tensile test, is often considered an important factor in material selection. It is assumed that, if a metal has a certain minimum elongation in tensile testing, it will not fail in service through brittle fracture. It is also assumed that if a little ductility is good, a lot is better. Neither of these assumptions is accurate. Metals normally considered very ductile can fail in a seemingly brittle manner, such as under fatigue or stress-corrosion conditions, or when the service temperature is below the ductile-to-brittle transition temperature. How much ductility is actually usable under service conditions and how best to measure it are very controversial. Several estimates of usable ductility (such as the ability of materials to absorb the movement within a large structure that is necessary to equalize the load among all of the members of the structure) fall in the range of 1 to 2% elongation in tensile testing. Larger amounts of ductility only indicate the possibility of more extensive permanent deformation of the structure. In many structures, any permanent deformation destroys the usefulness of the structure; for example, the aerodynamic efficiency of an aircraft wing can be substantially reduced by only 1 to 1  $\frac{1}{2}$  % deformation. The amount of ductility required for processing may far exceed that actually usable in service. Steel sheet, for example, often must have considerable ductility, far more than a part might need in service, but nevertheless enough to allow the part to be formed to its required shape.

## Manufacturing Process Considerations

The properties considered in the preceding section relate to the ability of a material to perform adequately in service without failing. But, first the part must be capable of being made, that is it must be producible. There are additional properties and producibility considerations that should be part of the material selection process. For a design to be producible the configuration should not introduce unnecessarily difficult manufacturing challenges.

This section will briefly describe the key factors that influence the relationship between materials selection and processing. Reference 2 provides more detailed information on the characteristics of various manufacturing processes.

### *Material Factors*

In a very general sense the selection of a material determines a range of processes that can be used to produce parts from the material. In the article "Introduction and Overview" in this Section, Fig. 4 shows the common classes of manufacturing processes and Table 4 indicates the manufacturing processes used most frequently with different metals and plastics. The melting point of a material and level of deformation resistance and ductility determine these relationships. Some materials are too brittle to be plastically deformed; other materials are too reactive to be cast or have poor weldability.

The melting point of a material determines the casting processes that can be employed. Low-melting-point metals can be used with any of a large number of casting processes, but as the melting point of the material rises, the number of available processes becomes limited. Ashby (Ref 3), has shown a correlation between the size (weight) of a cast part and the melting point of the material (Fig. 2). This plot shows the regions of size that can be handled by different casting and

molding processes and shows how the available number of processes decreases dramatically for materials with high-melting point. This is one of a number of process selection charts, dealing with casting, metalworking, polymer processing, powder fabrication and machining, introduced by Ashby in Ref 3 to aid in the selection of manufacturing process in the conceptual stage of design.

**Fig. 2** Ashby process chart for casting. The size in this chart is measured by weight,  $W$ . It can be converted to volume via the density,  $\rho$ , or to the approximate linear dimension,  $L$ , shown on the right-hand axis via  $L = (W/\rho)^{1/3}$ . Source: Ref 3

Similarly, yield strength, or hardness, determines the limits in deformation and machining processes. Forging and rolling loads are related to yield strength and tool life (tool load and temperature generation) in machining scales with the hardness of the material being machined. Ultimately the limit of these processes is determined by the workability of the material. See the section "Fabricability" in this article.

## Shape Factors

Each process has associated with it a range of shapes that can be produced. Thus, the first decision in selecting a process is whether it is capable of producing the required shape. A simple classification of shape is as follows:

Two-dimensional (2D)	Profile of product does not change along its length. Examples: wire, pipe, aluminum foil. Many 2D products are used as raw material for processes that make them into 3D shapes.
Three-dimensional (3D)	Profile of the product varies along all three axes. Most products are 3D.
Sheet	Has almost constant section thickness that is small compared with the other dimensions
Bulk	Has a complex shape, often with little symmetry. Solid: has no significant cavities. Hollow: has significant cavities

Whether the process can accommodate shapes with undercuts, or reentrant angles, or parts with an element positioned perpendicular to the main die motion also needs to be determined. For more in-depth considerations of shape and its relationship to process selection, see Ref 2.

### ***Process Factors***

Key manufacturing process factors include cycle time, quality, flexibility, materials utilization, and operating cost. A rating system for evaluating these five process characteristics is given in Table 3. This is applied to rating the most common manufacturing processes in Table 4.

**Table 3 Scale for rating manufacturing processes**

Rating	Cycle time	Quality	Flexibility	Materials utilization	Operating costs
1	>15 min	Poor quality, average reliability	Changeover extremely difficult	Waste > 100% of finished component	Substantial machine and tooling costs
2	5 to 15 min	Average quality	Slow changeover	Waste 50 to 100%	Tooling and machines costly
3	1 to 5 min	Average to good quality	Average changeover and setup time	Waste 10 to 50%	Tooling and machines relatively inexpensive
4	20 s to 1 min	Good to excellent quality	Fast changeover	Waste < 10% finished part	Tooling costs low/little equipment
5	<20 s	Excellent quality	No setup time	No appreciable waste	No setup costs

Rating scheme: 1, poorest; 5, best. Source: Ref 4

CVD/PVD	All	1	5	5	4	3

2D, two dimensional; 3D, three dimensional. Rating scheme: 1, poorest; 5, best. Ratings from Ref 5

**Cycle time** is the time required to process one unit once the process has been set up and is operating properly. The inverse of cycle time is production rate.

**Quality** is an inclusive term describing fitness for use. Included under this characteristic is surface roughness, ability to manufacture parts to a set tolerance, product integrity (freedom from voids, pores, cracks, and inclusions), and ability to produce controlled properties (microstructure control).

**Flexibility** in manufacturing is the ease with a process can be adapted to produce different products or variations of the same product. In an era where product customization is becoming more important, this characteristic has gained importance. Flexibility is influenced greatly by the time to change and set up tooling.

**Materials utilization** measures the amount of material processed in addition to the material required in the product. Most machining operations generate 60 to 80% scrap. Net-shape forging and injection molding are at the other extreme. As materials costs become the greater part of the product cost, materials utilization becomes of greater importance.

**Operating cost** involves both the capital cost of plant, machinery, and tooling and the labor costs of setting up and running the process. Process selection often is constrained by the available equipment, particularly if the desired process is costly to install. In any manufacturing situation, one available decision is whether to outsource the production to a qualified subcontractor.

## Fabricability

Fabricability, or ease of manufacture, describes the capability of a metal to be fabricated by various manufacturing processes. Such terms as formability, workability, castability, machinability, and weldability are implied by this topic.

Whenever possible, product design should incorporate those materials that can be readily fabricated using the desired process(es) without special precautions. Materials that can be fabricated by several methods offer convenient alternatives in the event unforeseen conditions suddenly preclude use of the principal fabrication method.

Questions regarding production, such as equipment and manufacturing capacity available for fabricating components, are directly related to fabricability, as is the quantity required. If several thousand duplicate parts are necessary, the high cost of dies or other specialized equipment for quantity production can be economically justified. If few pieces are required, hand production from relatively expensive materials in stock may be less expensive than use of more elaborate methods and less expensive materials. Even so, an engineering estimate should be made of the relation between product cost and quantity for each proposed production method.

Fabricability and mechanical properties are interrelated, and they quite often act in opposite directions. As strength levels are increased, often by increasing carbon or alloy content, weldability and machinability frequently decrease. Although most materials can be welded, higher-strength materials generally require special techniques; the designer must be aware of the added cost built into the part in order to meet the welding requirements. In some instances, there may be no practical method of regaining the strength of the base metal lost through welding. As machinability is increased by additions of sulfur or lead, long-life fatigue resistance is decreased.

In the remainder of this section, emphasis has been placed on the material characteristics that aid or hinder the production of a part without defects. Certain characteristics of a material are inherent in the selection of the manufacturing process;

for example, a molten metal that reacts strongly with the atmosphere would not be selected for casting in air. As will be described below, there are more subtle issues and materials selection tests that also need to be considered.

## Castability

Castability deals with a complex combination of liquid-metal properties and solidification characteristics that promotes accurate and sound castings. The factors that influence castability are fluidity, shrinkage, and resistance to hot cracking.

**Fluidity** is the ability of liquid metal to run freely and fill a mold cavity. Because the viscosity of molten metals is very low, fluidity is determined more by the solidification dynamics of the metal and the mold. A high surface tension of the liquid metal reduces fluidity. Oxide films forming on the surface of the molten metal thus have a significantly adverse effect on fluidity. Insoluble inclusions also reduce fluidity. The pattern of solidification of the alloy is important. Fluidity is inversely related to the temperature range over which solidification occurs. Thus, pure metals and eutectic alloys, with short freezing range, have greater fluidity. Fluidity is usually evaluated by pouring the metal into a narrow spiral mold cavity and measuring the length of penetration of the metal before it solidifies.

**Shrinkage** is an important castability factor in deciding whether the alloy has a high tendency to form shrinkage porosity. Unfortunately, there is no standard test for shrinkage. For a discussion of how to control shrinkage porosity in casting design, see the Section on "Casting" in this Handbook.

**Resistance to hot cracking** is the ability of the alloy to withstand stresses developed by the contraction while cooling from the hot-short temperature range.

Castability is an integrated property that combines these three factors. One way to approach this is to rate the alloys on a scale of one to five for each of the important factors, use a weighting for the importance of each factor, and use a decision matrix to arrive at a ranking for each casting alloy (Ref 6). Table 5 shows typical applications for metal alloys and relative ratings with respect to castability, weldability, and machinability. Note that these are general overall ratings for a class of alloys. Within each class, different alloys vary considerably with respect to specific process characteristics.

**Table 5 Typical applications for castings and general rating of castability, machinability, and weldability**

Casting alloy type	Applications	Castability	Machinability	Weldability
Aluminum	Pistons, clutch housings, exhaust manifolds	1-2	1-2	3
Copper	Pumps, valves, marine propellers	1-3	1-2	3
Gray iron	Engine blocks, gears, brake disks and drums, machine bases	1	2	5
Magnesium	Crankcases, transmission housings	1-2	1	2
Malleable iron	Farm and construction machinery, heavy-duty bearings, railroad rolling stock	2	2	5
Nickel	Gas-turbine blades, pump and valve components for chemical plants	3	3	3
Nodular iron	Crankshafts, heavy-duty gears	2	2	5
Steel (carbon and low	Die blocks, heavy-duty gear blanks, railroad wheels	3	2-3	1

alloy)				
Steel (high alloy)	Gas-turbine housings, pump and valve components, rock-crusher jaws	3	3	1
White cast iron	Ball mill liners, shot-blasting nozzles, railroad brake shoes, crushers	2	4	4
Zinc	Door handles, radiator grilles, carburetor bodies	1	1	5

### **Workability and Formability**

Two kinds of plastic deformation processes must be recognized. In three-dimensional, or bulk deformation, processes the material is deformed in all three principal directions. Here, the limit on deformation is concerned chiefly with the fracture of the material, and so ways to describe its workability are of interest. In two-dimensional, or sheet-forming, operations the deformation limit is caused by buckling, excessive thinning, or fracture; therefore, ways to describe the formability of the material are considered.

**Workability** is a complex technological concept that depends not only on the fracture resistance (ductility) of the material but also on the specific details (stress state) of the deformation process as determined by die geometry, work-piece geometry, and lubrication conditions. The greater the workability of a material the greater the deformation and/or the more complex the shape that can be produced before fracture occurs. Ease of manufacture also is aided when the material has a low-flow stress (yield strength) so that the force that must be applied by the processing equipment and the stresses on the dies are lower. Because flow stress decreases with increasing temperature, much plastic deformation of metals is carried out at elevated temperature (hot working).

Crack formation that limits workability is usually a form of ductile fracture. At temperatures lower than about one-half the melting point (absolute scale), this is the familiar dimple-rupture mode, but at higher temperature fracture initiated by grain-boundary sliding or cavitation can occur (Ref 8). Workability problems can also arise when deformation is localized to a narrow zone. Flow localization is caused by the formation of a dead-metal zone between the workpiece and the tooling, either because of poor lubrication or because the dies are cooler than the workpiece. Localized flow can also result from flow softening due to structural instabilities such as adiabatic heating, grain coarsening, or spheroidization.

The workability of a material is not a fixed material property. The state of stress in the workpiece imposed by the geometry of the deformation process greatly affects the workability. Stress states with high compressive components that impede crack initiation or propagation enhance workability. A general workability parameter,  $\beta$ , that corrects for stress state is given as (Ref 9):

$$\beta = \frac{3\sigma_m}{\bar{\sigma}} \quad (\text{Eq 1})$$

where  $\sigma_m$  is the mean or hydrostatic component of stress:

$$\sigma_m = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3) \quad (\text{Eq 2})$$

and  $\bar{\sigma}$  is the effective stress:

$$\bar{\sigma} = \frac{1}{\sqrt{2}} \sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2} \quad (\text{Eq 3})$$

Figure 3 shows the strain to fracture plotted against the parameter  $\beta$ . The curve is determined from three basic mechanical property tests: tension, torsion, and compression. The appropriate parameters for each of these tests are given in Table 6. Figure 3 also shows the location of the most common bulk metal deformation processes in terms of the level of compressive stress state.

**Table 6 Evaluation of the workability parameter,  $\beta$**

Test	Principal stresses	Effective stress	Mean stress	$\beta$	Strain-to-fracture measurement
Tension	$\sigma_1; \sigma_2 = \sigma_3 = 0$	$\sigma_1$	$\sigma_1/3$	1.0	$\epsilon_f = \ln (A_0/A_n)$ at necking
Torsion	$\sigma_1 = -\sigma_2; \sigma_3 = 0$	$\sqrt{3}\sigma_1$	0	0	$\epsilon_f = (r\theta/\sqrt{3}L)$
Compression	$-\sigma_1; \sigma_2 = \sigma_3 = 0$	$\sigma_1$	$-\sigma_1/3$	-1.0	$\epsilon_f = \ln (A_f/A_0)$

**Fig. 3 Influence of stress state on strain to fracture. Source: Ref 8**

One of the most successful and useful design tools to assess workability for free-surface fracture is the fracture locus diagram (Fig. 4) (Ref 10). The plot shows the locus of free-surface strains (one tensile and the other compressive) that cause fracture. These are obtained from tests on upset compression and bend-test specimens. For many metals the fracture locus is a straight line of slope  $-\frac{1}{2}$ . To use the fracture diagram, the calculated surface strains estimated to be developed during the deformation process are super-imposed on the fracture locus diagram. If the final strain for processing the part lies above the fracture line for the material, the part failure is expected. As shown in Fig. 4, a change to a material B with better workability or a change in the process conditions (lubrication, die design, or preform design) to reduce the level of surface tensile strain, for example, strain path b, can be made.

**Fig. 4 Schematic workability diagram for bulk deformation processes. Strain path (a) would lead to failure for**

material A. Both strain paths can be used for the successful forming of material B. Source: Ref 10

A large number of workability tests have been developed for bulk deformation processes (Ref 11, 12). In addition to the primary tests of tensile, upset compression, bend, and torsion, there are tests such as plane-strain compression, partial-width indentation, ring compression, and forgeability tests such as wedge forging, sidepressing, and the notched-bar upset tests. Some of these tests are further described in the Section on "Mechanical, Wear, and Corrosion Testing" in this Handbook.

**Formability.** The term formability is commonly used to describe the ability of a sheet metal to maintain its structural integrity while being plastically deformed into a shape. Failure can occur by tearing, buckling and wrinkling, or excessive thinning. An ideal material from the standpoint of formability should:

- Distribute the strain in the sheet uniformly (high  $m$ )
- Achieve high strain levels without necking or fracture (high  $n$ )
- Withstand in-plane compressive stresses without wrinkling
- Withstand in-plane shear stresses without fracturing
- Retain part shape on removal from the die
- Retain a smooth surface and resist surface damage

The strain distribution is determined by three material properties measured with the tensile test. The *strain-hardening exponent*, also known as the  $n$  value, is expressed as:

$$n = \frac{d(\ln \sigma)}{d(\ln \epsilon)} \quad (\text{Eq 4})$$

where  $\sigma$  is true stress and  $\epsilon$  is true strain. The *strain-rate sensitivity*, also known as the  $m$  value, is expressed as:

$$m = \frac{d(\ln \sigma)}{d(\ln \dot{\epsilon})} \quad (\text{Eq 5})$$

The *plastic strain ratio* (normal anisotropy), or  $r$  value, is expressed as:

$$r = \frac{\epsilon_w}{\epsilon_t} = \frac{\ln (w/w_0)}{\ln (t/t_0)} \quad (\text{Eq 6})$$

where  $\epsilon_w$  is the true strain in the width direction of the tensile specimen and  $\epsilon_t$  is the true strain in its thickness direction.

The  $r$  value is a measure of the ability of the material to resist thinning while undergoing width reduction. A high  $r$  value is the measure of a material with good deep-drawing characteristics. High values of  $n$  and  $m$  lead to good formability in stretching operations because they promote uniform strain distribution, but they have little effect on drawability.

A forming limit diagram has been established for sheet metals by subjecting the sheet to various ratios of major to minor in-plane strains and plotting the locus of strain ratios for which local thinning (necking) and failure occur (Fig. 5). Strain conditions on the left side, where circles distort to ellipses, represent drawing conditions, while the right side where circles distort to larger circles corresponds to stretch conditions. When the minor strain is 0, a plane strain condition is developed. A forming limit diagram for a sheet metal can be used in conjunction with a trial run of the part to determine how close the material is to failure and how lubrication or die parameters should be adjusted to take the material away from a failure condition. The surface of the sheet is covered with a grid of circles produced by electrochemical marking. When the sheet is deformed, the grid of circles distort and the ratio of major to minor strain can be determined at critical points. These strains are plotted in Fig. 5 to determine how close the material is to failure.

**Fig. 5** Typical forming limit diagrams for different sheet metals. To use the diagram, locate the position on the chart for the major strain (always positive) and minor strain that is the most critical combination in the part to be formed. Failure will occur if the point is above the forming limit diagram for the sheet metal. Source: Ref 7

Many simulation tests for the formability of sheet metals have been developed (Ref 13). Olsen and Erichsen cup tests and the hemispherical dome tests measure stretching, while the Swift cup test measures drawing. The Swift round-bottomed test and the Fukui conical cup tests are involved with combined stretch and drawing. More detailed information on these test procedures is found in the Section on "Mechanical, Wear, and Corrosion Testing" in this Handbook.

## Machinability

Machinability is the relative ease or difficulty of a material to be machined. A material has good machinability if the tool wear is low, the cutting forces are low, the chips break into small pieces instead of forming long snarls, and the surface finish is acceptable. This illustrates the problem of defining machinability as a characteristic material property. Machinability is more a system property that depends on the workpiece material plus the cutting tool material and its geometry, the type of machining operation, and the operating conditions of speed, feed, depth of cut, cutting tool geometry, nature of the cutting fluid, and the rigidity of the machine tool. The one material generalization that can be applied to machinability is that the higher the hardness of the workpiece material, the poorer the machinability. Even this fails at low hardness levels where soft, gummy materials develop chips with built-up edge and lower machinability. The requirement for the material to have good machinability varies with the machining operation (see Table 7).

**Table 7** Common machining processes listed in decreasing order of relative difficulty with respect to machinability of the workpiece

Internal broaching
External broaching
Tapping

Milling

Shallow drilling  
Planing and shaping  
Turning with single-point tools  
Sawing  
Grinding

Source: Ref 14

The terms machinability index and machinability rating are used as qualitative and relative measures of the machinability of a material under specified cutting conditions. This concept was introduced early in this century when high-speed steel tools dominated the field. The tool life obtained in turning B1112 resulfurized steel with a high-speed steel tool at 180 sfm was assigned a machinability rating of 100. Suppose the tool lasted for 60 min. If in another steel the identical tool lasted for 40 min, then this material would be given a machinability rating of  $(\frac{40}{60}) 100 = 67$ . Because small changes in cutting speed produce large changes in tool life, it is more practical to measure machinability as the cutting speed that causes tool failure in a specified time period, usually 60 min. This makes use of the Taylor tool life equation; the cutting speed times tool life raised to an exponent equals a constant,  $(VT^n = C)$ . Figure 6 shows the plot and method of determining the machinability exponent.

Material	Cutting speed for 60 min tool life		Machinability rating
	m/min	sfm	
A	189	620	100
B	146	480	$77 (\frac{146}{189}) \times 100$
C	122	400	$65 (\frac{122}{189}) \times 100$

Fig. 6 Relationship between tool life and cutting speed based on Taylor equation. Table shows how the machinability rating would be determined. Source: Ref 15

Surface finish is another criterion for evaluating machinability. The better the surface finish under a given set of conditions, the higher the machinability of the material. Similarly, cutting force tests to measure the feed force under a given set of conditions are sometimes used. The most fundamental measure of machinability is the energy consumed in machining a unit volume of material (Ref 16). See Table 8 for some values. For details on conducting machinability tests, see Ref 14, 15, and 18.

**Table 8 Approximate energy per unit volume requirements for machining different metals and alloys**

Material	Hardness, HB	Unit energy <sup>(a)</sup> , (W/s)/mm <sup>3</sup>
Aluminum	50-100	0.55
Aluminum alloys	100-150	0.65
Cast irons	125-175	0.87
	175-250	1.3
Carbon steel	150-200	1.3
	200-250	1.7
	250-300	2.2
Alloy steel	200-250	1.7
	250-300	2.2
	300-350	2.8
	350-400	3.5
Copper	...	1.5
Brass	100-150	1.7
Bronze	100-150	1.7
High-temperature alloys	...	3.3-8.5
Titanium alloys	...	3.0-4.1
Refractory metals	...	3.8-9.3

Finally, it needs to be understood that machinability data show considerable scatter. For B1112 steel, within the composition range permitted by that grade, it was found that the machinability index varied as much as 20% below and 60% above the nominal value of 100 assigned to this grade because of unintentional variations in carbon, sulfur, and silicon content. In general, differences of 5% in machinability ratings are not likely to be significant or reproducible.

The weldability of a particular metal combination describes the ease with which the weld can be made and the quality and soundness of that weld. All metals can be welded to themselves by at least one of the welding processes (Table 9); these processes are discussed in the Section on "Joining" in this Volume. The primary factor that controls weldability is the composition of the base metal and the filler metal. A fusion weld cannot be made between dissimilar metals unless they have metallurgical solubility. Barring this, brittle compounds may be formed. Weldability is affected by such defects as cracking in the weld metal, porosity, or cracking in the heat-affected zone (HAZ). Weld cracking in steel can be caused by the presence of very small amounts of hydrogen, the formation of martensite in the weld, and the presence of high-residual stresses. Free-machining steel with high-sulfur content cannot be fusion welded without cracking due to hot shortness. Hardenable steels must be welded with caution to avoid brittle martensite formation. Preheating the weld to reduce the quench rate and postheating to temper any martensite should be practiced. To estimate whether hardenability problems are likely to affect weldability of a steel, the carbon equivalent  $CE$ , is determined:

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%Ni}{15} + \frac{\%Cu}{15} + \frac{\%Cr}{5} + \frac{\%Mo}{5} + \frac{\%V}{5} \quad (Eq\ 7)$$

### Table 9 Weldability of specific metals and alloys

[illegible]

Stainless steel (austenitic)	A	A	A	A	A	B	A	A	C
Tool steels	No	C	C	No	No	No	No	A	A
Titanium	No	A	A	No	A	No	No	No	No
Tungsten	No	B	A	No	No	No	No	No	No
Zinc	No	C	C	No	No	No	No	No	C

Metal or process rating: A, recommended or easily weldable; B, acceptable but not best selection or weldable with precautions; C, possibly usable but not popular or restricted use or difficult to weld; No, not recommended or not weldable. Source: Ref 19

The quality of welds is determined from a variety of tests. Tension and bend tests of specimens containing the weld are commonly used. A variety of drop weight and fracture toughness tests are used with steel welds. A large number of tests have been developed for determining the susceptibility of the weld joint to cracking during fabrication. These can be divided into restraint tests, externally loaded tests, underbead cracking tests, and lamellar tearing tests (Ref 20). These tests are also described in the Section "Joining" in this Handbook.

## ***Heat Treatability***

Satisfactory response to heat treatment is the capability of a material, fashioned into a particular part, to be heat treated to a desired microstructure, hardness, and strength level without undergoing cracking, distortion, or excessive size change, that is, the heat treatability of the material. The most important factors affecting response to heat treatment are the recrystallization, phase-decomposition, and/or transformation characteristics of the material, the configuration and mass of the part, and control of the heat treating operation.

Before determining what response to heat treatment is needed for a particular application, it is important to determine that heat treatment is absolutely necessary. The economy that may be realized by eliminating heat treatment can be considerable, but is often neglected due to the automatic assumption that a part--particularly a steel part--will be heat treated.

Because heat treatment can create substantial thermal stresses in the part (even if the part is not quenched), the part should be designed so that the deleterious effects of these thermal stresses are minimized; thermal stresses are greatest during quenching. The basic objective is to design the part so that the temperature distribution during heating and cooling is as uniform as possible. Sharp corners, particularly internal corners, must be avoided, because they concentrate thermal stresses, thus accentuating their effect on the part. The largest possible radii should be used in corners. Uniform section thickness facilitates uniform temperature distribution. Designing a part to minimize thermal stresses during heat treatment usually permits choice of the least costly material that can provide the required properties.

Perhaps the most common heat treatment is the austenitize, quench, and temper sequence, which is the dominant process for hardening carbon and alloy steels. The critical aspect of this sequence is that the hardened steel part must contain a minimum percentage of martensite in order to meet the specified hardness. In other words, the hardenability of the steel must be sufficient to provide that percentage of martensite when the part is quenched into a medium that is appropriate to the size, shape, and distortion tolerance of the part.

To achieve particular combinations of mechanical properties, it may be necessary to specify other heat treatments, such as austempering, induction hardening, flame hardening, carburizing, or nitriding. Each of these processes places certain restrictions on the choice of steel; the restrictions may include carbon content, hardenability, or the need for certain alloying elements.

Seemingly minor changes in the heat treating operation can often produce significant reductions in manufacturing costs, particularly if the change reduces the scrap rate, permits a change to a less costly alloy, or facilitates a subsequent fabricating operation.

## Other Major Factors in Materials Selection

**Design Configuration.** The shape of an object is partly responsible for service demands placed on the material from which it is made. Cross-sectional dimensions, for example, may determine the stresses imposed on the material by service loads. These apparent stresses may be increased through the effects of notches and changes in section size. Design configuration determines whether or not a component will be subjected to particular hazards, such as wear or exposure to a corrosive environment. It may also determine the product form from which the item is made. A long, slender part is often made from strip or bar simply because the raw material has the same general shape. A part with a high degree of rotational symmetry is often turned on a lathe. A hollow sphere can be made by joining two hemispheres stamped from flat sheet.

**Available and Alternative Materials.** Regardless of the merits of a material for a given application, if that material is not readily available in the desired form and quantity, it is a poor choice for that application. The question of material availability is compounded by shortages caused by market fluctuations, political instability in the ore/metal-producing source, inability or reluctance of producers to supply the desired material in the desired form or quantity, and changes in the relative costs of various materials. A further complication may exist if a particular part is made in several locations, especially if these locations are in different countries. Thus, it is desirable to select more than one material for an application and, if possible, to give an order of preference.

Sometimes, an alternative material will be necessary as a substitute for a preferred but unavailable material. In other instances, the alternative material will be selected because of superiority in the specific situation. For example, a tool manufacturer had been purchasing AISI 1078 and 1086 carbon steel bars, which have overlapping composition ranges. This manufacturer decided to use only 1078 and thus reduce his inventory. Even more important, because it is a more widely used grade, 1078 is produced more frequently than 1086, and thus is more available and easier to schedule.

An alternative material for a pressure vessel may have slightly greater strength than a material it can replace. Even a small increase in strength, however, can mean a significant reduction in wall thickness. It also may permit fabrication of slightly larger vessels. The pressure-vessel designer, however, must be sure that the increase in strength does not concurrently reduce fracture resistance below acceptable values.

The desired form can also cause availability problems. A material that can be obtained only in castings obviously cannot readily be used in applications requiring drawn tubing, extrusions, wire cloth, or other fabricated shapes.

**Corrosion and Degradation in Service.** A material can be regarded as either resistant or susceptible to corrosion and degradation in service, depending on the nature of the application. Sometimes, it may be preferable to use a low-cost, frequently replaced component and assume that it will be corroded or degraded in a short time; in other situations, however, this approach may not be acceptable because of high potential danger to personnel or for other reasons.

There are other factors that should be considered when dealing with corrosive media, because neglect of these can lead to erroneous interpretations of corrosion tests and handbook data:

- A sample in a simple static test at a given temperature may corrode in a manner and at a rate significantly different than if the material were simultaneously transferring heat to the corrosive medium or if there were significant relative movement between the material and the corrosive medium.
- The test medium can become contaminated during the experiment, and its corrosive characteristics may change.
- Lack of correlation between laboratory tests and operating conditions may be caused by a limited ratio of solution volume to surface area of test material in the laboratory test.
- Pressure of gas or vapor above a corrosive liquid can appreciably affect the amounts of oxygen or other gases that may be dissolved in the solution.
- Alloys that owe their corrosion resistance to development of passive films are particularly susceptible to development of concentration cells.
- The ability of the material to withstand stress-corrosion cracking or corrosion fatigue in service is not always accurately predicted by standard laboratory tests for these qualities. If the material is, in fact, susceptible to either failure process in the service environment, sudden and unpredictable service failures can occur because cracks propagate so rapidly under the combined action of stress and corrosion.

**Stability** of material in service can be affected by temperature, fluctuations in temperature, length of time at temperature, and, in some applications, exposure to radiation. Elevated temperature not only reduces strength and induces creep but also can produce changes in microstructure, such as tempering of martensitic steels and overaging of precipitation-hardening alloys. Obviously, duration of exposure is important in determining the extent to which these phenomena occur and, consequently, in determining appropriate stability requirements. A rocket motor, for instance, may be required to operate only briefly, whereas a steam turbine is expected to operate for many years. In many applications, it is essential to avoid any and all failures that would require the equipment to be shut down for repairs. In others, especially those involving mechanical wear, replacement at regular intervals is anticipated, and the affected part is designed to be readily replaced.

Other aspects of stability are the consequences of failure. For instance, a leak in a teakettle may be only a nuisance, but a leak in a vessel containing a flammable or radioactive fluid is critical. It should be noted that many designs for long-term operation involve extrapolation or educated guessing because the best available data typically represent lifetimes much shorter than those anticipated in actual service. The need for conservatism in design for such service should be obvious.

**Properties of Unique Interest.** For most problems in materials selection, the choice represents a compromise among a large number of properties and fabrication characteristics of the material; each of these properties and fabrication

characteristics has a significant effect on final choice. Often, however, one or two properties are far more important than all others. Some examples of applications where a single property of unique interest dominates the selection of a material are:

- *High density*: gyroscope rotors and winding weights in self-winding watches
- *High stiffness-to-weight ratio*: aircraft frame components
- *Low melting point*: fusible links in sprinkler systems and fire doors
- *Expansion during freezing*: type metal
- *Special thermal-expansion characteristics*: metal-to-glass seals
- *Electrical conductivity (including superconductivity)*: power-distribution systems
- *Wear resistance*: many applications, from plowshares and ore-crusher jaws to gear teeth and cam surfaces.
- *Biocompatibility*: prosthetic devices and dental implants/alloys

These are only a few examples of applications where a requirement for one or two properties of special interest severely limits the number of candidate materials. More detailed information on such materials can be found in the Section "Special-Purpose Materials" in this Handbook.

A requirement for a particular combination of properties further limits the number of candidate materials. Beryllia ( $\text{BeO}$ ) conducts heat as well as aluminum alloys but is an electrical insulator, the only known material with high thermal and low electrical conductivities. For applications demanding high toughness at low temperatures, the choice of materials is limited to metals with face-centered-cubic lattices and certain high-nickel steels. Turbine blades in the hot stages of gas turbine engines must resist deformation and corrosion at operating temperatures and must not fail in thermal fatigue.

**Cost.** In almost every situation, final selection of a material for a specific application depends on a compromise. In some applications, there are specialized requirements that restrict the choice to relatively few materials. Even then, there is a compromise among the contending factors. The compromise and final selection also involve economic considerations. Initial cost of a piece of equipment involves raw-material, fabrication, assembly, and installation costs. Although the cost of material has a major influence on the cost of a manufactured part--60% of the cost of manufactured goods according to Ref 21--it is generally a relatively small part of the total life-cycle cost of the equipment. After the equipment has been placed in service, there may be additional costs, such as required rate of return on investment, depreciation, taxes, product-liability costs, replacements due to failure, shutdown expenses when equipment is undergoing repair or replacement, and production loss.

No industry is immune to savings through more effective application of materials. At least three major approaches may be taken to reduce cost through better use: (1) reconsider the material and mill form selected, (2) reconsider the shape of the part and its method of fabrication, and (3) redesign to take full advantage of properties. Although these apply primarily to production-line parts rather than tailor-made parts, the philosophy is applicable to all products.

In many situations, definite savings can be realized by the simple expedient of changing from one material to another without substantially changing the form or processing procedure. There are other applications for which two or more materials can be considered as alternates, with the choice at any given time dictated by current market prices.

Great savings can often be realized by changing the fabrication procedure or form in which material is used. One prominent example is the automobile-engine crankshaft. For many years, crankshafts were machined from forged steel that had to meet rather stringent specifications of strength and toughness. However, high toughness is an unnecessary requirement because a bent crankshaft is just as useless as a broken crankshaft, and impact loading on a crankshaft is not severe. Realization of these facts made it possible to effect a change to cast crankshafts. Today, there are millions of cast crankshafts in successful operation, all incapable of appreciable plastic bending, but having adequate rigidity and wear resistance. The cost of a cast and machined crankshaft is significantly less than that of a forged and machined crankshaft.

# Structure/Property Relationships in Irons and Steels

Bruce L. Bramfitt, Homer Research Laboratories, Bethlehem Steel Corporation

---

## Introduction

THE PROPERTIES of irons and steels are linked to the chemical composition, processing path, and resulting microstructure of the material; this correspondence has been known since the early part of the twentieth century. For a particular iron and steel composition, most properties depend on microstructure. These properties are called structure-sensitive properties, for example, yield strength and hardness. The structure-insensitive properties, for example, electrical conductivity, are not discussed in this Section. Processing is a means to develop and control microstructure, for example, hot rolling, quenching, and so forth. In this Section, the role of these factors is described in both theoretical and practical terms, with particular focus on the role of microstructure.

## Basis of Material Selection

In order to select a material for a particular component, the designer must have an intimate knowledge of what properties are required. Consideration must be given to the environment (corrosive, high temperature, etc.) and how the component will be fabricated (welded, bolted, etc.). Once these property requirements are established the material selection process can begin. Some of the properties to be considered are:

<b>Mechanical properties</b>
<b>Strength</b>
Tensile strength (ultimate strength)
Yield strength
Compressive strength
<b>Hardness</b>
<b>Toughness</b>
Notch toughness
Fracture toughness
<b>Ductility</b>
Total elongation
Reduction in area
<b>Fatigue resistance</b>
<b>Other properties/characteristics</b>
Formability
Drawability

Stretchability Bendability
Wear resistance
Abrasion resistance Galling resistance Sliding wear resistance Adhesive wear resistance
Machinability Weldability

Table 1 lists mechanical properties of selected steels in various heat-treated or cold-worked conditions.

Table 1 Mechanical properties of selected steels

Source: Ref 1

(a) All values are estimated minimum values; type 1100 series steels are rated on the basis of 0.10% max Si or coarse-grain melting practice; the mechanical properties shown are expected minimums for the sizes ranging from 19 to 31.8 mm (0.75 to 1.25 in.).

(b) Most data are for 25 mm (1 in.) diam bar.

In the selection process, what is required for one application may be totally inappropriate for another application. For example, steel beams for a railway bridge require a totally different set of properties than the steel rails that are attached to the wooden ties on the bridge deck. In designing the bridge, the steel must have sufficient strength to withstand substantial applied loads. In fact, the designer will generally select a steel with higher strength than actually required. Also, the designer knows that the steel must have fracture toughness to resist the growth and propagation of cracks and must be capable of being welded so that structural members can be joined without sacrificing strength and toughness. The steel bridge must also be corrosion resistant. This can be provided by a protective layer of paint. If painting is not allowed, small amounts of certain alloying elements such as copper and chromium can be added to the steel to inhibit or reduce corrosion rates. Thus, the steel selected for the bridge would be a high-strength low-alloy (HSLA) structural steel such as ASTM A572, grade 50 or possibly a weathering steel such as ASTM A588. A typical HSLA steel has a ferrite-pearlite microstructure as seen in Fig. 1 and is microalloyed with vanadium and/or niobium for strengthening. (*Microalloying* is a term used to describe the process of using small additions of carbonitride forming elements--titanium, vanadium, and niobium--to strengthen steels by grain refinement and precipitation hardening.)

**Fig. 1** Ferrite-pearlite microstructure of a typical HSLA structural steel (ASTM A 572, grade 50). 2% nital + 4% picral etch. 200×

On the other hand, the steel rails must have high strength coupled with excellent wear resistance. Modern rail steels consist of a fully pearlitic microstructure with a fine pearlite interlamellar spacing, as shown in Fig. 2. Pearlite is unique because it is a lamellar composite consisting of 88% soft, ductile ferrite and 12% hard, brittle cementite ( $\text{Fe}_3\text{C}$ ). The hard cementite plates provide excellent wear resistance, especially when embedded in soft ferrite. Pearlitic steels have high strength and are fully adequate to support heavy axle loads of modern locomotives and freight cars. Most of the load is applied in compression. Pearlitic steels also have relatively poor toughness and cannot generally withstand impact loads without failure. The rail steel could not meet the requirements of the bridge builder, and the HSLA structural steel could not meet the requirements of the civil engineer who designed the bridge or the rail system.

**Fig. 2** Microstructure of a typical fully pearlitic rail steel showing the characteristic fine pearlite interlamellar spacing. 2% nital + 4% picral etch. 500×

A similar case can be made for the selection of cast irons. A cast machine housing on a large lathe requires a material with adequate strength, rigidity, and durability to support the applied load and a certain degree of damping capacity in order to rapidly attenuate (dampen) vibrations from the rotating parts of the lathe. The cast iron jaws of a crusher require a material with substantial wear resistance. For this application, a casting is required because wear-resistant steels are very difficult to machine. For the machine housing, gray cast iron is selected because it is relatively inexpensive, can be easily cast, and has the ability to dampen vibrations as a result of the graphite flakes present in its microstructure. These flakes are dispersed throughout the ferrite and pearlite matrix (Fig. 3). The graphite, being a major nonmetallic constituent in the gray iron, provides a tortuous path for sound to travel through the material. With so many flakes, sound waves are easily reflected and the sound dampened over a relatively short distance. However, for the jaw crusher, damping capacity is not a requirement. In this case, an alloy white cast iron is selected because of its high hardness and wear resistance. The white cast iron microstructure shown in Fig. 4 is graphite free and consists of martensite in a matrix of cementite. Both of these constituents are very hard and thus provide the required wear resistance. Thus, in this example the gray cast iron would not meet the requirements for the jaws of a crusher and the white cast iron would not meet the requirements for the lathe housing.

# Steelmaking Practices and Their Influence on Properties

B. Mishra, Department of Metallurgical & Materials Engineering, Colorado School of Mines

## Introduction

THE MODERN PRACTICE of iron and steelmaking can be summarized by referring to the simplified flow diagrams shown in Fig. 1(a) and 1(b), which represent the sequence of steps for producing practically all steel products. Liquid iron, commonly referred to as pig iron, is produced in a blast furnace from iron ore, limestone, and coal (coke) (see Fig. 1(a)). Because it contains excessively high levels of silicon, manganese, carbon, and other elements, this liquid iron, together with scrap and fluxing agents, is then introduced into either a basic oxygen furnace or electric-arc furnace for further refining with oxygen that reduces the silicon, manganese, and carbon to acceptably low levels in the resulting steel. The steel is then tapped or poured into refractory-lined ladles. During this tapping operation, alloying elements that will determine the final chemistry of the steel are added to the ladle along with deoxidizing materials, which have a major influence on the final quality, formability, and cost. Following ladle treatment, which can also be supplemented by a remelting/refining step not indicated in Fig. 1(a), the steel is either cast into ingots or continuously cast. As shown on the lower right-hand portion of Fig. 1(a), ingots undergo a primary rolling step (ingot breakdown) before they are processed into semifinished shapes (blooms, billets, and slabs). Continuously cast steels require no primary rolling step. The semifinished products are then hot rolled. Some flat products are also cold rolled. Figure 1(b) presents the processes involved in converting the raw steel into the various mill-product forms.

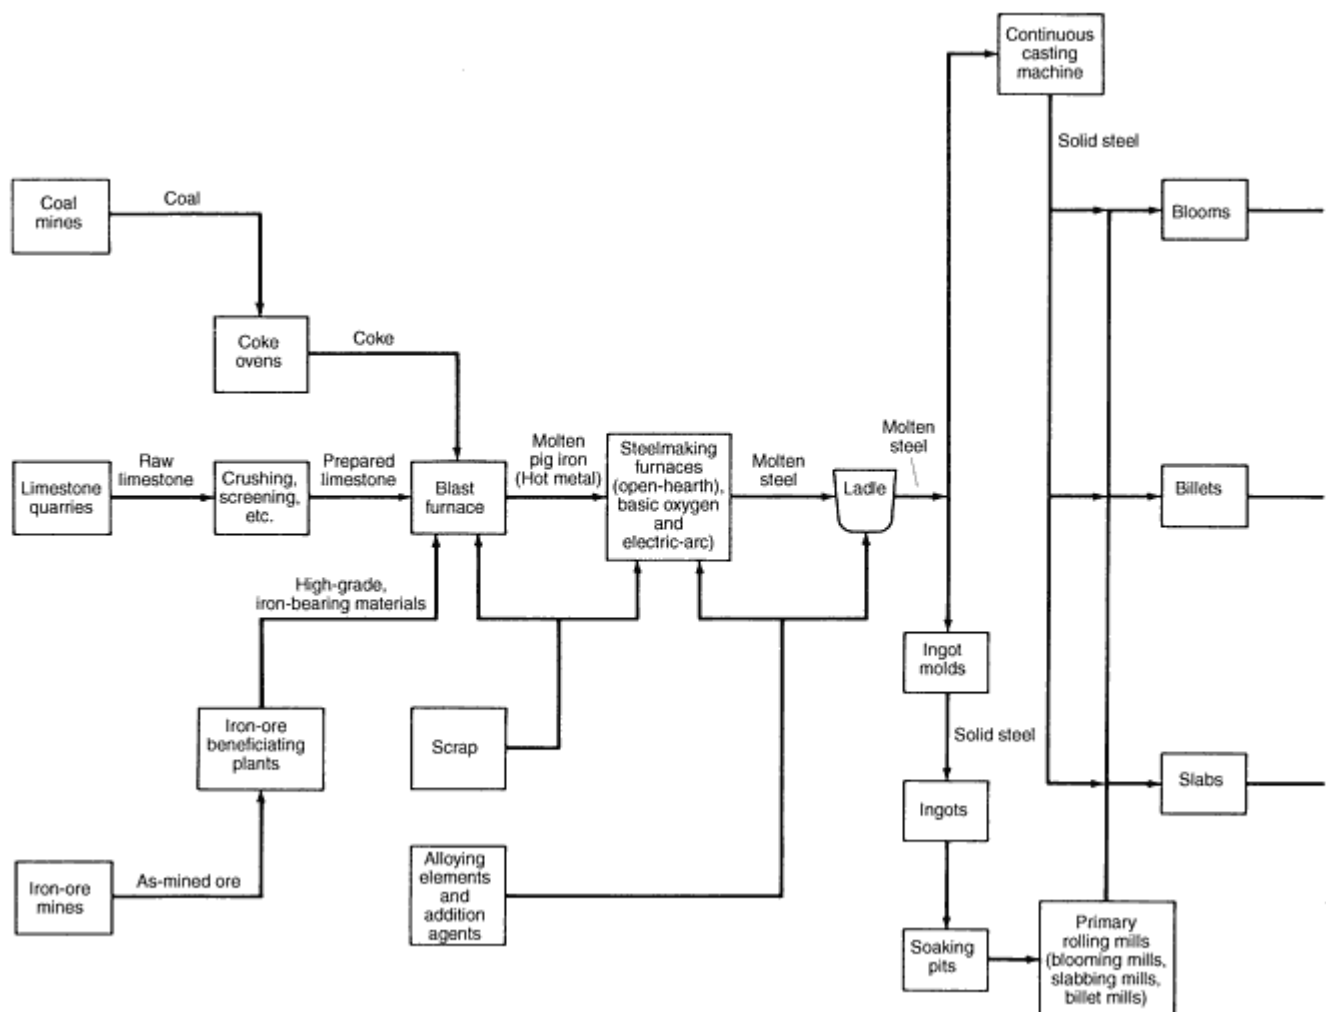

Fig. 1(a) Flow diagram for blast furnace production of pig iron and steel

## Ironmaking

### Physical Chemistry

**Raw Materials.** The modern practice of iron and steelmaking has evolved over seven centuries (Ref 1, 2, 3). The essential raw materials required for the present practice of pig iron production are iron ore, coal, limestone, and air. The important commercial forms of iron ore are hematite ( $\text{Fe}_2\text{O}_3$ ), magnetite ( $\text{Fe}_3\text{O}_4$ ), and limonite ( $\text{HFeO}_2$ ), and concentrating steps. Iron ore is also used in the partially reduced and fluxed form of sinter as well as agglomerated forms of briquettes and pellets.

A good quality coal to produce coke is characterized by low contents of ash (<15%), inert material, and sulfur and high content of fixed carbon (Ref 4). Coal carbonization is carried out in coke ovens to produce metallurgical coke, which is the solid fuel burned in air inside the ironmaking reactor to produce the primary reductant of carbon monoxide gas. The reduction of iron oxide in the blast furnace also partially occurs directly by carbon in the coke.

Limestone ( $\text{CaCO}_3$ ) and dolomite ( $(\text{Ca,Mg})\text{CO}_3$ ) are the common fluxes used in ironmaking. These carbonates are mostly calcined to affect the endothermic, pressure-sensitive decomposition reaction outside the blast furnace. The primary function of the flux is to combine with the gangue comprising silica and alumina in the ore, sulfur, and ash in the coke. Formation and separation of molten slag by this combination enables the production of liquid pig iron with controlled amounts of silicon, sulfur and manganese. The hot air used in the furnace at an average temperature of  $1200^\circ\text{C}$  ( $2190^\circ\text{F}$ )

and a pressurized flow rate of 70 m<sup>3</sup>/s (150,000 scfm) provides oxygen for burning the coke, supports the counter-current flow of gases in the reactor, and partially meets the heat requirements of a typical furnace.

The furnace is lined with alumina-silica bricks, and the hearth is made of carbon blocks. As stated earlier the product of the blast furnace is a liquid pig iron, which is used to produce steel by further refining. Liquid slag also collects in the bottom of the blast furnace over the liquid metal pool in the hearth, and a by-product gas with useful calorific value is collected from the top. The productivity of a blast furnace is measured in terms of the production of hot metal or pig iron per day per unit inside volume of the reactor. Typical productivity of an efficient blast furnace is in the range of 2 to 3 metric tons/m<sup>3</sup> per day.

**Chemical Reactions in the Blast Furnace.** The preparation of the descending burden essentially determines temperature-dependent reducibility. The temperature profile must be such that only sufficient heat is available at the appropriate locations for reduction and melting in the furnace. Premature formation and melting of slag causes irregular burden descent. The consumption of coke and flux and the heat loss with the off gas are minimized in the modern blast furnaces to improve the productivity. It can be readily seen that lower coke and flux rates provide higher volumes for iron units in the furnace.

In the blast-furnace stack (Fig. 2) there is countercurrent flow of gas and solids. As oxygen is transferred from solids to gas, heat transfer occurs from gas to solid (Ref 5). Carbon dioxide gas (CO<sub>2</sub>) is produced in front of the tuyeres where excess oxygen is available in the blast (reaction 1, Eq 1) but immediately converts to carbon monoxide (CO) by reaction 2 (Eq 2) due to thermodynamic equilibrium conditions. The temperature in front of the tuyeres, known as the raceway adiabatic flame temperature (RAFT), exceeds 2000 °C (3630 °F) when high exothermic heat is generated by carbon combustion. Principally, two types of gas-solid chemical reactions occur in the stack where coke is oxidized by CO<sub>2</sub> to produce CO gas and iron oxides are reduced by carbon monoxide in the presence of an excess carbon at a high temperature (Ref 6, 7, 8). These reactions are shown as follows:

Reaction 2 is also known as the "solution-loss" reaction as carbon is lost before it can reach the tuyeres. This endothermic reaction is promoted by increased temperature, decreased pressure, and a high ratio of CO<sub>2</sub> to CO. The reverse reaction catalyzed by iron or iron oxide occurs at lower temperatures causing deposition of carbon. The reduction of iron oxide by carbon monoxide can occur in three steps at temperatures over 600 °C (1110 °F), where Fe<sub>2</sub>O<sub>3</sub> successively reduces to Fe<sub>3</sub>O<sub>4</sub>, FeO, and finally iron. In addition to reducing the oxides of iron, carbon monoxide reduces the oxides of manganese, silicon, and phosphorus present in the gangue of the ore and ash of the coke:

Fig. 2 Schematic diagram of a blast furnace showing the gas reactions as a function of temperature

The distribution of manganese, silicon, phosphorus, and sulfur in the metal and slag primarily depend on the temperature and composition (basicity) of the slag and the furnace oxygen potential at the hearth. The hot metal is usually saturated with carbon. Blast furnaces offer little in terms of lowering phosphorus in the metal, but conditions are suitable for sulfur control. Silicon and manganese levels in the hot metal are usually dictated by the steelmaking practice.

The water vapor in the hot blast also plays an important role in the reduction, as hydrogen gas is produced by the reduction of water by carbon. Hydrogen gas serves as an efficient reductant, particularly at lower temperatures in the furnace:

It is the oxidation of carbon by the hot blast and some of the reduction reactions involving carbon monoxide that furnish the heat in the furnace to dry the charge, decompose the limestone, replace the heat losses, and provide the sensible heat of the hot metal, off gas, and slag.

**Slag Chemistry.** Slag is the fusible material formed by the chemical reaction of a flux with the gangue of an ore, with the ash from a fuel, or with the impurities oxidized during the refining of a metal. The compounds in a slag are formed by the neutralization reaction of basic and acidic oxides. In a blast furnace, the slag that forms first in the bosh zone (Fig. 2) is  $\text{FeO-CaO-Al}_2\text{O}_3\text{-SiO}_2$  type if fluxed sinter is used in the burden. The actual composition depends on the amount of gangue materials in the ore and the degree of gaseous reduction in the furnace. As this slag comes in contact with the coke, FeO is reduced, and the slag changes to  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-MgO}$  type. The final slag in the hearth is formed when the coke ash is taken into solution. The composition of the final slag comprising  $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-MgO-CaS-MnO}$  depends on the desired basicity and temperature of the slag, which in turn controls the partitioning of manganese, sulfur, and silicon in the hot metal. Typically, 40 wt% of silica and calcia are present with smaller quantities of magnesia, alumina, calcium sulfide, and manganese oxide. High-alumina refractory slags are undesirable, therefore, some removal of alumina is practiced during beneficiation of the iron ore.

There are two main considerations concerning the slag in the blast furnace. One is to have a slag that will be molten at the hearth temperatures and will not hinder the free descent of the burden in the furnace; the other is to control the

composition of the iron from the furnace, particularly in respect to silicon and sulfur. Oxygen potential, temperature, and basicity are factors that determine the ability of the slag to control the hot metal sulfur, manganese, and silicon levels.

**Physical Condition of the Reactor.** The blast furnace may be structurally divided into three zones. The highest temperatures ( $>2000\text{ }^{\circ}\text{C}$ , or  $3630\text{ }^{\circ}\text{F}$ ) are attained in the hearth immediately in front of the tuyeres. Temperatures fall steeply (to  $1600\text{ }^{\circ}\text{C}$ , or  $2910\text{ }^{\circ}\text{F}$ ) on the same horizontal plane closer to the furnace center line. The inverted, truncated-cone section is the bosh, and above this is the stack (see Fig. 2). Temperature falls uniformly to  $\sim 1100\text{ }^{\circ}\text{C}$  ( $2010\text{ }^{\circ}\text{F}$ ) at the top of the bosh and to  $\sim 800\text{ }^{\circ}\text{C}$  ( $1470\text{ }^{\circ}\text{F}$ ) midway up the stack. A temperature of  $\sim 250\text{ }^{\circ}\text{C}$  ( $480\text{ }^{\circ}\text{F}$ ) is attained at the top of the furnace. The oxygen in the air blast is entirely consumed by reaction with the coke charge within a small radius of the tuyeres outside which  $\text{CO}_2$  reacts with more coke to form carbon monoxide. At temperatures  $>1000\text{ }^{\circ}\text{C}$  ( $1830\text{ }^{\circ}\text{F}$ ), the concentration of  $\text{CO}_2$  is negligible and the total pressure of carbonaceous gases is equal to the partial pressure of carbon monoxide. Between the temperatures of  $400$  and  $1000\text{ }^{\circ}\text{C}$  ( $750$  and  $1830\text{ }^{\circ}\text{F}$ ), the partial pressures of both the gases are significant. The total gas pressure is usually close to atmospheric at the top of the stack and between  $1.3$  to  $1.5\text{ atm}$  at the tuyere level consisting of  $\sim 60\text{ vol\%}$  of  $\text{N}_2$ . The temperature conditions and the  $\text{CO-CO}_2$  balance determines the oxygen potential at any location within the blast furnace. The ability and rate of the furnace to reduce the iron ore depends on the temperature, diffusion of oxygen, amount of volume change upon reduction, availability of hydrogen, onset of slag formation, reduction with solid carbon, presence of gangue, and the use of prereduced sinter material. The top gas analysis in terms of  $\text{CO/CO}_2$  ratio is a good indicator of blast furnace performance in addition to the temperature and compositions of the hot metal and slag produced.

### ***Composition of Pig Iron***

**Charge Balance.** The primary impurities in molten pig iron or hot metal are carbon, sulfur, manganese, silicon, and phosphorus. While manganese, silicon, and phosphorus are present in the ore as oxides, carbon and sulfur are in the coke of the burden. Silica is also present in the ash of the coke. A typical hot metal has  $1.0$  to  $2.0\%$  Si (determined by the blast furnace operating conditions, slag chemistry, and the steelmaking heat requirements),  $0.1$  to  $0.5\%$  P,  $0.04$  to  $0.07\%$  S,  $0.75$  to  $1.25\%$  Mn, and up to  $4.5\%$  C. Carbon is usually dissolved in molten iron close to the solubility limit at the temperature. Carbon is insoluble in slag. Phosphorus oxide is reduced, and phosphorus is dissolved in molten iron. Blast furnace slags are not suitable for removing phosphorus. Sulfur is mostly transferred to the slag as calcium sulfide. A reducing furnace condition, high temperature, and high slag basicity ( $\text{CaO/SiO}_2$ ) are conditions that favor sulfur transfer to the slag (Ref 9). Therefore, good desulfurization cannot be achieved during steelmaking as the conditions are highly oxidizing (see the section on steelmaking).

Oxygen potential in the system affects the distribution of all the elements that partition themselves between the metal and the slag. Oxygen potentials favorable for sulfur control in hot metal are unsuitable for silicon and manganese removal. For a given carbon activity and carbon monoxide partial pressure in the hearth zone, an increase in temperature helps increase the partitioning of manganese, silicon, and sulfur. The activity of various oxides in the slag and the activity coefficient of different solutes in molten iron are important factors in determining the distribution of impurities in pig iron. Empirical relationships have been established between the slag composition and the activity of oxide components (Ref 10, 11, 12, 13) as well as the sulfide capacity of the slag (Ref 14). An increase in lime and magnesia content of slag increases the sulfide capacity. Higher partitioning of sulfur in the blast furnace is also encouraged by a higher carbon activity in the hot metal. If a low-silicon, low-sulfur hot metal is desired, a pretreatment of hot metal becomes necessary prior to steelmaking (see the section "Hot Metal Pretreatment" ). Use of a low-ash, low-sulfur coke is also desired for making low-sulfur pig iron. Other important solutes that partition between the slag and metal are chromium and titanium. These metals are present as oxides in some ore bodies used for ironmaking. Normally  $\sim 50$  to  $60\%$  of the chromium is reduced into the hot metal. Titanium oxide is reduced to titanium carbide and carbonitrides. Sometimes titania-bearing ore is charged in the furnace to protect the hearth from eroding by making the slag and metal viscous.

### ***Advances in Blast Furnace Technology***

Significant improvements have been made over the last forty years in blast furnace productivity in terms of hot metal produced per unit volume of the furnace and the amount of fuel used. These improvements are the result of several advancements. Use of high-strength, super-fluxed sinters permitting the use of higher flame temperatures, coal washing, and blending to lower ash and sulfur; stamp (compression) charging for carbonization and uniform sizing of coke for higher coke strength and furnace permeability; and charging sequence optimization for proper distribution of burden using movable throat armors are some of the developments in charged material management.

High hot-blast temperatures of 1250 °C (2280 °F) are now commonly used in several blast furnaces around the world, which has a direct bearing on the coke rate of the furnace. The ability to use high blast temperatures and the need to control the flame temperature has allowed the use of hydrocarbon fuel injection. This development enhances the reducing power of the bosh gas and in turn lowers the coke rate. Natural gas, coke-oven gas, oil, tar and pulverized coal, or oil-coal slurry have all been effectively used as a fuel supplement to the blast furnace. The discovery of methods to control the flame temperature also allows the enrichment of blast air with oxygen. A 1% increase of oxygen typically improves the furnace productivity by 2 to 4% depending on the burden reducibility.

High top-pressure capability has allowed the use of higher wind rates to the furnace without causing burden lifting. There is a corresponding increase in the production rate when the gas inside the furnace is compressed. Approximately 205 MPa (30 psi) top pressures have been successfully used. The development has also necessitated improvements in the off-gas handling system.

### ***Hot Metal Pretreatment***

The blast furnace does not always produce a molten metal with desired compositional levels of sulfur, silicon, and phosphorus due to the fact that process conditions required for desirable partitioning of these elements between the slag and the metal are often conflicting. Higher levels of these solutes may be present in the hot metal due to higher gangue in the ore and/or high sulfur in the coke. Therefore, a pretreatment of the hot metal is carried out before the hot metal can be used for steelmaking. Pretreatment may be carried out at the blast furnace runner, hot-metal ladle, or the mixer because temperature of the metal is different at these three stages. The blast furnace runner also allows a large reaction area between the reagents and the hot metal. The silicon, sulfur, and phosphorus can be lowered by a basic refractory lining of the mixer and by forming a lime-rich oxide slag. An active mixer practice could thus be used by feeding a combined source of iron oxide and lime to the melt in the mixer, such as a fluxed sinter, a mixture of lime and mill scale, or lime and iron-ore fines.

Ladle desulfurization has become an important process step due to the demand for ultralow sulfur steels. Soda ash, calcium oxide, calcium carbide, or a mixture of these, is injected with air through a lance immersed in hot-metal ladles. Calcium serves as the desulfurizing agent producing calcium sulfide. Sulfur levels of 0.015 and 0.008% have been reported using lime or calcium carbide as the reagents, respectively (Ref 15). Use of lime-soda ash mixtures is the most economic method where the kinetics of desulfurization can be enhanced mechanically.

### ***Alternative Sources of Iron***

**Direct-Reduced Iron.** The need to employ low-grade ores and types of fuel unsuitable for blast furnaces has been driving the search for alternative sources of iron. Processes that produce iron by reduction of iron ore below the melting point of the iron produced are generally classified as direct-reduction processes and the products are known as direct-reduced iron (DRI) or sponge iron. The processes that produce molten iron, similar to blast furnace hot metal, are classified as smelting-reduction processes. These processes usually split the solid-state reduction steps and the liquid melting and slagging steps into two separate reactors eliminating the need for high-strength prepared burden. Direct-reduced iron contributes 5 to 6% of the world's total ironmaking capacity with ~34 million metric tonnes of DRI produced annually in 1996. Direct-reduced iron is mostly used as a substitute for scrap in steelmaking. Availability of low-cost scrap and the high cost of electricity are deterrents for the use of DRI in industrialized nations, whereas countries endowed with inexpensive natural gas, non-coking coals, hydroelectric power, and access to suitable ore reserves prefer this alternative route to making iron.

Chemical reactions for making DRI are similar to those in the blast furnaces. When reduction is carried out below ~1000 °C (1830 °F) and H<sub>2</sub> gases are primary reductants (generated externally) and the product is porous. Metallic iron also absorbs some carbon to produce 1 to 2.5% iron carbide as cementite when gaseous reduction is carried out. When pure carbon monoxide is used to reduce dense Fe<sub>2</sub>O<sub>3</sub>, the reduction stops at ~40% at 700 °C (1290 °F) and at ~85% at 800 °C (1470 °F), but is completed at higher temperatures (Ref 16). Above 1000 °C (1830 °F), carbon reacts with moisture and CO<sub>2</sub> gas producing carbon monoxide and H<sub>2</sub>, thus renewing the reduction potential of the gas. Processes that produce DRI directly from solid coal without prior gasification of its fixed carbon use temperatures in excess of 1000 °C (1830 °F). In the case of iron oxide reduction with coal, the reactions between carbon and iron oxide particles begin only at the points of contact, but are disrupted once metallic iron is formed in the intermediate phase. Thereafter, the reduction can proceed only as a result of the diffusion of carbon atoms through the metallic iron layer to the residual oxide. Thus, in direct-reduction processes based on either solid or liquid reductants, it is essential to convert the reductant to a reducing gas.

A temperature of 1200 °C (2190 °F) is considered the upper limit for the direct-reduction processes, above which the metallic iron formed absorbs carbon resulting in fusing and melting of the solid. The direct-smelting processes thus operate with product temperatures >1300 °C (2370 °F), because carbon is absorbed rapidly and a liquid hot metal forms. Table 1 lists the gas-based and coal-based direct-reduction processes as well as the electricity and fuel-based, smelting-reduction processes. A complete description of all these recent developments can be found in Ref 17.

Source: Ref 17

The effectiveness of a direct-reduction process is measured through several indices. Percent total iron and percent metallic iron (including cementite) lead to the commercially used index of degree of metallization, which is the percent ratio of total weight of metallic iron to the total weight of iron in the product. The degree of metallization normally ranges between 90 and 95% depending on the reducibility of the original iron oxide and the process chosen. Percent reduction is a measure of the amount of oxygen removed during reduction. The amount of gangue in DRI, the level of sulfur (particularly for coal-based DRI), and the amount of fines affect the productivity of the steelmaking reactor where DRI is used.

Both moving- and static-bed shaft furnaces, as well as fluidized-bed processes, are used for making DRI using externally generated reducing gases. Usually a kiln-type furnace, a rotary hearth, or a retort furnace is used when coal is directly used as the fuel in DRI manufacturing. In all coal-based direct-reduction processes, sized ore and a coarse fraction of noncoking coal are fed into the rotary kiln from the inlet end in the required proportions. The growth of gas-based, direct-reduction processes is more favorable than the coal-based methods due to easier process control, higher availability of

reactor, better energy efficiency, lower sulfur, and higher carbon in the product. In addition, the productivity of a rotary kiln is between 0.3 to 0.5 metric tons/m<sup>3</sup> per day compared with over 2 metric tons/m<sup>3</sup> per day for a natural gas-based process.

**Smelting-reduction processes** that produce molten iron use low-shaft electric furnaces. A burden of agglomerated or lump ore, coal, or coke and limestone are directly charged into the furnace. The submerged-arc concept is used with Soderberg self-baking carbon electrodes. As an alternative to the electric-arc furnace, oxyfuel smelting systems are also used for smelting reduction. Flash smelting of the concentrate by coal and oxygen is accomplished in the first stage where close to 90% of the process energy is supplied. In the first stage, the ore is prereduced to FeO. In the second stage, the prereduced and heated material is further reduced mainly by direct reduction with carbon and then smelted. The COREX (or KR) process for smelting reduction conducts the blast furnace functions of preheating and gaseous reduction and smelting in two separate reactors (Fig. 3). Essentially, the process comprises a two-stage operation in which DRI from a shaft furnace is charged without cooling into a connected melter gasifier operating at 3 to 5 atm of pressure.

**Fig. 3** Schematic diagram of the COREX smelting-reduction process

Several plasma-arc reduction processes have also been developed to produce molten iron directly from unprepared burden. There are many processes for smelting reduction presently being developed through different stages of commercialization. Several of these rely on the recovery of calorific value of the exhaust process gas to make the technology viable. Although coking is not necessary, some processes are restricted by the ash and volatile contents of coal that can be used. Smelting-reduction processes have significant potential for the production of ferroalloys.

**Iron Carbide.** A promising alternative source of iron has been found in iron carbide, which is produced by the reduction of iron ore fines by hydrogen gas and subsequent carburization by carbon monoxide gas in a fluidized-bed reactor. The process produces iron carbide powder, which is hard, nonfriable, resistant to oxidation, and has the potential to replace DRI, scrap, or molten iron to produce steel at a lower cost. The process typically operates at a temperature of 600 °C (1110 °F) and pressure of 1.8 atm, producing a 7% C 93% Fe material. The reactions for the production of iron carbide from hematite or magnetite fine ore are:

The combined carbon in iron carbide forms a latent source of energy to the extent that a 1200 °C (2190 °F) preheated iron carbide can constitute 100% of the charge in oxygen steelmaking (Ref 18). Capital cost per annual ton of iron is about one-third that of blast-furnace, coke oven combinations and about one-half that of current DRI plants. Quality steel can be produced because iron carbide does not contain tramp elements and has no sulfur. Equations 9 and 10 indicate that water is the only by-product in iron carbide production.

## Steelmaking

In the previous section it was shown that the end product of ironmaking is molten iron produced through large capacity blast furnaces or sponge iron produced through smaller capacity direct- or indirect-reduction processes. Liquid steel is produced as the end product of steelmaking, which is subsequently cast as an ingot or continuously cast. The smelting-reduction or direct steelmaking processes under development will eliminate this sharp distinction, if successfully developed. Steelmaking can be broadly classified into two steps: primary steelmaking in a converter or furnace and secondary steelmaking in a ladle. Ordinary grades of steel may bypass the secondary steelmaking processes. The two most important steelmaking processes are the electric-arc furnace (EAF) process and the basic oxygen furnace (BOF) process or LD (Linz-Donawitz) process. The EAF process accounts for 35 to 40% of the world steel production and BOF produces 55 to 60% of steel. Some other processes, such as the open-hearth furnace, are still practiced in a few countries to produce special steels.

### Basic Oxygen Steelmaking (Ref 19)

**Charge Constituents.** Oxygen steelmaking uses gaseous oxygen as the primary agent for autothermic generation of heat as a result of the oxidation of dissolved impurities present in hot metal and scrap, such as carbon, silicon, manganese, sulfur and phosphorus, and to some extent, by oxidation of iron. Top blowing is the most common form of oxygen steelmaking, but bottom as well as combined blowing are process variations that are also practiced. In the top-blowing process, oxygen is blown at supersonic velocity with the help of a water-cooled lance inserted through the mouth of the vessel. The vessel is lined with basic refractories like tar-bonded dolomite or carbon magnesite. The charge consists of

steel scrap, hot metal, and flux--all charged through the mouth of the converter. While scrap is added as the source of iron units as well as a coolant, iron ore also provides a source of oxygen and is sometimes charged in the vessel. Lime is the primary flux for making slag but fluorspar and silica can also be added depending on the slag requirements. Typically 10 to 30% of the metallic charge is scrap, which helps control the heat generated by the exothermic oxidation reactions. The flux requirement and the slag volume produced strongly depends on the hot metal composition.

**Process Description.** Figure 4 shows a schematic diagram of a BOF. The converter is tilted approximately 30 to 40°, and the scrap is charged into the vessel using charging buckets. Scrap is usually screened and presorted for compositional consistency. Hot metal is then poured on the scrap. The vessel is then tilted back to an upright position for blowing oxygen. An oxygen lance is gradually lowered to a specified distance from the bath surface, and oxygen is started simultaneously. Within the first five minutes, all the lime is added through mechanized hoppers to flux the oxides of silicon, manganese, and iron. The limesilicate slag formed essentially contains  $\text{CaO}$ ,  $\text{SiO}_2$ ,  $\text{FeO}$ ,  $\text{MnO}$ , and  $\text{P}_2\text{O}_5$ . After specified periods the lance is gradually lowered to the lowest position where carbon is oxidized to carbon monoxide and carbon dioxide. Only ~10%  $\text{CO}_2$  is present in the top waste gas, which is collected through hoods placed on top of the vessel mouth during blowing. Total blowing time varies between 17 and 22 min, depending on the impurity content and the lance design. The lance is raised at the end of the blow. Steel is tapped into a ladle between 1650 and 1700 °C (3000 and 3090 °F) and the slag is removed by tilting the converter. Refractories require a preheat only when cold started for the first heat. Subsequent heats are produced on a continuous basis until the vessel is ready for a change of the refractory lining.

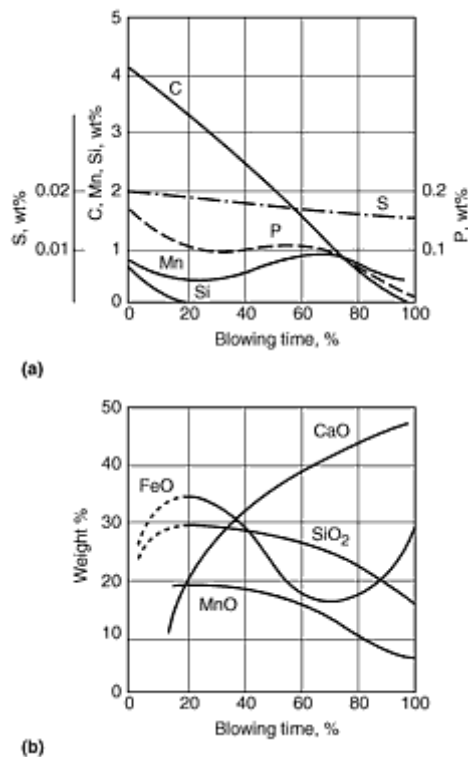

**Fig. 4** Schematic diagram of the basic oxygen furnace

The typical end-point composition of steel is 0.04-0.06 wt% C, termed "turn-down" carbon; 0.2 wt% Mn, and 0.02 wt% P and S, depending on the composition of the charge materials used. The generation of metal droplets due to the impact of the jet on the metal surface and the evolution of metal and slag composition during the progress of a blow, as well as the kinetics of gas-metal-slag interactions, are important process characteristics which determine the efficiency of the converter. The important gas-metal and gas-slag reactions during steelmaking are:

- Oxidation of dissolved impurities in iron such as carbon, silicon, manganese, and phosphorus by gaseous oxygen
- Reduction of  $\text{FeO}$  and  $\text{MnO}$  in the slag by rising  $\text{CO}/\text{CO}_2$  gas bubbles
- Dissolution of gases such as hydrogen and nitrogen in liquid steel

Figure 5 shows the evolution of bath composition and slag composition in a BOF converter. This figure shows that silicon is oxidized first within the first 3 to 4 min of the blow. However, transfer of sulfur, phosphorus, manganese, and carbon occurs over the entire blow period. As the blow progresses, lime ( $\text{CaO}$ ) gradually dissolves in the slag, and the mass of slag increases over blowing time due to lime and iron oxide dissolution. The temperature of the liquid metal gradually increases from an initial 1250 to 1400 °C (2280 to 2550 °F) to ~1600 to 1700 °C (2910 to 3090 °F) at the end of the blow.

**Fig. 5** Composition of (a) steel bath and (b) slag in a basic oxygen furnace converter as a function of blowing time

At the beginning of the blow, the distance of the lance tip from the bath surface is kept high, and after the formation of an initial slag rich in FeO and SiO<sub>2</sub>, the lance is lowered. The slag starts to foam by around one-third of the blow, and the FeO content of the slag begins to decrease. Beyond three-quarters of the blow, the decarburization rate falls and the FeO content of the slag continuously increases to accommodate most of the oxygen that is not used for carbon oxidation. Toward the end of the blow, the rate of increase of FeO in the slag depends primarily on the lance height and the carbon content of the metal and on the amount of undissolved lime and viscosity of the slag. It can be readily seen that a high level of FeO in the slag directly affects the converter productivity. The equilibrium oxygen activity in liquid steel at tapping temperatures is a function of the turn-down carbon content (Ref 20).

At the end of the blow and after the lance is withdrawn, a temperature measurement is taken with an immersion thermocouple and a chemical analysis is done on the bath sample within five minutes. If the bath is too hot, ore or limestone is added as a coolant. A short-period reblow may be necessary if the temperature is too low. Temperature in the BOF is controlled by using a thermally balanced charge of hot metal and scrap such that composition and temperature are achieved at turn down, as desired. The BOF end points are completely computer controlled.

**Process Capabilities.** The basic oxygen process is characterized by (1) use of gaseous oxygen as the sole refining agent, (2) a charge largely composed of molten-blast furnace iron, and (3) rapid chemical reactions in a low surface-to-volume bath, minimizing external heat losses. Basic oxygen furnace steelmaking is an autothermal process, which relies on the oxidation of impurities in hot metal, therefore, a certain amount of hot charge is essential. Important attributes of a tapped steel product are the levels of carbon, oxygen, and other gaseous impurities, as well as the temperature, which affect secondary steelmaking. Control of oxygen and carbon are related to the loss of iron as FeO in the slag, which is undesirable. High levels of silicon in the hot metal require higher amounts of lime for fluxing and lower the converter productivity because larger volume of the converter is occupied by the slag. On the other hand, if low-silicon hot metal is refined, addition of sand can be necessary to create the required volume of slag for refining reactions. Control of sulfur and phosphorus are important for steel properties. Thus, the capabilities of a BOF reactor in terms of productivity are limited by the hot metal composition, scrap rate, desired carbon level, and the finishing temperature.

### ***Electric-Arc Steelmaking (Ref 21)***

**Furnace Description.** The classical blast furnace/BOF integrated steel plants are giving way to modern establishments of EAF/continuous-caster minimill steel production route. For steelmaking purposes, three-phase, alternating current (ac) direct-arc and direct current (dc) direct-arc furnaces, as well as induction furnaces are commonly used. In three-phase, ac direct-arc processes, current is passed from one electrode down through an arc and the metal charge, then from the charge up through an arc to another electrode. In the dc direct-arc furnaces, current passes from one electrode through an arc and the metal charge to an electrode in the bottom of the furnace. Current is induced in the steel by an oscillating magnetic field in low-, medium-, or high-frequency induction furnaces. Indirect-arc furnaces use radiation heating to heat the charge where the arc is directly struck between the two electrodes. These furnaces are not common for steelmaking. Presently, high-alloy, stainless, bearing, and other high-quality steels as well as low-alloy and plain-carbon steels are produced in EAFs.

Figure 6 shows a schematic cross section of an EAF. Commercial EAFs are almost exclusively lined with basic refractories of burned magnesite or direct-bonded, chrome-magnesite bricks with roofs made of high alumina-bricks. All the ingot cast, continuous cast, and most of the foundry-grade steels are produced in basic-lined furnaces, which can melt highly alloyed steel scrap as well as plain-carbon scrap. Basic furnaces can produce steel from a wide range of scrap compositions with the added advantage of refining high-sulfur and high-phosphorus melts. The time required for working the heat due to faster oxidation and the loss of iron in the slag due to lower slag volume are lower in the acid process, which uses a siliceous slag.

**Fig. 6** Schematic cross section of a typical electric-arc furnace showing the application of different refractories

**Burden Preparation.** Segregation of scrap is an important function in burden preparation for electric furnaces. Grade-wise separation of scrap is done (1) to conserve the valuable alloy content of steel scrap, (2) to use virgin alloys economically, and (3) to ensure that only the desired alloying elements end up in the finished steel product. The segregation is usually done online by spark testing along with accurate chemical analysis using spectrography. Separation of scrap on the basis of size and bulk density is also performed to blend the charge properly. Exclusive use of light scrap (bundles, turnings, punchings, etc.) lowers the productivity by occupying a large volume in the furnace. Light scrap is also prone to oxidation. Light scrap as the initial charge can damage the hearth as the arc can bore through the metallic charge. A charge comprising all heavy scrap (ingots, butts, crops, etc.) is also not suitable as the roof and walls of the furnace are not shielded causing refractory damage. Essentially, the scrap charge is mixed for optimum melting, power utilization, and electrode consumption at minimum operating costs.

Direct-reduced iron can be used to partially or fully replace the scrap in an electric furnace charge. Often, DRI is preferred because it has a known uniform composition and contains no residual elements, such as copper, nickel, tin, or chromium. Direct-reduced iron also helps in the formation of a foamy slag due to the presence of carbon and iron oxide. Usually a 30% DRI and 70% scrap charge mix is used depending on the price of the two materials.

**Charging Sequence.** Electric-arc furnaces have removable roofs so scrap can be quickly and easily charged into the furnaces. The scrap is charged into the furnace using drop-bottom buckets. Large heavy scrap charges are loaded using magnets and placed slowly on the furnace bottom. Alloying materials which are difficult to oxidize, for example, copper, nickel, and molybdenum, can be charged prior to the melt down. Excess carbon is desired in the bath for meltdown, which is accomplished by oxygen injection or ore addition. If the carbon is low in the metallic charge, coke or scrap electrodes are used as recarburizers to allow ~0.20% higher carbon in the bath at melt down than is required in the finished steel. Oxygen injection is preferred for decarburization rather than mill scale or ore addition. If DRI is used as the metallic charge, it is added over the entire melt-down period through an opening in the furnace roof. Flux is added along with the metallic charge and placed away from the pitch of the electrodes as it is non-conducting.

**Process Description.** The process of making steel in the basic-lined EAF can be divided into (1) the melt-down period, (2) the oxidizing period, (3) the composition and temperature adjustment period, and (4) the tapping period.

Once the charging is complete, the electrodes are lowered to about an inch above the charge material and arcs are struck. Power and electrode consumption are highest during the melt-down period. Melting occurs by direct arcing as well as through radiation from the molten pool of metal collecting in the hearth. Burned or calcined lime as the flux is added toward the end of the melting of the first load of scrap charge.

The oxidizing period begins from the time the molten metal forms until the entire charge is in solution. During this period, phosphorus, silicon, manganese, carbon, and iron are oxidized. The sources of oxygen are the injected oxygen, furnace atmosphere, oxides of added alloying elements, and the ore, cinder, and mill scale added to the charge. The oxidizers are added in a controlled fashion to prevent excessive formation of carbon monoxide, which forces the slag to foam and spill out of the furnace. The bubbling action caused by carbon monoxide, called "carbon-boil," stirs the bath and makes it uniform in temperature and composition. Hydrogen and nitrogen are also lowered in the bath during carbon boil. Because electric-furnace steelmaking is not autothermal, that is, it relies on energy from the electric power used, the bath can be made hotter than a BOF. Thus, phosphorus reversal can occur if the slag is not highly basic.

Most carbon and low-alloy steel grades are made with a single-slag practice. The steel is finished by adjusting the composition and temperature to the desired value followed by tapping. The oxidizing period overlaps the adjustment period, and further lowering of sulfur and oxygen, if desired, is carried out in the ladles through secondary steelmaking.

In the double-slag practice to make high-quality carbon and alloy steels, the first oxidizing slag is removed from the furnace, and a reducing slag is prepared using burned lime, fluorspar, coke, and sand on top of the molten bath. Calcium carbide formed in the slags helps in desulfurization (see the section "Hot Metal Pretreatment" ); however, ladle treatment to lower sulfur is now preferred. The composition is controlled by the slag chemistry as in the BOF. A typical melt-down slag comprises 41% lime, 14% each of iron oxide and silica, 9% magnesia, 4% alumina, and 13% manganous oxide, besides small quantities of phosphorus oxide and sulfur.

The electrodes are raised to allow tilting of the furnace for tapping. Stream oxidation is prevented during tapping of steel into ladles. Slag is removed from the furnace before, during, or after steel tapping depending on the practice used. A "wet-heel" practice is often used where a small amount of liquid steel is left behind in the furnace for the next heat. This helps in lowering the slag carry-over to the ladle. Sophisticated slide-gate arrangements are used to prevent slag carryover.

The main advantage of the arc furnace lies in flexibility in accepting charge materials in any proportion, that is, scrap, molten iron, prerduced material, and pellets, although industrial practice is mostly restricted to scrap and DRI. The control of electric power can be well regulated to impart heat to the bath at different desired rates. This allows a precise control of refining reactions. Oxygen can be blown to speed up the melt-down refining processes. The EAF offers a wide range of possibilities in controlled production of ordinary as well as high-quality special steels. Alloy steels can be made directly with secondary treatments. The process is best suited for the production of higher alloy steel grades, such as tool steels and stainless steels, because of the inherent advantage of process control. Small-capacity EAF can be put into service, whereas small oxygen furnaces are usually uneconomical. Because EAF is primarily scrap based, and the impurity control in scrap is of utmost importance, elements like copper and nickel are hard to remove under the steelmaking conditions.

## ***Advances in Steelmaking Technology***

**Oxygen Bottom-Blowing Process.** The essential difference from the oxygen top-blowing process, or BOF, is that all of the required oxygen gas is introduced through the bottom of the vessel with the help of tuyeres (Fig. 7). Lime can be

injected in fine powder form along with oxygen to enhance the rate of dissolution of lime and the formation of a well-mixed homogeneous slag. The oxygen bottom-blowing process is also known as OBM, Q-BOP, or the LWS process depending on the type of tuyere design used for injecting oxygen. Natural gas or oil is used to shroud and protect the tuyeres from the intense heat of oxidation at the tip. The noise generated in bottom-blown processes as well as the turbulence in the bath are low compared with top-blown converters. Because bottom-blown processes operate more closely to the equilibrium conditions, the oxidation potential is much lower than top-blowing processes. This control of slag-metal equilibrium allows lower iron losses as FeO to the slag, higher manganese recoveries, less splashing (slopping) of the furnace, faster blow times, improved phosphorus and sulfur control, and lower dissolved oxygen and nitrogen contents. Bottom-blown converters have about ~2.0% higher yield. Easier process control is available in a Q-BOP as variability due to lance practice does not exist. Also, scrap rate in a bottom-blown process is lower along with a 10% lower oxygen rate than a top-blown process.

**Fig. 7 Schematic representation of a bottom-blowing process**

In general, less heat is produced in the bottom-blown oxygen steelmaking because less iron and manganese are oxidized for the same turn-down carbon level. Conversion of carbon to carbon dioxide is lower in bottom-blown converters and some of the heat is taken away by the hydrocarbon coolants used to protect the tuyeres. Thus, Q-BOP can melt about ~4% less scrap than a top-blown converter. Reproducibility of the thermochemical reactions is much higher in bottom blowing as the absence of an oxygen lance provides better control of the end point. Turned-down steel has slightly higher hydrogen due to the use of hydrocarbons. The levels of carbon, sulfur, and nitrogen in the steel and the amount of FeO in the slag are, however, less in the bottom-blowing process, compared with the top-blowing. Bottom-blown processes typically have a higher bottom-furnace erosion rate and decreased furnace availability due to high heat generation in the vicinity of the tuyeres.

**Combined-Blowing Process.** The advantages and limitations of bottom-blown processes over the top-blown classical BOF led to the development of combined-blowing processes where gases are blown both from the top and bottom of the converter, as shown in Fig. 8. Several patented schemes exist under this broad category of steelmaking, which are different only in the type and amount of gases blown from the top and bottom. Some processes also differ in the style of the tuyeres used, such as small uncooled tuyeres, cooled tuyeres, or permeable elements. Oxygen is typically blown through the top lance with either inert stirring gas (LD-KG, LD-AB, and LBE processes), inert oxidizing gas (LD-OTB, LD-STB, and BSC-BAP processes), or oxygen gas (LD-OB, K-BOP, and OBM processes), blowing through the bottom. Processes, such as Krupp-COIN, and KMS, which have the flexibility to operate on a 100% scrap charge, are also categorized as combined-blowing processes. These methods are characterized by the means employed for increasing the scrap melting rate using a post-combustion lance, scrap preheating, and/or carbon injection.

**Fig. 8** Schematic representation of a combined-blowing process

Processes that employ submerged-gas injection to increase bath agitation help increase decarburization efficiency while decreasing oxidation of the metals in the bath. These processes also reduce dissolved oxygen levels and flux consumption while allowing a higher manganese retention. Lower dissolved oxygen in combined blowing through permeable elements at any given carbon level with respect to top-blown processes allows better recovery of the alloying elements and decreases the need for deoxidizers in ladle metallurgy. Lower oxygen is the result of better mixing and near-equilibrium refining of steel in combined-blowing processes. Combined-blown processes have  $\sim 1.0\%$  higher yield due to less oxidation of iron and manganese and a lower slag rate. Lower oxidation of metallics result in a lower scrap rate for the process. Processes using cooled bottom tuyeres allow the injection of hydrocarbons, powdered lime, or coal to enhance the refining rate and scrap melting. Use of uncooled small tuyeres at the bottom using argon gas injection for stirring is limited due to the cost of argon and the clogging effects at high argon flow rates.

**Process Control.** Significant online computerized process control capabilities are available for steelmaking depending on the final product mix, decarburization reactions, metallurgical requirements of the plant, and the response time for corrective actions. Carbon removal rate, carbon level, and bath temperature can be continuously monitored. Some measurements use models that call for consistency in the shop practices and quality of materials used, as well as close adherence to the computer recommendations. Online process control results in improved control of carbon, sulfur, and phosphorus amounts and tapping temperature, decreased heat time, increased scrap rate and heat size, decreased flux, coolant, and oxygen consumption, and an overall improved quality of steel. Precise control of the end point carbon and the temperature eliminates time consuming and expensive reblow or cooling procedures.

The static-charge model prescribes the proper combination of the charge materials--hot metal, scrap, fluxes, and oxygen--required to meet the desired end point composition and temperature. Part of the calculations are completed in advance, and trimming calculations are done when the actual material balance is available. Calculations also occur during the heat to determine the reblow or cooling requirements to get to the desired end point. Dynamic procedures using in-blow measurements are used for precise control of 100% of the heats in combination with the static charge models. Water-cooled sub-lance systems to measure online carbon and temperature, off-gas analysis with continuous recomputing of carbon level, and sonic analysis for carbon level through sound intensity are some of the methods practiced industrially. Immersion thermocouples usually provide the direct temperature measurement.

## ***Refractories in Iron and Steelmaking***

Refractories are the primary materials used by the steel industry in the internal linings of furnaces for making iron and steel, such as blast furnaces, BOF, EAF, etc., and in ladles and tundishes for holding and transporting metals and slags. Thus, the refractories are often required to withstand temperatures in excess of  $1700^\circ\text{C}$  ( $3090^\circ\text{F}$ ). Refractories affect the quality of the product as well as the energy consumption in iron and steelmaking. Refractories are chosen on the basis of service life and cost.

**Basic Refractories.** The most important group of refractories for the basic steelmaking processes are magnesite-based and are either natural or synthetic magnesite, brucite, and dolomite. Dense synthetic magnesia is produced from sea water and has a purity of 95 to 99%  $\text{MgO}$ . Natural magnesite is present as a hydroxide or a carbonate. The double carbonate of dolomite ( $\text{CaCO}_3 \cdot \text{MgCO}_3$ ), is found in abundance. High-temperature calcining (firing in kilns to dissociate the

carbonates) is required in all the cases to produce a dense material with minimum impurities. Magnesite-chrome refractory spinels are also commonly used without firing in combination with magnesite refractory.

**Acid Refractories.** The siliceous group of refractories that fall under the "acid" class of materials are beneficiated from quartzite, sandstone, or zircon-type raw materials. Electrical fusion is used to produce special-purpose refractories of fused silica or stabilized zirconia. Several types of fireclays, hydrated aluminosilicates, and kaolin firebricks are usually used for low-temperature refractory needs. The plasticity of fireclays allows it to be used for sealants and grouts.

**Other Refractories.** Alumina refractory bricks, as high-alumina silicates or pure sintered alumina, are common for high-temperature refractory applications. Carbon bricks and blocks made from petroleum coke, foundry coke, or anthracite coal are extensively used as furnace hearth lining. Silicon carbide and silicon nitride refractories, produced by firing coke and silica mixtures at high temperature, are used in pure form as well as in combination with other refractory materials.

In general, refractories are required to withstand a wide range of temperature and sudden changes in temperature to accommodate the thermal shock. Resistance to small compressive stresses, abrasive forces, corrosive actions of molten metal, slag, and process and effluent gases is required. In addition, refractories are required to function as an insulator, heat absorber, or a heat conductor depending on the application. Chemical and physical characteristics of iron and steelmaking refractories, as well as the selection of lining materials for different reactors, have been discussed elsewhere (Ref 22).

### ***Fluxes in Iron and Steelmaking***

The function of fluxes in iron and steelmaking is twofold: (1) to render the high melting refractory oxide impurities or gangue fusible and separable from the molten metal, and (2) to provide a medium with which the impurity elements or compounds would combine in preference to the metal. Practically all of the slag-forming compounds that enter a smelter or refiner can be classified as basic or acid. Silica is the only substance used as a strictly acid flux, although in slags phosphorus oxide behaves in a strongly acidic manner. Neutral fluxes are sometimes added to improve the fluidity or to lower the melting point of the slag for better reaction kinetics and slag handling. Ores contain both acidic and basic oxide impurities with the acidic component predominating. Amphoteric oxides, such as alumina and titania, have a basic or an acidic nature, depending on the slag condition. In acid steelmaking processes, silica is often picked up from the furnace lining itself. In basic processes, such as BOF or EAF, silica is added when excess lime or insufficient silica is present in the system.

Primary basic fluxes are either limestone ( $\text{CaCO}_3$ ) or dolomite ( $(\text{Ca, Mg})\text{CO}_3$ ) and either or both can be used as a blast-furnace flux, depending on the other slag constituents present and the required ability of the slag to remove sulfur. Limestone is preferred for large sulfur removal. The basic oxygen steelmaking process uses burned or calcined lime or burned dolomite to flux silica produced by silicon oxidation. The presence of magnesite in the slag helps protect the magnesite brick lining of the furnace. Limestone and dolomite are precalcined or burned outside the steelmaking vessel, because dissociation of these compounds is endothermic, and an extra heat load on an autothermal process is not desired. Burned lime contains >95%  $\text{CaO}$ , and the calcined dolomite is comprised of >57%  $\text{CaO}$  and >40%  $\text{MgO}$ . Fluorspar or calcium fluoride with >50%  $\text{CaF}_2$  is used in steelmaking as a more efficient desulfurizer. Quality and quantity of fluxes in iron and steelmaking are important as they occupy a useful volume in the reactors and influence productivity.

### **Secondary Steelmaking**

## Ladle Metallurgy

Secondary steelmakings, or ladle metallurgy, is performed to produce clean steel. Clean steels satisfy stringent requirements of surface, internal, and microcleanliness quality and of mechanical properties. The secondary step of ladle metallurgy follows the primary refining in a converter or an EAF, as described in the previous section. Ladle metallurgy has become a routine part of steelmaking due to the growing stringent requirements on the steel composition. Ladle metallurgy is used for deoxidation, decarburization, and adjustment of chemical composition including gases. Refining times in the furnace can often be shortened and production rates increased with an efficient secondary steelmaking practice. Ladle metallurgy also allows the control of teeming temperature, especially required for continuous casting. Steels with as low as 0.002 wt% S can be produced free of oxide or sulfide inclusions. Inclusion shape control is also performed in ladles to improve mechanical properties.

**Deoxidation and Alloying.** Steels are required to meet certain temperature and chemical requirements for proper ladle metallurgy. Toward the end of tapping some amount of furnace slag is carried over into the ladle. Deoxidation and alloying additions can be made during tapping. Intense agitation of the bath caused by the falling stream of liquid metal helps in alloy dissolution, deoxidation, and homogenization. Loss of deoxidizing elements added, such as aluminum and silicon, depends on the amount and composition of the carried-over slag (Ref 23). The loss of deoxidants is minimized as they are expensive, and the entrapment of deoxidation products adversely affects steel cleanliness. Typically, a deoxidant, such as aluminum, would be partly oxidized by the furnace slag and the entrained air. Aluminum is also dissolved in steel depending on the existing equilibrium condition. The primary role of aluminum as a deoxidant is to react with the dissolved oxygen and float up as alumina. However, some of the finer alumina particles are retained in the steel as inclusions. Making low-inclusion steels requires further treatment to float the fine oxide particles. Slag carry-over is minimized to control the hydrogen and nitrogen pick up by the steel as well as the phosphorus reversal due to reduction of  $P_2O_5$  by deoxidizing agents. Several types of devices are available as slag stoppers.

**Argon Rinsing and Vacuum Treatment.** Stirring treatment with argon gas, also known as online argon rinsing, can be done to homogenize the bath and to promote decarburization by lowering the carbon monoxide partial pressure. Argon rinsing also helps in lowering the nitrogen and hydrogen content, as well as enhancing alloy dissolution and slag-metal reactions due to stirring effects. Exchange treatments with synthetic (low FeO) slags (Ref 24) or conditioned (high CaO) slags (Ref 25) can be carried out during or before tapping followed by argon rinsing to promote deoxidation, desulfurization, and inclusion modification. Methods for argon rinsing are shown schematically in Fig. 9. Although a stopper-rod arrangement is shown in Fig. 9 for teeming the ladle, use of slide-gate systems are more prevalent now.

**Fig. 9** Schematic illustrating methods for using the argon-stirring process. (a) The lance method. (b) The porous-plug method

Vacuum treatment is done to facilitate degassing and enhance the kinetics of deoxidation and decarburization. Alloy additions can also be made during the vacuum treatment. Alloy additions susceptible to oxidation, for example, iron-niobium, are added after deoxidation. The recovery of expensive alloys is improved by ensuring complete dissolution. Injection treatment in ladles with inert gas, inert gas-oxygen mixtures, or pure oxygen is practiced. Injection of powdered agents of CaSi,  $CaC_2$ , CaAl, rare earths, and magnesium with an inert gas carrier, or of submerged cored wire with a prior synthetic slag treatment allows for simultaneous deoxidation, desulfurization, and sulfide shape control. If ultra-low

carbon steel grades are to be produced, deoxidation is usually not performed at the time of tapping since dissolved oxygen is later required to react with carbon.

Accurate assessment of temperature, chemical composition, and quantity of steel in the ladle must be known for efficient secondary processes. The use of high-quality refractories in the liquid steel handling facilities are desirable to achieve lower oxygen activity when steel is contained in ladles or tundishes. Ladle preheating and temperature control is an integral part of secondary steelmaking as ladles essentially act as heat sinks.

**Synthetic Slags.** Ladle refining to produce ultraclean steels and efficient desulfurization are achieved when steel is treated under a basic, nonoxidizing slag. These synthetic slags have low oxygen potential, low melting point, moderate fluidity, and high solubility for alumina and sulfur.

### ***Processes and Objectives***

Secondary steelmaking processes define the ways in which the liquid steel is handled in order to achieve the objectives. Table 2 lists the primary methods and equipment used for ladle treatment and their relative capabilities. These methods can be categorized under four major groups (Fig. 10): stirring, injection, vacuum, and heating processes (Ref 26, 27).

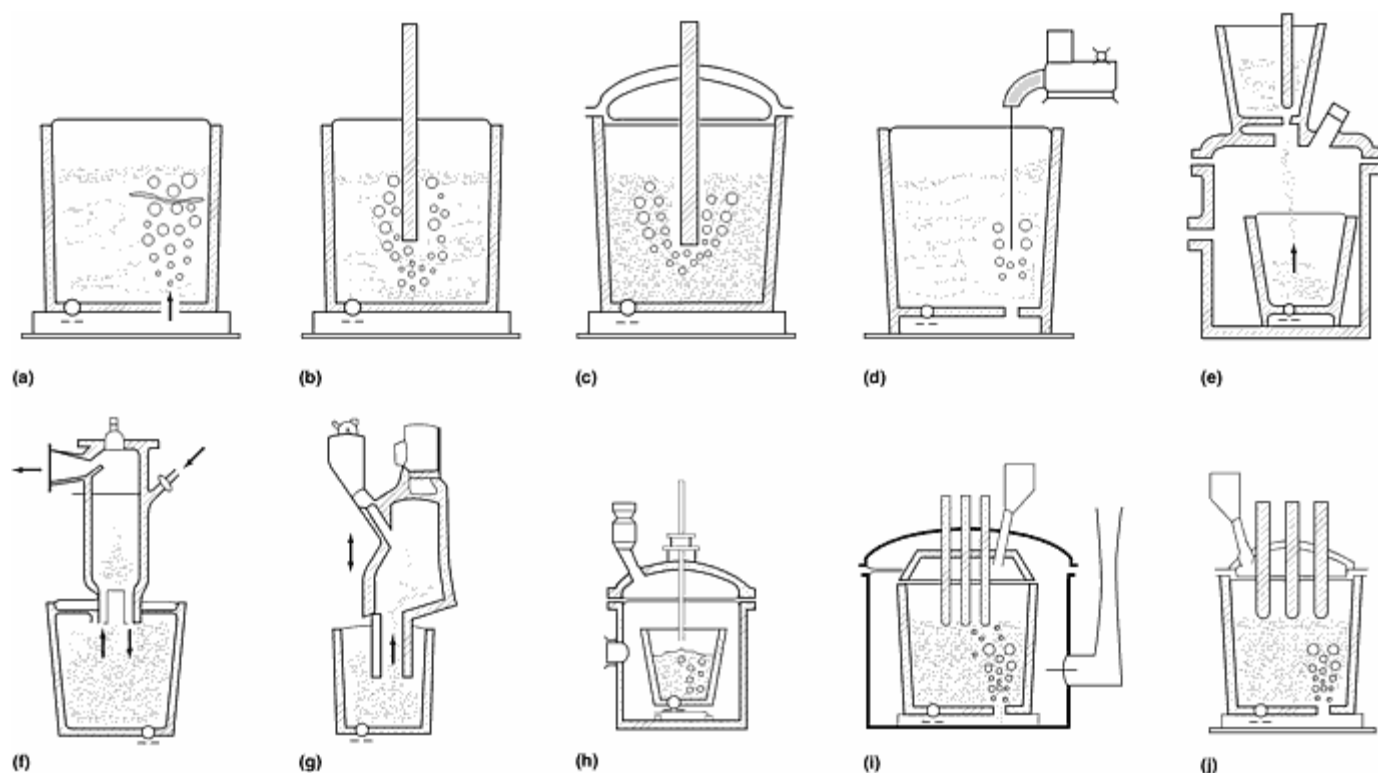

**Table 2 Relative efficiency of secondary steelmaking processes**

0, none; 1, good; 2, better; 3, best

Steelmaking processes	Metallurgical functions							
	Composition control	Temperature control	Deoxidation (O <sub>2</sub> )	Degassing (H <sub>2</sub> )	Decarburization	Desulfurization	Microcleanliness	Inclusion morphology
Stream degassing	1	0	1	3	1	0	1	0

**Fig. 10** Processes for secondary steelmaking. Stirring process: (a) bottom injection and (b) lance injection. Injection processes: (c) powder injection and (d) wire feeding. Vacuum processes: (e) stream degassing, (f) R-H degassing, and (g) D-H degassing. Heating processes: (h) VOD process, (i) VAD process, and (j) ladle furnace process

Stirring is simple purging or rinsing of liquid steel by inert argon gas passed either through a porous plug or a submerged lance (Fig. 9) to achieve bath homogenization and oxide flotation. Deoxidation and desulfurization by enhancing slag-metal reactions can also be achieved by argon purging if a synthetic slag is used. Alloy additions or deoxidation reagents are introduced either in a powder form through a submerged lance with the help of a carrier gas or by encasing the materials in a wire by injection metallurgy. Vacuum processes are designed to reduce the partial pressure of hydrogen, nitrogen, and carbon monoxide gas in the ambient atmosphere to enable degassing, decarburization, and deoxidation. Vacuum treatments can be broadly classified into vacuum stream degassing, ladle degassing, and recirculation degassing (Table 2 and Fig. 10). The loss in temperature during secondary treatment is compensated by either using a higher superheat in the primary steelmaking or by an additional reheating process, such as the ladle furnace with submerged electrodes. Vacuum-induction melting or vacuum-oxygen degassing are other examples of heating processes. Some of the prominent processes are described in greater detail later in this section and in the section "Processing of Special-Quality Steels."

## Treatments

**Degassing.** Liquid steel absorbs gases from the atmosphere and from the materials used in steelmaking and can cause embrittlement, voids, inclusions, etc., in the steel when solidified. The major gases to be eliminated are oxygen, hydrogen, and nitrogen. Oxygen is the principal refining agent in steelmaking and plays a role in determining the final composition and properties of steel and influences the consumption of deoxidizers. The production of rimmed, semikilled, or killed grades of steel essentially refers to oxygen management in liquid steel before solidification. If the oxygen content of molten steel is sufficiently high during vacuum degassing, the oxygen will react with some of the carbon to produce carbon monoxide. The evolved carbon monoxide is removed by the created vacuum, known as vacuum-carbon deoxidation. In undeoxidized steel, the carbon and oxygen contents approach equilibrium at a given temperature and pressure according to:

$$K_{1600\text{ }^{\circ}\text{C}}^{\text{eq}} = \frac{p_{\text{CO}} (\text{atm})}{\text{wt}\% \text{ C wt}\% \text{ O}} \quad (\text{Eq 12})$$

where  $K^{\text{eq}}$  is the thermodynamic equilibrium constant and  $p_{\text{CO}}$  is the partial pressure of carbon monoxide.

Figure 11 shows the contents of carbon and oxygen in equilibrium at 1600 °C (2910 °F) as a function of partial pressure of carbon monoxide. As the pressure is lowered by vacuum treatments, more and more carbon reacts with oxygen to establish the new carbon monoxide partial pressure, thus making the oxygen unavailable for inclusion formation with the added deoxidizers. Strong deoxidizers, such as aluminum, titanium and silicon, react with oxygen with greater affinity than carbon at atmospheric pressure (Fig. 12) so carbon cannot react with oxygen when vacuum degassed. If not floated properly, oxides of deoxidants can result in inclusions when solidified. Carbon is a stronger deoxidizer than aluminum, titanium, or silicon below a pressure of 0.01 atm.

**Fig. 11** Carbon-oxygen equilibrium relationship in liquid steel at 1600 °C (2910 °F) for various partial pressures of CO gas above liquid steel. If carbon and oxygen levels are at 0.04 and 0.05 wt%, respectively, at the start of vacuum treatment (region A), then enough oxygen is available to lower the carbon content to 0.01 wt% at  $p_{\text{CO}}$  of 0.01 atm. However, for carbon levels greater than 0.05 wt% (region B), an external oxygen source is necessary before vacuum treatment to raise the oxygen level to region O, if 0.01 wt% carbon is desired in the steel at  $p_{\text{CO}}$  of 0.01 atm. Note that regions A and B are above and below the CO gas stoichiometric line, respectively.

**Fig. 12** Equilibrium relationship between the contents of total oxygen and various deoxidizing elements in a steel bath

Hydrogen causes bleeding ingots, embrittlement, low ductility, thermal flaking, and blowholes. Hydrogen is usually picked up from the moisture in the charge and the environment and can be lowered by an effective vacuum treatment, according to Sievert's law:

$$[\% \text{H}] = K (p_{\text{H}_2})^{1/2} \quad (\text{Eq 13})$$

The amount of hydrogen dissolved in molten steel, [%H], is related to the partial pressure of hydrogen gas above molten steel,  $p_{H_2}$ . The equilibrium constant  $K$  is equal to 0.0027 at 1600 °C (2910 °F). Hydrogen removal during vacuum degassing is affected by factors such as surface area exposed to vacuum, degassing pressure, steel composition, extent of prior deoxidation, and hydrogen pickup from alloy additions, slags, and refractories.

Nitrogen is particularly harmful for low-carbon steels intended for drawing applications and should be lowered as much as possible. Although nitrogen follows Sievert's law, its removal by argon flushing or vacuum degassing is limited due to the tendency of nitrogen to form stable nitrides. Primary control of nitrogen is attempted during steelmaking practices.

**Decarburization.** It is difficult to produce steel by conventional steelmaking with <0.03% C. Carbon can be lowered to 0.01% from 0.04 to 0.06% levels by simply exposing it to a vacuum, as shown in Fig. 11. Particular attention must be paid to the amount of carbon in alloying additions made after decarburization of steel.

**Desulfurization.** It was mentioned previously that primary steelmaking has very limited capability in removing sulfur from steel due to the highly oxidizing conditions present. However, ladle processes do allow for external desulfurization by judicious selection of an agent.

Oxygen is a deterrent in sulfur removal and, therefore, should be pre-deoxidized to the lowest practicable oxygen content, preferably with aluminum. Simultaneous deoxidation and desulfurization is also commonly performed. Efficiency of desulfurization is lowered by the carry over of oxidizing furnace slags as the oxides are unstable during the sulfur removal treatment. In addition, FeO lowers the desulfurization efficiency. Similarly oxides in the ladle lining can affect the efficacy of sulfur removal. Because desulfurization involves slag-metal reactions, intimate mixing of steel and desulfurizing agents is a prerequisite. In addition to the previous requirements, the initial and final levels of sulfur are critical according to the law of mass action. Thus, steels with less than 0.006% S are difficult to make.

## ***Secondary Steelmaking Equipment***

Secondary steelmaking is usually performed in a ladle, vessel, or special furnace to achieve refinements that cannot be done in the primary reactor. A primary reactor is emptied into a tapping ladle, and then the steel can be transferred into other ladles, furnaces, or vessels for treatment. Alternatively, the steel can be treated in the tapping ladle before being poured into molds.

**Vacuum Degassing Processes.** The processes where liquid steel is exposed to a low-pressure environment to decrease gaseous content, particularly hydrogen and oxygen, are referred to as vacuum-degassing processes. The effectiveness of these methods is directly linked to the surface area of molten steel exposed. As described earlier, hydrogen removal is dependent on the partial pressure and diffusion, whereas oxygen removal primarily relies on the chemical reaction between carbon and oxygen and the partial pressure of carbon monoxide gas. These processes also accomplish composition and temperature control, decarburization, microcleanliness, and inclusion morphology control. Vacuum degassing is accomplished primarily by three methods: (1) stream degassing, (2) recirculation degassing, and (3) vacuum degassing in the ladle.

Because heat losses during degassing occur through radiation and absorption of heat by ladles or vacuum vessels, and because heat losses vary for different processes, tapping temperature of the steel must be adjusted for compensation of temperature losses. Ways of conserving heat during vacuum processing are the retention of a slag layer on the molten steel surface, use of radiation shields, vessel preheating, supplemental heating arrangements, and optimization of processing time. The vacuum in most modern degassing systems is created by steam ejectors installed in series to provide multistage pumping capability. A greater number of pumping stages are used for low-carbon steels in the partly deoxidized condition than for deoxidized high-carbon steels when treated at the same rate. A reheating type vacuum-induction melting process uses up to six stages, whereas a recirculating type R-H (Ruhrstahl-Heraeus) or D-H (Dortmund-Hörder-Hüttenunion) degasser uses five. A four-stage steam ejector is common for other vacuum degassing systems. Moreover, vacuum-degassing processes allow the addition of deoxidizers and alloy additions to the molten steel while under reduced pressure. These additions are optimized for the capability of the system to manage the heat and mixing.

**Stream degassing** methods include ladle-to-ladle, ladle-to-mold, and tap degassing. Ladle-to-ladle degassing achieves hydrogen removal as well as oxygen removal by carbon deoxidation. A preheated teeming ladle with either a slide-gate mechanism or a nozzle and stopper-rod arrangement is placed inside the tank, and the opening in the tank is covered with an aluminum disk. The tank is evacuated to 0.1 torr, and a superheated, partly deoxidized steel in the tapping ladle is placed on top of the evacuated tank. The stream of molten steel from the tapping ladle melts the aluminum disk cover and

flows into the teeming ladle while other deoxidants are added through the addition hopper under vacuum. The pressure stabilizes at  $\sim 0.8$  torr during degassing. Nitrogen is used to bring the system back to atmospheric pressure after degassing.

In the ladle-to-mold degassing, an ingot mold is placed on a base, fitted with hot top, and preheated using burners. The vacuum tank is placed around the base and makes a vacuum tight seal. A transfer or "pony" ladle, fitted with stopper rod and nozzle assembly, is placed in line with the mold inside the tank. A preheated refractory collar is fitted into an opening in the top of the tank to direct the pouring stream from the pony ladle nozzle into the mold. The tank is evacuated to 0.10 to 0.20 torr, and the tapping ladle containing the superheated steel is placed above the pony ladle for bottom pouring of steel. Once the pony ladle is two-thirds full, the stream of steel is allowed to enter the tank through the collar. The stream breaks up into tiny droplets after entering the vacuum chamber and attains a very large surface area enhancing the degassing process. Several tapped steel heats can be vacuum cast into large ingots by this method. Nitrogen or air is allowed into the tank to break the vacuum.

Tap degassing consists of a special ladle with a flange at the top and an "O"-ring seal plate for the nozzle opening at the bottom, a ladle cover, and a stoppered tundish having an aluminum-disk seal just below the nozzle. The nozzle is sealed, and the special ladle is covered with the lid. An alloy addition hopper is inserted through the ladle cover. The preheated stoppered tundish is placed on top of the ladle cover, and the entire assembly is positioned such that the tapping stream from the steelmaking furnace can be captured in the tundish. The ladle is evacuated to 0.2 to 0.5 torr, and the stopper rod of the tundish is pulled when the tundish is full with the superheated steel tapped from the furnace. The required deoxidizers are added through the hopper during degassing. After degassing, the ladle is restored to atmospheric pressure and teemed by conventional methods described in the section "Casting."

**Recirculating degassing** methods use atmospheric pressure to force the liquid steel from a ladle into an evacuated chamber where it is exposed to low pressure and then flows back into the ladle. The metal can recirculate 40 to 50 times to achieve degassing where the vacuum is used to recirculate the metal stream as well as to degas. A refractory-lined vacuum vessel with a "snorkel" tube, an electric-resistance graphite heating rod, an alloy addition hopper, a mechanism to lower or raise the vacuum vessel or ladle, and a steam-ejector system comprise the D-H degassing method (see Fig. 10g). The vacuum vessel is internally preheated to the desired temperature, and the alloying additions are placed in the hopper. The superheated steel is tapped in an unoxidized or partially oxidized condition in a ladle and placed beneath the vacuum vessel. Either the ladle or the vacuum vessel are moved vertically. The snorkel is immersed in the molten steel, and the vacuum vessel is evacuated, causing the steel to be sucked into the vessel. Once the steel is degassed, the snorkel is raised, causing the steel to partially run back into the ladle. The gases are sucked out of the vessel at this stage. Several cycles of this operation degasses the steel to the desired level. Alloy additions are subsequently made before the vacuum vessel is returned to atmospheric pressure. Some snorkels are designed to allow the passing stream of steel to be exposed to argon or oxygen.

Two legs or snorkels are used in the R-H process where one leg is fitted with a gas-inlet pipe (see Fig. 10f). The preheated vessel, similar in construction to the D-H degasser, is lowered in the molten steel ladle containing the superheated steel until  $\sim 150$  mm (6 in.) of both the legs are immersed. The vacuum chamber is evacuated, and an inert gas is introduced through the gas-inlet pipe and the lower density of the gas-liquid mix causes the steel to rise and flow into the vacuum vessel. The metal is deoxidized and returned to the ladle through the other leg under gravity. Several cycles of this process at a pressure of 0.3 to 0.6 torr degasses steel to the desired level before conventional casting. A variation of the R-H process, known as RH-OB process, is used primarily to remove hydrogen and carbon from steel. The difference between the R-H and the RH-OB processes lies in the gases injected into the system during the process of degassing. The RH-OB process also introduces oxygen, in addition to an inert gas into the system to enhance decarburization. Inert gas also helps in stirring the melt.

**Vacuum ladle degassing** processes include induction stirring and vacuum-oxygen decarburization (VOD). In the induction stirring process, induction coils are used to induce eddy currents in the molten steel to produce a stirring effect. Steel is contained in a ladle with shell sections made of nonmagnetic austenitic stainless steel and lined with high alumina or basic refractory. Superheated, fully deslagged, non-deoxidized steel is tapped at a relatively higher temperature than other vacuum degassing processes. The ladle is placed inside the induction coil positioned inside the vacuum chamber, a heat radiation and splash shield is placed on the vacuum tank, and the chamber is evacuated slowly to 0.1 torr. During degassing, the induction coils are energized to stir the steel. Alloy additions, primarily ferrosilicon, aluminum, and carbon, are added through a hopper towards the end of degassing. Stirring is continued for a few minutes to mix the alloys. After the vacuum tank is returned to atmospheric pressure, a synthetic slag is placed on top of the steel surface to conserve heat and prevent reoxidation.

The VOD method was designed for the production of stainless steel. A stainless steel heat is prepared by charging and melting ferrochromium, stainless steel scrap, ferrosilicon, burned lime, and fluorspar and then heating it to the tapping temperature. The stainless steel is tapped in a preheated basic-lined ladle equipped with porous plugs for blowing argon. The ladle is placed inside a vacuum chamber and evacuated to low pressures while oxygen is lanced above the steel bath and argon is bubbled through the bottom plugs in the ladle (see Fig. 10h). After the oxygen blowing period, further decarburization and deoxidation can be accomplished by additional vacuum time. Deoxidants could also be added during vacuum if desired. A desulfurizing slag can be added to the heat after the vacuum treatment, enabling the removal of up to 50% of initial sulfur. Argon blowing through bottom plugs can be replaced with induction stirring.

**Injection Metallurgy.** The primary objective of introducing powdered reagents into liquid steel, with the help of either a cored wire or carrier gas, is for desulfurization, deoxidation, alloy dissolution, and inclusion shape control. A wide variety of powders, mechanically mixed or premelted and granulated, are used in industry. Calcium silicide treatment is most prevalent for simultaneous sulfur and inclusion shape control. Lime, alumina, and fluorspar mixtures are also injected to form the synthetic slag. Alloy additions that are usually made through injection include, Fe-Si, CaCN<sub>2</sub>, graphite, NiO, MoO<sub>2</sub>, lead, tellurium, and ferroalloys of Fe-B, Fe-Ti, Fe-Zr, Fe-W, etc. Several commercial systems are available for powder injection through a lance as well as for cored-wire feeding.

When a powder is fed through the lance in the steel melt, particles are accelerated by the high velocity of the carrier gas upon entering the gas stream. For example, in gas-borne powdered injection with the help of a submerged lance, 0.6 to 1.0 mm (0.02 to 0.04 in.) Ca-Si particles are injected at a carrier gas pressure of 5 to 15 atm. At the lance tip, the gas expands as a result of a pressure drop and rise in temperature. In most steelmaking applications, jetting usually occurs during the injection, which is in the form of a gas-jet cone. On leaving the nozzle, the particles travel in a straight line downward due to their high momentum until the jet breaks up into a swarm of rising gas bubbles. The majority of the powder particles are trapped in the rising gas bubbles. If the powder particles are wetted by liquid steel, they can break away and be recirculated in the melt. A slag-metal-gas emulsion thus forms near the top surface. Wire feeding allows the introduction of additions at the bottom of the ladle and, therefore, a better alloy recovery. Injection metallurgy is also used for addition of deoxidants, such as aluminum, in the form of wire feeding as well as lance injection. The initial capital investment for a powder injection installation is much more than that for a wire feeder, but cored wires are more expensive than ordinary metal or alloy powders. Figures 10(c) and 10(d) show a schematic of the injection processes.

### ***Sulfur and Phosphorus Control***

It has been emphasized that the primary removal of sulfur is affected during ironmaking in the blast furnace where reducing conditions prevail. However, in steelmaking, direct oxidation at the gas-metal interface in the jet impact zone causes 15 to 25% of dissolved sulfur to directly oxidize into the gaseous phase due to the turbulent and oxidizing conditions existing in the impact zone. Regression equations based on operational data are employed to predict the end-point sulfur within acceptable limits (Ref 28):

$$(\%S)/[S] = 1.42B - 0.13 (\%FeO) + 0.89 \quad (\text{Eq 14})$$

where  $B$  is the slag basicity defined as the ratio of the weight percents of basic to acidic slag components. For example,  $(CaO + MgO)/(SiO_2 + Al_2O_3)$ ,  $(\%FeO)$ , and  $(\%S)$  are FeO and sulfur concentrations in the slag, respectively, and  $[S]$  is the sulfur concentration in the metal. Desulfurization and inclusion morphology control are accomplished through injection metallurgy in secondary steelmaking. In essence, a powdered reagent, such as Ca-Si, CaC<sub>2</sub>, magnesium, CaO+CaF<sub>2</sub>, or CaO+Al<sub>2</sub>O<sub>3</sub>, is introduced into the liquid steel with the help of a cored wire or a carrier gas. Desulfurization during powder injection with carrier gas has been described using a reactor model (Ref 29).

If the synthetic slag used in ladle metallurgy has a high sulfide capacity, sulfur removal can be accomplished to ultralow levels of 10 ppm sulfur. If the activity of alumina in the slag is low, then the deoxidation product alumina can then be absorbed in the top slag. Thus calcium aluminate type synthetic slags (typically 50 CaO:7 SiO<sub>2</sub>:43 Al<sub>2</sub>O<sub>3</sub>) can deoxidize and reduce total oxygen in the steel as well as desulfurize, simultaneously. Several empirical relationships have been developed to relate the slag composition to the sulfide capacity (Ref 30). Melting and mixing of slag is as important as composition. Premelted slags are commonly used. Vigorous argon stirring of the metal-slag emulsion is necessary for proper deoxidation and desulfurization. Top slag heating is also performed in practice to prevent a thermal gradient in the slag layer. Alternatively, an exothermic mixture of burned lime, hematite, and aluminum powder is used, which helps lower the sulfur content of steel to 0.003 wt% or less, when strongly stirred with argon.

The partitioning of phosphorus between the slag and metal is very sensitive to process conditions in steelmaking. An empirical relationship is used to define the phosphorus partitioning parameter,  $k_{ps}$  (Ref 31, 32):

$$k_{ps} = ((\%P_2O_5) \times (1 + (\%SiO_2)))/[\%P] = f((\%FeO), B) \quad (\text{Eq 15})$$

where  $B$  is the slag basicity,  $(\%P_2O_5)$ ,  $(\%SiO_2)$ , and  $(\%FeO)$  are the respective oxide contents in the slag,  $[\%P]$  is the level of phosphorus in the metal, and  $f$  is the function of  $FeO$  and  $B$ .  $k_{ps}$  is independent of basicity for  $B > 2.5$ . The distribution of phosphorus is also linked to the turn-down carbon level. In general, high basicity and low temperature favor dephosphorization. The addition of fluxes, for example, ilmenite, fluorspar, lime, etc., to lower slag viscosity, also helps to lower the metal phosphorus content. Phosphorus can be essentially captured in the slag during early stages of steelmaking through judicious adjustment of both the blowing practice and hot metal silicon level (Ref 33). Thus, phosphorus control in secondary steelmaking refers to the control of phosphorus reversal occurring through the use of synthetic slags, which is dependent on the activity of  $P_2O_5$  in the slag and the amount of aluminum and silicon in the metal. The Perrin process was developed for ladle dephosphorization using appropriate synthetic slags. It is important to do a slag-free tapping if synthetic slag-aided deoxidation with aluminum or silicon is carried out. The kinetics of deoxidation by aluminum in an argon-stirred vessel or a R-H degasser has been reported in literature (Ref 34).

### Inclusion Shape Control

If nonmetallic inclusions must remain in the steel, they should be made innocuous to the desired steel properties by changing their shape and/or composition. Steels can be made with more isotropic properties by changing the "stringer" sulfides to globular sulfides by a calcium compound or rare-earth metals treatment. Ladle injection technology, as described earlier, is an appropriate method for adding rare earths by the plunging method. The calcium treatment, primarily carried out for sulfur control, also has a modifying effect on inclusion morphology. A complete modification of type II manganese sulfide inclusions (Fig. 13) takes place when the sulfur content is  $<0.07\%$ . In practice, 0.5 to 0.7 kg per metric ton of steel is necessary for inclusion shape control (Ref 24). These reagents could be wire fed or powder injected. However, for wire feeding, recovery of calcium is three to six times greater than powder injection. Rare earth metals (REM) are very efficient in morphology control (stringer type to globular type), although they only have a minor role in desulfurization. Rare earth metal additions are usually accompanied by a magnesium addition to provide the agitation needed for uniformly distributing the REM throughout the heat.

Fig. 13 Schematic representation showing modification of inclusions which calcium treatment

### Effect of Residual Elements on Steel Properties

The removal or addition of specific elements in steel is governed by the desired steel properties. Residual solid, as well as gaseous elements in steel, such as sulfur, phosphorus, oxygen, nitrogen, and hydrogen, that are present due to thermodynamic and kinetic limitations in the primary and secondary steelmaking, are mostly undesirable and have a

pronounced effect on steel quality and properties. Except for specific grades of steel, a lowering of these elements is preferred. Other elements, such as carbon, silicon, and manganese can be controlled (lowered or raised) to the desired level. Other alloy additions, such as chromium, nickel, titanium, copper, etc., may be present as residuals from the scrap used in steelmaking or as intentional additions to manufacture special alloyed steels. The effect of these elements on the steel properties is briefly described.

**Carbon** is the primary element in steel that controls the microstructure for any given heat treatment condition either by interstitially dissolving in iron or by precipitating out as a carbide. Carbon is the most economical strengthening element for steel and is used as such. It can impart greater hardness with less accompanying brittleness than any other element in soft steels. Carbon decreases impact resistance of steels. However, it is desirable to keep the carbon content below certain maximum values when arc welding is involved to avoid embrittlement of the heat-affected zone. The choice of carbon level in steel is generally a strategic balance between the desired hardenability and weldability. There are other ways to control these two parameters besides carbon content.

**Sulfur** injures the rolling qualities of steel by "hot shortness," causing it to crack and tear during rolling and lessening its welding capacity. The harmful effects of sulfur increase with copper content and casting temperature and decrease with manganese content. Sulfur has beneficial effects on the machinability of steel by allowing chips to crumble rather than curl. The presence of sulfur in steel is mostly as elongated sulfide inclusions, which gives rise to anisotropic effects.

**Phosphorus.** "Cold shortness," or brittleness in the cold condition, is caused by high phosphorus contents and also gives rise to primary segregation tendencies during casting. This effect is enhanced in the presence of high-carbon content. Phosphorus can increase the strength of steel up to a certain extent, although is not used for this purpose due to other deleterious effects. Phosphorus, like sulfur, has a beneficial effect on free machining. Phosphorus is known to help prevent sticking during rolling of steel sheets. In association with copper, phosphorus is also known to improve atmospheric corrosion resistance of steels.

**Silicon.** High silicon content improves the magnetic permeability of steel and increases electrical resistivity. It improves the soundness of ingots and other castings because it opposes the formation of blowholes and gas cavities. Silicon has been found to slow down the etching rate of ferrite. Silicon helps in improving the atmospheric corrosion resistance of steels, particularly in acid environments. Silicon is known to affect some of the critical thermal points (transformation temperatures), such as  $Ac_1$ ,  $Ac_2$ ,  $Ar_1$ ,  $Ar_2$ , etc. (consult the iron-carbon phase diagram for definitions). In general, as silicon content increases, elongation decreases, and hardness, yield point, and tensile strength increase. Silicon can also lower the solubility of graphite in iron considerably.

**Nitrogen** has a strong strengthening effect and makes the steel brittle. It is used in moderate quantities in sheet steels to impart strength with good formability. Nitrogen promotes quench aging and strain aging in steels which manifest in increased hardness, yield, and tensile strength, reduced ductility, and increased notched impact transition temperature. Dynamic strain aging or "blue brittleness" can occur due to a high nitrogen level. Strong nitride formers, such as aluminum, are often used to prevent strain aging. In high-speed steels, carbonitride formers are used to enhance the abrasion resistance. Nitrogen is also a grain refiner. Vacuum melting of type 304L stainless steel can cause removal of nitrogen and, therefore, grain growth. Often these large grains are of the same order as the thickness of a thin-walled tube.

**Oxygen.** If present in large amounts, oxygen produces tearing during forging or rolling and makes the steel brittle under shock when cold. Oxygen also occurs in the form of iron and manganese oxides and silicate and aluminosilicate inclusions, which can impair notch toughness of steel if shape control is not employed. Aluminum oxide stringers are very detrimental to rolling contact fatigue resistance in bearing steels. These stringers are more likely to occur in continuous cast material where aluminum wire feeding is performed above the mold as the final deoxidation step. If inclusion removal is not adequate in the mold, aluminum oxide stringers form within the metal.

**Hydrogen** is present in steel as a dissolved gas or sometimes as dissolved methane or marsh gas. If not degassed properly, hydrogen has a definite embrittling effect and the steel shows a loss in ductility. The ductility can be regained by baking off the hydrogen at a moderate temperature. Hydrogen in excess of 0.005 wt% causes flaking, which is manifested as internal cracks or bursts, usually occurring during cooling from rolling or forging. Hydrogen pickup during welding is a problem for high-carbon, large-section steel pieces. Hydrogen is often associated with delayed brittle cracking of steels under sustained tensile stresses.

**Manganese** increases strength and improves notch toughness. The amount of manganese above that required to form manganese sulfide, is present as manganese carbide or silicide. Manganese sulfide inclusions upon rolling give rise to

"banded" structures. Manganese improves the forgeability or the ability to be rolled through its ability to tie up sulfur. Thus, manganese is the element that turns iron into steel and allows hot working and welding without tearing or hotshortness due to the presence of low-melting iron sulfide. Manganese is known to increase the impact strength of steel and retards the coarsening of grains during high-temperature rolling. Plasticity of steel is also reported to improve by higher manganese content, but the tendency to crack on quenching is enhanced. Manganese is also known to affect the thermal critical points for steels. Manganese is often substituted for carbon to improve the steel weldability. The presence of manganese is essential in steels.

**Other Elements.** Certain other residual elements, such as nickel, copper, molybdenum, chromium, and tin can be introduced in the steel through the scrap. Aluminum, vanadium, titanium, zirconium, etc., may be present from the deoxidation practice. These elements can also be intentionally added to the steel in varying amounts for achieving particular physical and mechanical properties, such as precipitation strengthening, solution strengthening, enhanced weldability, corrosion resistance, machinability, etc. For example, over 12 wt% Cr is added in steels to render it stainless (corrosion resistant), and nickel stabilizes austenite at room temperature allowing cold workability in 300 series of stainless steels. The effects of these alloying elements are discussed in the section "Specialized Processing Routes" and throughout this Handbook in the sections describing various types of steels.

In brief, nickel, chromium, molybdenum, and copper increase the hardenability of steels and can cause problems for steels requiring high ductility such as deep-drawing applications. These elements also change the heat treatment characteristics. Nickel can serve as a grain refiner and ferrite strengthener in larger quantities and also stabilizes the austenite. At cryogenic temperatures, nickel increases toughness, that is, lowers ductile-to-brittle transition temperature. Chromium generally forms carbides in steels and is known to increase the elastic limit, tensile strength, and hardness of steel while decreasing ductility. Chromium stabilizes martensite. It also has strong beneficial effects on corrosion resistance of steel, although chromium in excess of 12 wt% is required. Molybdenum allows the steel to be heated for forging through a wide range of temperatures without injury. Molybdenum in steels promotes resistance to impact and wear and imparts toughness.

Vanadium, even in very small quantities, increases the tensile strength and raises the elastic ratio without lowering the ductility appreciably. Vanadium increases impact resistance, fatigue strength, and resistance to abrasion. Vanadium prevents grain coarsening through stable carbide precipitation. Tin in small amounts is harmful to deep-drawing steels. Aluminum is generally desirable because it acts as a grain refiner and tends to decrease the susceptibility to strain aging. It, however, promotes graphitization and is harmful for high-temperature applications. Other deoxidizers, such as titanium or zirconium in trace quantities, are generally innocuous to steel properties. Some of the beneficial effects of these elements may require more than trace quantities and, therefore, have to be provided by alloying during secondary steelmaking. For example, titanium, niobium, zirconium, and vanadium may be used as microalloying additions to serve as precipitation hardeners by forming carbides.

## **Processing of Special-Quality Steels**

Some steels, such as bearing steels, heat-resistant steels, ultrahigh strength missile and aircraft steels, and rotor steels have higher quality requirements and tighter composition control than plain carbon or ordinary low-alloy steels. The production of special-quality steels requires vacuum-based induction or electric remelting and refining capabilities. Because longer durations are required for producing ultraclean steels and often require larger alloy additions, facilities to reheat the steel during secondary steelmaking operations are essential. These methods provide the following benefits:

- Contents of gases, for example, hydrogen, nitrogen and oxygen, are substantially reduced
- Cleanliness is improved, that is, there are fewer nonmetallic inclusions
- Center porosity and segregation in the ingot resulting from ingot casting the process are eliminated because of progressive melting and solidification of steel
- Hot workability of the metal is improved
- Mechanical properties of the remelted steel improves at room temperature as well as elevated temperatures, such as the ductility, impact, fatigue, and creep-rupture strengths

### ***Vacuum Induction Melting (VIM)***

Both channel and coreless type induction electric furnaces are used in the steel industry (Ref 35). In the remelting process, the charge material has basically the same chemical analysis as the final melt. No major refining or metallurgical work is performed other than lowering the residuals and inclusions. When remelting alloy steel, certain elements that readily vaporize or oxidize have to be added under controlled conditions. As a rule of thumb, alloying elements that oxidize should be added as late as possible, and difficult-to-dissolve elements should be added early and during high stirring periods. The furnace lining is dependent on the nature of the slag and the desired finish temperature. Vacuum melting is often employed as a remelting operation for very pure steels and as a first stage in a duplex refining operation in which the product from the vacuum induction furnace, for example, VIM, is remelted in either a vacuum consumable-electrode (vacuum-arc remelting, or VAR) furnace or an electroslog remelting (ESR) furnace. These processes are described in greater detail later in this section. Oxygen, hydrogen, and to some extent nitrogen, can be removed during vacuum melting. Carbon can also be lowered to produce some types of stainless steels. Pressures as low as 5  $\mu$ m of Hg are used in these furnaces. The control of pressure and composition of gas over the melt makes it possible to deoxidize the melt with carbon or hydrogen, because they produce gaseous deoxidation products, preventing the formation of nonmetallic inclusions. Use of low pressures also eliminates nitrogen pickup by steel. The volatility of certain alloying elements such as chromium, aluminum, and manganese can result in high losses that can be minimized by replacing the vacuum with an inert gas atmosphere over the melt during additions.

Modified vacuum induction equipment (such as the Therm-I-Vac process) can be used either as a vacuum induction melter under low pressure or as a stream degasser. The system can be used for cold charging of steel in the induction furnace, and melting, refining, and teeming of steel under low pressure. The steel could also be hot charged under low pressure in the vacuum furnace during which stream degassing occurs, reheated to compensate for the losses during degassing, adjusted for alloy additions to meet the chemical composition specifications, and teemed, all under low pressure. Superheating of steel is not required if hot charging is performed. The steel can be partly deoxidized before charging into the vacuum induction melter. This equipment is mostly used as a vacuum induction unit to melt a cold charge.

### ***Vacuum Degassing with Reheating***

Ladle refining furnaces allow the addition of heat to the secondary steelmaking process, which, in turn, allows larger alloy additions required for some special steels and stainless steels. The furnace's ability to provide heat during refining by arc reheating using electrodes provides the capability to desulfurize, deoxidize, and perform metallurgical operations using synthetic slags, as described in the section "Secondary Steelmaking." These furnaces can either reheat or reheat and vacuum degas. The plain heating furnaces can perform composition and temperature control, deoxidation, and facilitate

microcleanliness. If the furnace is also equipped to vacuum degas, it can additionally desulfurize the steel. Gas stirring or induction stirring is used in addition to arc reheating as a prominent process design variation. The Finkl-Mohr VAD degassing system uses gas stirring whereas the ASEA-SKF ladle refining furnace uses induction stirring. Gas stirring is designed for desulfurization and other steelmaking refinements including degassing. The process is similar to a ladle vacuum degassing method described in the subsection "Secondary Steelmaking Equipment," except that the steel can be heated before or after the degassing operation using an electric arc provided by electrodes inserted through the vacuum tank cover (Fig. 14). An inert gas is used to stir molten steel in the ladle degassing process.

**Fig. 14** Schematic arrangement of equipment used in the gas-stirring, arc-reheating process

When induction stirring is performed (ASEA-SKF process), the system comprises a ladle furnace, a mobile induction coil, a vacuum cover with exhaust line, a steam ejector system, and a cover fitted with three carbon electrodes. Sections of the vessel shell are produced from nonmagnetic austenitic stainless steel. The same ladle can be used to tap the heat from the converter and then serve as a heating furnace, vacuum vessel, and teeming ladle. The steel is tapped without superheat and without any deoxidant addition. Slag-free tapping is performed. The ladle is placed in the mobile induction coil and covered with the top containing the three electrodes. The arcs are struck to begin the reheating and refining period. Fluxes are added to prepare a basic slag, and alloy additions are made to meet the compositional specifications. Sulfur is reduced to below 0.005%. Heat loss is restored and the vessel is ready for degassing. The cover is replaced with the vacuum furnace cover, and the vessel is evacuated. Induction coils are energized to stir the steel. Aluminum and silicon are added toward the end of degassing. Following the degassing, the same ladle is moved to the teeming platform for ingot casting, or the steel is poured into a tundish for continuous casting (see the section "Casting" ).

### ***Vacuum-Arc Remelting***

Consumable-electrode melting under vacuum, or VAR, is the refining process used for special-quality steels and stainless steels that are first made by conventional steelmaking methods and subsequently cast or forged into electrodes for vacuum drip melting into a water-cooled copper mold under very low pressures of 0.1 torr. Because of the high arc temperature and the small pool of liquid metal, sound ingots with dense crystal structure, low hydrogen and oxygen contents, and minimal chemical and nonmetallic segregation are produced. Direct current is employed for melting. The diameter of the electrode and its relationship to the crucible is critical and must be matched for the melting rate. Melting rates as high as 1150 kg/h (2500 lb/h) are used to produce ingots as large as 1.5 m (5 ft) in diameter.

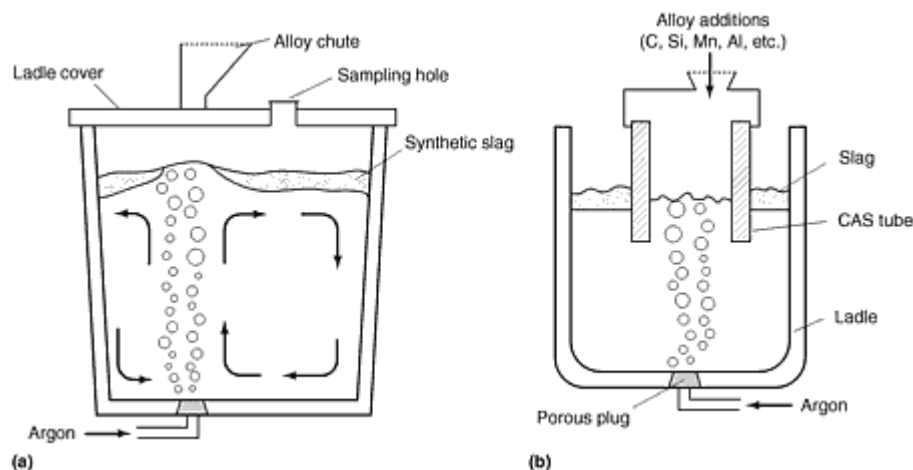

### ***Nonvacuum Refining***

Secondary steelmaking processes used for special and clean steel production and carried out at atmospheric pressure without any supplemental reheating include argon bubbling processes such as capped argon bubbling (CAB), composition adjustment by sealed argon bubbling (CAS), argon-oxygen decarburization (AOD), ESR, and ladle injection methods. (Ladle injection methods are described in the sub-section "Secondary Steelmaking Equipment." )

**Argon Bubbling Processes.** Argon bubbling--argon stirring, trimming, and rinsing--is used for quick and uniform mixing of alloys, temperature homogenization, adjustment of chemical composition, and partial removal of nonmetallic inclusions. These functions are accomplished by either blowing argon through a refractory-protected lance lowered to within 300 mm (12 in.) of the ladle bottom or by blowing argon through porous refractory plugs inserted in the bottom or side wall of the ladle. Argon bubbling often supplements other secondary steelmaking operations by promoting bulk movement of steel in the ladle for chemical and thermal homogeneity, enhancing the flotation of inclusions, and promoting intimate metal-slag mixing for refining operations, such as desulfurization and deoxidation.

Argon stirring is the most vigorous of the bubbling treatments, injecting the highest flow rates of up to  $0.3 \text{ m}^3/\text{min}$  (10 scfm) through liquid steel. Stirring, which usually follows tapping, is used to mix the slag and metal and for temperature and chemical homogenization. The high flow rate breaks through the top synthetic slag layer and creates an opening for alloy and deoxidant additions. Sometimes radiant heat losses are promoted during stirring to prepare the heat for continuous casting. Carry over of slag from the converter should be minimized. Argon rinsing follows the stirring to help float the inclusions into the slag, and the gas flow rate is below  $0.15 \text{ m}^3/\text{min}$  (5 scfm). During argon rinsing, the gentle flow rate of argon prevents the formation of new heat-radiating surfaces. If the steel composition requires adjustment through ferroalloy additions, it is carried out during argon trimming which occurs between the stirring and rinsing steps. Just enough gas flow ( $0.15$  to  $0.3 \text{ m}^3/\text{min}$ , or 5 to 10 scfm) during the trimming period allows the ferroalloys to mix in the steel and not become lost in the slag layer. The specified rates in this description are somewhat dependent on the ladle size.

The CAB and CAS methods for argon bubbling were developed to make controlled additions to the ladle as well as to improve the steel refining capability. The CAB process uses a conventional ladle with a cover and requires a synthetic slag over the steel surface after tapping (Fig. 15a) to act as a sponge for the absorption of nonmetallic inclusions. The introduction of argon into the covered ladle through a porous bottom plug stirs the metal vigorously and creates a slag-metal mix, unlike other argon bubbling methods, which require an intact slag layer to protect the melt from oxidation. The cap on the ladle prevents any air from affecting the metal. The slag-metal emulsion is useful in enhancing microcleanliness, chemical homogenization, desulfurization, and deoxidation. The CAS process (Fig. 15b) uses a refractory-lined snorkel, which is lowered inside the melt during argon stirring so the steel inside the snorkel is slag free. This allows the addition of ferroalloys and deoxidizers without any slag interference and, therefore, is an effective secondary steelmaking process for achieving compositional control.

**Fig. 15** Schematic arrangement of equipment used in argon-bubbling processes. (a) Capped argon bubbling (CAB) process. (b) Composition adjustment by sealed argon (CAS) bubbling process

**The AOD process** was designed for economical production of chromium-bearing stainless steels. A premelt is prepared in an electric-arc furnace by charging high-carbon ferrochrome, ferrosilicon, stainless steel scrap, burned lime, and fluorspar and melting the charge to the desired temperature. The heat is then tapped, deslagged, weighed, and transferred into an AOD vessel, which consists of a refractory-lined steel shell mounted on a tiltable trunnion ring (Fig. 16). As shown in Fig. 16, process gases (oxygen, argon, and nitrogen) are injected through submerged, side-mounted tuyeres. The primary aspect of the AOD process is the shift in the decarburization thermodynamics that is afforded by blowing with mixtures of oxygen and inert gas as opposed to pure oxygen.

**Fig. 16 Schematic of argon oxygen decarburization vessel**

The heat is decarburized in the AOD vessel to 0.03% C in stages during which the inert gas to oxygen ratio of the blown gas increases from 1-to-3 to 3-to-1. During the blowing, fluxes are added to the furnace and a slag is prepared. Following the decarburization blow, ferrosilicon is added and the heat is argon stirred for a short period. The furnace is then turned down, a chemistry sample is taken, and the heat is deslagged. Additional alloying elements are added if adjustments are necessary, and the heat is tapped into a ladle and poured into ingot molds or a continuous casting machine. With the AOD process, steels with low hydrogen (<2 ppm) and nitrogen (<0.005%) can be produced with complete recovery of chromium.

**The ESR process**, like VAR, is a secondary refining process for electrode ingots of essentially the same composition as the finished product, except that ESR is carried out at normal atmospheric pressure and has a greater melting rate than VAR. Rotor forgings, rolls, molds and dies, nuclear containment vessels, and special casting shapes are produced by ESR. Alloy steels, stainless steels, and nickel-base superalloys are also commonly produced using ESR facilities. Electroslag remelting units consist of an open-bottom, water-cooled copper mold that contains the molten slag and metal, a high-current, low-voltage ac or dc power source, and an electrode feed mechanism. The mold rests on the starting plate at the beginning of melting and gradually moves upward as melting progresses (Fig. 17). Castings can be produced generally in any geometrical shape. The arc is struck between the base plate and the electrode to melt the slag, which is electrically conductive. As the electrode tip melts in the form of droplets and passes through the slag layer, some refining occurs. As melting proceeds, the molten pool of metal gradually solidifies. The rate is adjusted such that a molten pool depth equal to one-half the electrode diameter is maintained. The slag composition can be adjusted to serve as a desulfurizer or dephosphorizer as well as a reservoir for floating inclusions. Sulfur can be lowered to below 0.002%. The slag is comprised of fluorspar, lime, and alumina. The ESR process is ineffective in lowering hydrogen, however, as the process is essentially atmospheric. The ESR process is capable of using multiple electrodes, which can be melted into a single mold. The product surface quality is excellent and requires no conditioning.

**Fig. 17 Schematic of the electroslag remelting process**

## Casting

After making and refining by a selected combination of process steps described previously, the steel is then ready to be cast. The ladle containing the refined steel is equipped with either a stopper-rod arrangement or a slide-gate system to control the flow of steel during teeming into a series of molds or a continuous casting tundish. Pit-side practice is one of the key activities in steelmaking, which includes the final process steps before the steel is solidified by the ingot casting method. Therefore, the steel quality is significantly influenced by the pit-side practice adopted for a given steel grade. The ingots are stripped from the molds after the steel is almost completely solidified. Solid steel ingots are soaked in a heated pit where the temperature is homogenized for primary rolling into semifinished products of blooms, slabs, or billets. An attempt is made to reduce the "track-time" between stripping and inserting into soaking pits to conserve energy. Alternatively, a refined steel ladle can be directly teemed into a continuous casting tundish, which supplies molten steel for direct casting into semifinished or near-net shape steel cross sections.

### *Ingot Casting*

An ideal ingot is characterized by a homogeneous chemical and physical structure with fine equiaxed crystals and with no chemical segregation and nonmetallic inclusions. However, depending on the nature of casting and solidification processes, ingots develop pipe, blowholes, chemical and nonmetallic segregation, internal fissures, and columnar crystal structure to varying extents. In addition, surface scabs and panel cracks also commonly develop on ingot surfaces. Ingot molds are usually tapered rectangular boxes of refractory-lined cast iron and are used in both orientations of "wide end up" or "wide end down." In the wide-end-down arrangement, molds may have an open top or a bottle top, whereas wide-end-up molds are generally equipped with open, closed, or plug bottoms. Casting of special high-quality steels presently employs wide-end-up configuration. The inner walls of the mold can be plain sided, cambered, corrugated, or fluted. Corrugating or fluting is done to minimize surface cracking of ingots during solidification by promoting a faster cooling rate and forming a thicker initial ingot skin. The liquid steel is fed into the mold either by top pouring or bottom pouring through refractory-lined feeders. The size and shape of an ingot is closely linked with the yield at the slabbing mill.

As the mold is being filled with steel, an ingot shell or skin forms next to the mold walls and bottom. This skin contracts as it cools to form an air gap between the mold wall and the solidified shell. Formation of an air gap reduces the rate of heat extraction from the ingot. As steel solidifies, the thermal gradient also becomes less steep and the rate of ingot skin formation slows down. The solubility of gases in molten steel decreases with decreasing temperature causing liberation of gases. Oxygen predominantly escapes as carbon monoxide after reacting with carbon. The amount of dissolved oxygen is decreased by the addition of deoxidizing agents. It is also dependent on the carbon level and chemical composition of the steel. The degree of deoxidation achieved during ingot solidification establishes four classes of steel: killed, semikilled, capped, and rimmed.

The rate of heat extraction from an ingot is affected by thickness, shape, and temperature of the mold, the amount of superheat in the liquid steel, the ingot cross section, and the type and chemical composition of the steel. Ingot size is selected to meet the product requirement and the capabilities of the hot-working facility. Ingots range from a few hundred kilograms in weight to as high as 300 metric tons for large forgings. An ideal cooling profile for a killed-steel ingot is shown in Fig. 18 as a function of time.

Fig. 18 Ideal solidification pattern of a hot-topped, wide-end-up ingot of fully killed steel

**Deoxidation Practices.** Because steel solidifies over a temperature range and as the carbon-oxygen chemical equilibrium is constantly changing with temperature, the carbon monoxide gas evolved from still liquid portions as a result of the new equilibrium condition may become trapped at solid-liquid interfaces to produce blowholes. The type of ingot structure is controlled by the degassing allowed during solidification. Figure 19 shows a series of ingot structures for a bottle-top mold casting, ranging from fully killed or dead-killed ingot (No. 1) to a violently rimmed ingot (No. 8) (Ref 36). The fully killed ingot, where no gas evolution is allowed due to full deoxidation through deoxidizer additions, is characterized by the intermittently bridged shrinkage cavity known as pipes. Fully killed steels are commonly cast in wide-end-up molds with hot tops to confine the pipe cavity near the hot top portion. Exothermic compounds are also used in killed ingot casting to allow flotation of nonmetallic inclusions and to keep the steel molten at the top. In a semikilled steel (No. 2), carbon monoxide is allowed to evolve slightly where the resulting blowholes compensate for the solidification shrinkage. The ferrostatic head helps keep the bottom half of the ingot free of blowholes, and the top begins to bulge due to the pressure exerted by the trapped gases. In ingot No. 3, more carbon monoxide is allowed to evolve resulting in greater volume of blowholes than required to compensate for the shrinkage. Some of the blowholes formed close to the side surface in the top half of the ingot are detrimental to the surface quality and lead to surface defects, known as seams, during subsequent hot working. The gas pressure punctures the initially frozen top surface and forces liquid steel up through the rupture causing bleeding. Excessive bleeding results in a spongy surface on products rolled from such ingots.

Fig. 19 Eight typical conditions of commercial steel ingots, cast in identical bottle-top molds, in relation to the

degree of suppression of gas evolution. The dotted line indicates the height to which the steel originally was poured in each ingot mold. Depending on the carbon and, more importantly, the oxygen content of the steel, the ingot structures range from that of a fully killed ingot (No. 1) to that of a violently rimmed ingot (No. 8).

Ingot No. 5 represents a typical capped ingot where numerous honeycomb blowholes extended from top to bottom as a result of strong gas evolution. This evolution causes the steel surface to rise after pouring, and a boiling action ensues, known as rimming action. This action is stopped by using a metal cap on the top of the mold. In this case, a thick, solid skin forms as blowholes are swept upward by the evolving gas. As the evolution slows down, honeycomb blowholes appear in the middle of the ingot. These blowholes do not pose any surface defect problems during rolling. Ingot No. 7 is a typical rimmed steel ingot structure where gas evolution is so strong that blowholes are confined to the lower quarter of the ingot only. The apparent increase in volume due to blowholes offsets the shrinkage that occurs during solidification, thus, causing a rather flat-top ingot surface. A description of the production of different types of ingots, including the formation of blowholes and pipes that occur in ingots as a result of the chosen ingot casting practice, appears in greater details in Ref 37.

**Major Casting Defects.** Several other casting defects occur in steel ingots, such as segregation, inclusions, columnar structure growth, fissures, internal and surface cracks, and scabs. The type and size of ingot and the chemical composition of the steel primarily influence segregation in steel castings. The first metal to solidify very close to the mold wall, namely the chilled zone, has very similar chemical composition to that of the poured steel. However, as solidification proceeds at a decreasing rate, dendrite crystals of purer metal, which are low in carbon, manganese, silicon, sulfur, and phosphorus and other elements, solidify first. The dendrite crystals reject these elements into the remaining liquid. The last material to solidify contains the largest amount of these rejected elements. Segregation is commonly expressed as the departure from an average chemical composition in a bulk material. A positive or negative segregation refers to an increase or a decrease of an element from the average composition, respectively. Sulfur has the greatest tendency to segregate followed by phosphorus, carbon, silicon, and manganese. Larger ingots, which take a longer time to solidify, show greater segregation. When steel is stirred during solidification by convection currents, or turbulence due to gas evolution, the tendency to segregate is enhanced. Thus, a killed steel shows minimum segregation, whereas a rimmed steel shows a sharp boundary between the negatively segregated rimmed zone and a positively segregated core zone. In killed steels, however, "V" segregation occurs along the central axis of the ingot giving rise to axial porosity. Inverted "V" or "A" segregation occurs as a result of ingot disturbance during solidification and gives rise to a defect known as ingot pattern (Ref 38).

The chill zone, or the first formed layer of steel adjacent to the mold wall, has a small and randomly oriented crystal structure, followed by a large dendritic crystal growth characterized by a branching structure. Growth of the individual dendrites occurs principally along the longitudinal axes perpendicular to the ingot surface and can extend all the way to the center of the ingot. An ingot predominantly possessing these large elongated dendritic crystals is referred to as having a columnar structure. Such ingots tend to crack excessively if heavy reductions are taken during initial rolling passes. Usually, columnar structure gives way to the formation of large, equiaxed, randomly oriented dendritic crystal structure toward the center of the ingot. The relative proportion of columnar and equiaxed dendritic crystal structure depends on the steel composition, mold temperature, pouring temperature, and gas content of the steel. Movement of liquid steel during solidification is sometimes practiced by various mechanisms to decrease or eliminate the formation of columnar dendritic zone (Ref 39). This is achieved by the removal of all superheat in the liquid core, that is, to reduce the liquid core temperature to the steel liquidus temperature and by generation of nuclei fragments in the liquid core. Nuclei fragmentation is achieved by either remelting the columnar dendrite tip or by mechanical breaking. Long columnar crystals, especially in higher-alloy grades that resist plastic flow at hot-rolling temperatures, are undesirable because of poor cohesive strength (Ref 40).

Large internal bursts or fissures can be produced by the tensile stresses generated in the interior of the ingot by heating, cooling, or rolling process. If sufficient hot working is performed, these fissures can be completely welded if they do not extend to the surface.

Longitudinal as well as transverse cracks in the ingot wall can be seen on the surface of a cold ingot or during primary rolling. These ingot cracks are caused by excessively high pouring temperature. Weak interdendritic zones are formed that extend from the surface to the center of the ingot. A larger number of shorter dendrites develop if the pouring temperature is low. Transverse ingot cracking is also caused by discontinuities in the ingot wall arising from the surging molten metal in the mold. Improved mold design and use of mold coatings help the formation of folds due to a liquid surge. The occurrence of transverse cracking is lowered as carbon content increases in the steel. A hanger crack can be produced as a transverse crack when fins are formed over the edge of the mold. Corner design of the mold or the use of

fluted molds give rise to longitudinal cracks. In general, these types of casting defects can be reduced by a proper mold and hot-top design. Molds cast in cement for ingot casting have also shown improved crack-free ingot surfaces.

Oxidized materials and sulfides, usually in combination, give rise to nonmetallic inclusions in the steel. These are deoxidation products in most cases, that were not removed during secondary steelmaking or during pouring. In some cases, these inclusions are added into the steel by the erosion of refractory linings used in ladles, furnaces, or molds.

In top-poured ingots, the pouring stream strikes the mold bottom and splashes against the lower mold walls. These splashes adhere and solidify forming a layer on the lower portion of the mold wall. As the liquid level rises, splashing diminishes. However, if the rate of rise for the molten pool is slow, the cooled splashed material oxidizes and attaches to the ingot surface as imperfectly bonded scabs. The thick scabs fold in by the rising steel level and, during rolling, give rise to seam or sliver type defects. In flat products, subsurface cracks occur parallel to these folds and produce surface laminations. A faster pouring rate can usually eliminate this kind of defect. Bottom-poured steels also do not have these cracks as the steel entering through the bottom in the mold does not splash and rises uniformly. Ingots can be scalped to remove major surface defects. The minor defects, however, are removed during the roughing (initial) passes as the scale is broken and removed during primary rolling.

### ***Continuous Casting***

The process of continuous production of semifinished shapes of blooms, billets, slabs, and rounds directly by solidification of refined liquid steel is termed continuous casting. The molten steel is fed into a steel reservoir called a tundish and transferred via nozzles into a continuous casting mold. Semifinished product yields as high as 95% can be realized in continuous casting as opposed to approximately 80% yield in the ingot casting/primary rolling route. Presently, 65 to 70% of finished steel is continuously cast worldwide. The combination of an electric-arc furnace and a small continuous billet, bloom, or slab caster, has led to the formation of minimills characterized by their economic efficiency and simplicity. The first commercial billet and slab casters were installed in the early 1950s.

Steel quality is also improved by continuous casting because better control of steel cleanliness can be generally administered in the tundish and the mold and favorable solidification structures obtained through controlled cooling. High-quality clean steels are also produced through ingot casting, particularly the high-carbon, low-oxygen grades. For special grades, like bearing steels, ingot casting is the preferred route because primary rolling allows a larger reduction ratio through hot working and, therefore, a more sound internal structure. A 30 to 1 reduction ratio is required as a minimum for certain bearing grades, which is not achievable from continuously cast billets, or even blooms, if large bearings are to be manufactured.

The yield improvement in continuous casting over ingot casting is primarily due to the elimination of scrap generation in three areas: primary rolling mill, steel pouring practice, and soaking-pit ingot heating. In addition, short ingots, ingot butts, and general pit scrap lower the ingot casting yield. Cropping of top and bottom parts in an ingot due to piping or high inclusion level is always associated with ingot casting. Conversely, it can be easily understood that the longer a continuous caster operates without an interruption (number of heats continuously processed), the higher is the yield for any given casting size and number of strands on a caster.

Quality improvement ensues from the fact that there is less variability in chemical composition and better solidification characteristics. Segregation is minimized, both vertically along the length of the billet or bloom and across the cross section. Inclusion levels, however, could be higher in continuously cast steels, particularly in transition zones (material cast during change of heats), and as a result are detrimental to bearing-grade steels, as discussed earlier. Further down the line, surface dressing requirements prior to finish rolling are also reduced as surface defects (seams, scabs, etc.) on a continuously cast product are less than a primary rolled product from ingots. This also improves the yield. In general, fewer internal and surface defects are present in continuously cast material.

Elimination of soaking and primary rolling steps considerably improves the energy efficiency of continuously cast product. Higher yield in continuous casting lowers the energy consumption per ton of steel processed. With the advent of hot charging of semifinished products from a caster into reheating furnaces prior to finish rolling, energy efficiency of continuous casting has been greatly enhanced. Soaking pits for ingot reheating burn fuel and are a source of pollution. Lower capital and operating costs are required in continuous casting by eliminating ingot processing steps and by yielding higher throughputs (Ref 41).

**Process Description.** Figure 20(a) shows the main components of a continuous caster. A casting machine essentially consists of a liquid-metal reservoir and a delivery system, known as a tundish, a water-cooled mold, a secondary cooling zone with a containment section, bending and straightening rolls, shearing equipment, and a cooling bed or run out table. A caster can have several strands (number of liquid streams tapped from the same tundish), each equipped with a mold, secondary cooling and containment arrangement, shearing station, etc. The number of strands used is a function of the heat size and the shape being cast.

**Fig. 20** Continuous casting. (a) Major components of a continuous casting machine. (b) Liquid metal flow from the ladle into the tundish and from the tundish into the mold

The casting process begins with the bottom end of the mold plugged with a dummy bar connected to an external mechanical withdrawal system. The tundish is filled to a certain height at a controlled rate by refined molten steel poured from ladles. The liquid steel flows from the tundish through nozzles and into the mold (Fig. 20b). When the steel level reaches a certain height in the mold, the dummy bar is withdrawn at a predetermined casting speed. Casting speed is dependent on the machine characteristics, such as cast section, cooling efficiency, metal feed rate from the tundish, and the desired cast structure. When the dummy bar head, which is now attached to the solidified shape being cast, reaches a certain position in the withdrawal station, it is mechanically disconnected and the dummy bar removed. The solidified casting continues through the withdrawal system to the shearing station.

Solidification begins in the water-cooled mold just below the liquid steel meniscus where a shell is formed in contact with the mold wall. The distance between the meniscus level and the point of complete solidification is known as the metallurgical length of the caster. The mold is vertically oscillated to prevent sticking of the solidified shell to the mold wall. In addition, molds are tapered to ensure that the solidified shell is in contact with the mold wall for better cooling efficiency. Friction between the mold wall and the solid shell is minimized by using mold compounds or lubricants, such as oil or fluxes that form a fluid slag. Casting conditions are established to ensure that the steel shell is thick and strong enough to withstand the ferrostatic pressure of molten steel in the mold after it leaves the mold. The material is fully solid before it reaches the cutter and in many cases, it is solid before it arrives at the straighteners. Further heat removal occurs

in the secondary cooling zone for complete solidification. Water and/or mist spray cooling is employed in this zone to maintain optimum cooling rates and strand surface temperatures. Support rolls guide the strand as well as prevent sectional bulging due to internal ferrostatic pressure from the molten pool at the strand core. Cooling sections are designed to minimize internal and external flaws or defects. After the secondary cooling, bending and straightening are performed before shearing into the desired length for further processing, either in hot or cold condition. Some of the casters can be used to cast more than one shape by changing the mold (Ref 42).

Capital cost of installation has been lowered over the years while improving the quality of the cast product by progressively reducing the height of the machine. Older installations are vertical machines with a straight mold and cut off in the vertical position whereas newer installations use a bow-type machine with curved mold and progressive straightening. New slab casters are usually bow type because slabs are not self supporting in the secondary cooling zone, whereas billets or blooms are self supporting and, therefore, can be cast on a vertical machine. Generally, the shape of the cast material, productivity and quality of the product, and the cost determine the type of machine chosen.

### ***Design Features in Continuous Casting for Quality***

Temperature control is more critical in continuous casting than in ingot pouring. Enough superheat must be maintained to allow the molten steel ladle travel from tapping to teeming stations and to prevent freezing at the tundish nozzles. At the same time too much superheat can cause insufficient solidification in the mold and thus a breakout after leaving the mold. Low superheat casts provide better uniform cast structures with a wider equiaxed crystal zone than high superheat casts. Homogenization of temperature is, therefore, practiced either by argon bubbling through a porous bottom plug or by lancing from the top in the ladle before the steel is teemed into a tundish.

Continuously cast steels must be fully killed (deoxidized) to prevent blowholes or pinholes from forming close to the surface of the cast product, which result in seams upon subsequent rolling. Full deoxidation is achieved primarily by silicon deoxidation for coarse-grain steels and by aluminum deoxidation for fine-grain steels. Aluminum-killed steels, however, can cause problems at the tundish nozzle by clogging them with alumina deposits. High-quality products commonly use a ladle refining practice prior to casting and take special measures for preventing nozzle blockage.

Liquid steel is fed continuously or semicontinuously from the ladle to the tundish and is distributed to individual molds through nozzles in a continuous stream (Fig. 20b). Stopper rod or hydraulically or electrically controlled slide-gate systems are used to transfer steel from the ladle to the tundish.

**Role of the Tundish.** Tundishes have nozzles located at the bottom, which serve primarily as a metal distributor to the mold. Metal flow patterns are very critical to the product quality. Flow-control devices, such as refractory dams and weirs, are attached to the tundish to distribute the metal flow, to minimize turbulence, and to eliminate dead flow zones (Ref 43). These devices enhance the stability of the metal streams entering the casting mold. Significant cold modeling work has preceded the design of optimal configuration of these flow-control devices. Metal is poured as far away as possible from the nozzle location directly on a wear resistant pad. A constant metal height above the tundish nozzle is required to discharge the metal at a constant rate and, in turn, to maintain constant casting speeds. Tundishes also perform the function of a metal reservoir which allows unabated casting during ladle change overs for sequence casting of heats. It is imperative that the ladle change be done in the shortest possible time.

The metallurgical role of a tundish is to facilitate separation of inclusions and slag from entering the mold. The metal residence time in the tundish is a key parameter in meeting this condition. Tundishes are preheated prior to metal pouring and are often covered to minimize radiation heat losses. Tundish nozzles are either a metering (or open) nozzle or a stopper-rod nozzle. Metering nozzles essentially control the metal discharge rate by the bore of the nozzle and the ferrostatic pressure (metal height in the tundish) above the nozzle. They are commonly used for silicon-killed billet or bloom castings. Stopper-rod nozzles are used for slab casting of aluminum-killed steel, and the flow is monitored by raising or lowering the rod above the nozzle opening. Alumina buildup and clogging is compensated by raising the rod if other means of preventing buildup are not in place. Inclusion levels in the metal rise, particularly during ladle change overs. The time available for floating inclusions is much shorter in continuous casting than in ingot casting. However, nozzle clogging is prevented by bubbling argon through the stopper head and nozzle units in modern installations. Slide-gate systems additionally provide the capability for changing nozzles during casting as well as changing nozzle size.

**Shrouding.** Stringent surface and cleanliness requirements placed on special-quality steels have necessitated the use of closed stream or shrouded castings. Open-stream castings pick up oxygen- and nitrogen-forming inclusions, which have deleterious effects on steel properties, as described earlier. Ladle-to-tundish and tundish-to-mold shrouding are commonly

employed to protect the steel from air, particularly the aluminum-killed grades, which have a potential of forming alumina inclusions. Inert-gas shrouding and refractory-tube shrouding are the general types of methods used. Refractory-tube shrouds are made of fused silica or alumina graphite. Figure 21 shows an example of a ladle-to-tundish and tundish-to-mold refractory-tube shrouding system.

**Fig. 21** Schematic of a refractory-tube shrouding system for minimizing oxidation during pouring

**Mold Characteristics.** The mold serves the function of partly solidifying the steel to such an extent that the shell thickness and shape, temperature distribution, and surface and internal structures are appropriate after exiting. Molds are open-ended boxes that contain an inner lining made of a copper alloy and are externally supported by a steel structure. Cooling water flows between the liner and the outer steel structure to extract heat from the solidifying steel in contact with the copper liner. Molds are either tubular or plate type. One-piece tubular thin copper linings are used for smaller billet and bloom casters. Plate molds consist of a four-piece copper lining attached to steel plates. In some designs, opposite plates can be adjusted to cast different rectangular slab shapes and, therefore, are more adaptable. Plate molds also allow the change of taper to accommodate different shrinkage characteristics of different steel grades. Silver-alloyed copper is used for high-temperature strength. The inside liner surface is often nickel or chrome plated to provide a harder working surface and to avoid copper contamination of the cast strand surface. Thermal and mechanical strains cause a distortion of the mold and thus affect product quality. Thermal strain distortions, which are highest at the meniscus level where the steel temperature is highest in the mold, cause permanent distortion due to lower yield strength of copper. Mold wear at the exit end also causes reverse taper phenomenon (Ref 44).

### ***Heat Transfer in Continuous Casting***

Heat transfer conditions in the mold have been thoroughly investigated through modeling and plant verification (Ref 45). The predominant transverse heat transfer can be considered as a flow of heat energy through a series of thermal resistances from the liquid steel at the core and the water sink of the cooling system. Heat transfers (a) in the solidifying casting, (b) from the steel shell surface to inner copper lining, (c) through the copper lining and (d) from the outer copper lining to the mold-cooling water. Sensible heat changes (the heat absorbed or evolved by a substance during a change of temperature that is not accomplished by a change of state) in the steel strand due to lowering of temperature and latent heat release due to phase changes comprise the heat to be transferred in the solidifying casting. In addition, a mushy zone exists between the liquid and the solid shell, the thickness of which is dependent on the steel carbon level. Also, the thickness of the solid shell changes continuously from the meniscus to the bottom of the mold, and transfer through this shell is by conduction. Transfer of heat from the steel shell to the mold wall is complex and occurs by radiation as well as conduction due to the tendency of the formation of an air gap between the mold and the shrinking cast shell. A large air gap, which can form longitudinally as well as in transverse direction, represents the slowest of the heat transfer steps and therefore, controls the overall rate of heat transfer. While bulging due to internal ferrostatic pressure tries to reduce the air gap, an increase in shell thickness away from the meniscus tends to resist bulging. Thus, the formation of the air gap is a dynamic phenomenon. Because mold taper is intended to reduce the air gap, it enhances heat transfer. At the inner copper wall, heat transfer is also affected by the quantity and type of mold flux and lubricant used. Fluxes and oil that wet copper assist in heat transfer. In general, the local heat flux down the mold length is maximum just below the meniscus and gradually decreases down the mold length. The average heat flux for the entire mold increases with increasing casting

speed. Heat transfer through the lining is essentially by conduction and is dependent on the copper conductivity and thickness, whereas the transfer through the cooling water is by forced convection. Water flow rate and pressure control the heat transferred through it. Typically, higher cold-face temperatures are encountered in billet casters due to the lower thickness of the copper lining than is the case with slab casters. Water flow must be uniform through the passages of the mold with an adequate volume, temperature, pressure, and quality. Usually water flows vertically upward in the mold. Optimum water pressure is required to suppress boiling and to prevent mechanical mold deformation. Water quality is important because scale buildup on the copper lining can be detrimental to heat transfer and copper strength. Use of baffles and headers in the water flow region is critical in maintaining a proper velocity. The difference between the water inlet and outlet temperatures,  $\Delta T$ , is a good indication of the mold cooling efficiency where high, low, or unequal mold face values indicate a low water flow rate, scale buildup, and an unsymmetrical pouring stream, respectively. Unequal temperature differences on two faces could also mean a strand misalignment.

**Mold Oscillation and Lubrication.** To minimize the risk of breakouts (in which liquid steel breaks through the thin solidified shell inside or just outside the mold) and mold-strand adhesion, the mold is lubricated and oscillated. Various hydraulic or mechanical actuators are used to reciprocate the mold. Sticking of the strand to the mold can be exacerbated by local rough areas in the mold or by the buildup of tensile forces on the skin. Generally, a negative strip is applied where the mold moves faster than the casting speed, which results in a compressive stress on the solid shell allowing closure of surface fissures and porosity. The upstroke is taken rapidly, and the mold is returned to the starting position quickly.

Both liquid and solid types of mold lubricants are used. Semirefined mineral or vegetable oils are used to form a film along the mold walls when casting silicon-killed billets or blooms. Solid mold fluxes or powders are used with submerged refractory tubes when casting slabs or blooms of aluminum-killed steels. These solid lubricants also help in heat transfer at the strand-mold interface and provide thermal insulation and reoxidation protection to the liquid steel at the meniscus. Mold fluxes also assist in absorbing nonmetallic inclusions. Mold fluxes melt and attain optimal fluidity when they come in contact with the molten steel. Solid mold fluxes are  $\text{SiO}_2\text{-CaO-Al}_2\text{O}_3\text{-Na}_2\text{O-CaF}_2$ -based with small additions of carbon. Iron oxide is avoided to prevent reoxidation. Fluxes are either fly-ash based or synthetically produced as frits or granulated powder.

**Cooling Characteristics.** Secondary cooling, strand containment, and a withdrawal mechanism form an integrated system, particularly in modern slab casters. The metal is control cooled through a secondary cooling zone while being supported and withdrawn by several sets of rolls to the cutoff table after leaving the mold. Secondary cooling is subdivided into a series of zones positioned through openings between the containment rolls. For more uniform cooling, water-mist sprays have replaced the conventional water-spray cooling in newer installations (Ref 46). At the desired casting speed for a grade of steel, secondary cooling is required to provide adequate water for complete solidification and to regulate the thermal gradients in the strand and the strand surface temperature. Secondary cooling also helps cool the containment rolls. Improper thermal gradients cause internal and surface cracks and shape distortion. Over or under cooling causes thermal strains and could exceed the low ductile strength of the shell at high temperatures. Improper cooling can also result in reheating of the shell by the liquid core heat. A smooth transition from the spray cooling to radiation cooling is desired to prevent reheating. A recirculating water system is used and the water flux (the amount of water per unit area of surface contact) is distributed through properly spaced nozzles along the zone. Changes in the water flux can be compensated for changes in the casting conditions.

**Strand Movement.** The strand is supported and guided from the mold exit to the cut-off position and is driven at a controlled speed by a series of retaining rolls extending across its two opposite faces in a horizontal direction. Containment can be further enhanced by edge rolls placed across the other two faces perpendicular to the casting direction. Mechanical stress and strain incurred during processing are minimized by containment. The strand is supported on all four faces below the mold and on two faces in the lower levels. The tendency to bulge is greatest just below the mold where the shell thickness is low and the internal ferrostatic pressure is high. Also, the roll spacing is shorter near the mold than away from it. In addition to containing the strand, the series of rolls placed along the prescribed arc to transition and guide the strand from vertical to horizontal have to be strong enough to withstand the bending reaction forces. Triple-point bending or bending through three arcs with progressively smaller radii is practiced in modern casters to ensure improved surface quality because sharp bends can crack the surface due to excessive tensile stresses generated during bending on the outer surface. Following bending, the strand goes through a multiroll straightener, which unbends the strand and reverses the tensile and compressive forces in the horizontal faces. In most continuous-casting machines used currently, curved molds, which do not require bending, are used. The strand goes immediately through straightening rolls.

Withdrawal of the strand is achieved by drive rolls placed in the vertical, curved, and horizontal sections of the machine. These rolls tend to impart compressive forces in the surface of the strand, resulting in better surface quality. Thus, the objective is to "push" the strand through the casting machine rather than "pull" the strand, which can produce tensile stresses and attendant surface defects. Drive rolls are, therefore, placed before the bending rolls, where possible, to offset tensile stresses. The required traction to drive the strand is distributed over the multiple sets of drive rolls used. To prevent shape deformation, excessive force by the drive rolls to grip the strand must be avoided. The strand subsequently moves to the cut-off section where smaller sections are mechanically sheared, and larger sections are torch cut.

### ***Productivity and Quality***

Since the commercial inception of continuous casting in the early 1960s, tremendous gains in productivity have been achieved through several measures. Machine downtimes have been reduced by (a) lowering machine set-up time between casts, (b) reducing mold change times, (c) reducing the number of stoppages due to strand breakouts, nozzle blockage, and uncontrolled metal flow, (d) minimizing occurrences of out-of-specification heat composition and temperature, and (e) cutting down machine maintenance needs. In addition to improved steelmaking practices and better caster design, the advent of sequence casting, slab slitting with oxyfuel torches to reduce the frequency of mold changes and reduce mold inventory, variable-width adjustable molds, split molds, top-fed dummy bars, and hot charging for direct rolling have improved the productivity substantially. It should be realized that hot charging implies the need for hot-surface preparation and inspection steps, and calls for excellent control of surface finish by the caster itself.

The quality of continuously cast product is dependent on the steelmaking and casting practices. Surface defects include deformed cross sections; longitudinal and transverse cracks; laps, scale, and trapped inclusions; and mold oscillation marks. Subsurface pinholes, blowholes, inclusions, and cracks also appear, whereas porosity, inclusions, segregation, and cracks are internal defects. Specific techniques are employed to minimize these defects. External cracks are usually reduced by proper mold and secondary cooling at controlled casting speed, mold lubrication, mold coatings, mold wear control, and machine alignment. Internal cracks and porosity can be minimized by machine alignment, electromagnetic stirring, in-line reductions, multipoint straightening, compression casting, and control of temperature and casting speed.

The lack of integrity of the pouring stream between the tundish and the mold and improper casting speed give rise to laps and scabs. Oscillation marks generally originate from the type of mold oscillation adopted. Proper deoxidation and stream shrouding can eliminate blowholes and pinholes, while segregation is minimized by electromagnetic stirring, control of superheat, and casting speed. Inclusions are avoided by improved steelmaking, deoxidation, and shrouding practices. The desire to roll flat products, which do not require prior surface conditioning, has driven the recent developments in "clean" steel manufacturing, electromagnetic stirring, and mist cooling at the secondary zone. The incidence of surface cracks has been dramatically reduced by these three developments.

Clean steel technology involves minimizing the formation of inclusions during deoxidation or reoxidation, lowering pickup from refractories, and enhancing inclusion separation and removal prior to casting. Control of sulfide and oxide inclusion morphologies are also critical. These controls are brought about through a variety of process steps, such as slag-free tapping, ladle metallurgy, shrouding all open liquid-metal streams, proper refractory selection, proper tundish design, use of mold powders, and electromagnetic stirring.

**Electromagnetic Stirring (EMS).** Stirring of the liquid steel during solidification using a magnetic field has resulted in sound internal quality (reduced segregation, cracking, and porosity), subsurface cleanliness through a modified flow pattern, reduced criticality of casting parameters (temperature and casting speed), and increased productivity through higher casting speeds. Initial applications of EMS on billet casters clearly showed a decreased columnar zone and a wider equiaxed crystal zone resulting in lower center-line segregation. In a rotary EMS system installed in the mold, a rotating magnetic field imparts a circular motion to the liquid steel. The flow breaks the dendrite tips and provides nucleation sites for equiaxed crystal growth while producing a solid skin by moving the lighter inclusions to the center of the billet. Linear EMS systems are placed below the mold generating a vertical circulation pattern. Inclusions are uniformly distributed while more equiaxed crystals form by a similar mechanism as that obtained by the rotary stirrer. In slab casters, EMS is additionally used to break the flow pattern of the incoming stream of metal into the mold, thus reducing the penetration of the stream into the liquid pool (Ref 47).

**Mist Cooling.** Conventional water sprays in the secondary cooling zone can aggravate the occurrence of surface cracks because cooling is uneven in both the longitudinal and transverse directions. Local overcooling can also occur due to trapping of water in different sections. The formation of steam bubbles and vapor film interferes with the heat transfer. An air-water mist provides improved cooling characteristics due to better heat transfer, removal of steam by the compressed air, and lesser use of water volume. Edge-to-edge temperature variations are less, and water trapping at containment and

drive rolls are eliminated. The air-water mist is created by an atomized nozzle in which cooling water and air are premixed and discharged under pressure (Ref 46).

### ***Special Continuous Casting Processes***

Besides the conventional methods of casting billets, slabs, blooms, and rounds in vertical machines for which a large number of installations are commercially available worldwide, alternative processes have been developed to reduce the capital cost, to improve the product quality, and to cast smaller section sizes. These include horizontal casting, rotary continuous casting, and strip casting. These processes are described in greater detail in Ref 48.

Horizontal casters require lower capital investment and smaller space. The cast sections inherently have low ferrostatic pressure resulting in less strand bulging and the absence of straightening and bending lowers stresses, which allow casting of crack-sensitive grades. The absence of tundish-to-mold reoxidation is also helpful. In rotary continuous casting, the strand and mold are rotated, which results in the development of centrifugal forces providing intimate contact between the mold wall and the steel. This results in high heat extraction rates during the initial stages of solidification.

In strip casting, strips are directly cast from liquid steel rather than by rolling of strip bars in hot strip mills. Significant cost savings can be realized by eliminating strip bar reheating and hot strip mills and by improving upon the yields of a conventional strip production route. Strip thicknesses of less than 1 mm (0.04 in.) can now be directly cast.

### **Hot Rolling**

All of the inherent quality aspects of steel that relate to cleanliness are derived during secondary refining and casting. Subsequent practices of primary and finish rolling are essentially the art and science of controlling the product microstructure and properties. Specialties in rolling practices pertain to a precise control of the amount of cross-sectional

reduction taken at, or within, a certain temperature range and the associated cooling profile of the product. Many forms of steel products require subsequent heat treatment for achieving the desired microstructure because the as-rolled microstructure is not adequate. Other practices of hot working, such as forging or pressing, are described elsewhere in this Handbook. In addition to hot working, several final products need cold working, particularly in flat or circular form, to achieve strength and/or texturing. Product forms such as strips and wires require an additional step of coiling at a fixed temperature, because cooling profiles in the coiled condition determine the final microstructure attained. Between the primary and finish rolling steps in hot working, the semifinished steels require a surface preparation, known as conditioning, particularly if they are rolled from ingots.

## ***Primary Rolling***

Primary rolling pertains to initial breakdown rolling of ingots to produce semifinished shapes of blooms, billets, slabs, and rounds. If the steel is continuously cast, these shapes are directly formed by the shape of the mold. There is no clear distinction between these shapes as some overlap exists. Billets and blooms tend to be square, while slabs are oblong. Blooms are larger in cross section than billets. Further subdivision of shapes is made on the basis of the final product shape, such as tube rounds, plate slabs, strip bars, etc. Generally, a square cross section of  $125 \times 125$  mm ( $5 \times 5$  in.) is used to distinguish a billet from a bloom. The length of these shapes depends on the starting ingot size and the finished product size as well as the mill capability (Ref 49).

Ingot cross section is first reduced to a square, oblong, round, or other convenient shape with rounded corners. During this operation the length of the ingot increases as the cross section is reduced. The ends are cropped, and the rolled piece is split into desired lengths for further rolling. Rolling of ingots directly into products is often desired as intermediate reheating is eliminated. However, such a practice is more suited for large cross-section finished products, such as wide flange beams and rails. Primary rolling mills are described by the center-to-center spacing of the work rolls. Usually, primary mills are multiple-stand mills and the size description relates to the first stand. The function of all primary mills is fundamentally that of cross-sectional reduction and cutting into desired lengths and weights, which is achieved by passing the stock through a series of rolling stands. Crops and mill scale are useful by products of the primary mill and are recycled to the steelmaking converter.

A series of thermal and mechanical operations are carried out during primary rolling. Reheating and homogenization of the ingot temperature is achieved in soaking pits (Ref 50). This temperature is optimized to maintain sufficient plasticity in the steel during rolling while minimizing overheating in the pit. Initial passes, known as break-down or roughing passes, break up the coarse crystalline structure of the ingot into a refined structure by heavy rolling pressure and recrystallization during hot working. Scales formed in the soaking pit are dislodged as soon as the ingot enters the first set of rolls. This is essential to prevent the scales from embedding into the surface. Solidification voids from ingot casting are welded shut. Further cross-sectional reduction of the steel occurs as the rolled piece passes through subsequent stands. Physically (fishtails) and chemically (high inclusion) unsuited ends are cropped. The semifinished product is then cut to desired length and weight and is left to cool if further rolling is not immediate.

**Primary Mill Types.** In most primary mills, a roll stand is required to impart more than one reduction. In this case, the mill roll-out stage must have facilities, that is, manipulators, to turn the rolled piece, and the rolls should be reversing. If the rolls are not reversing, as is the case in some older installations, there are mechanisms to return the steel to the rolling entry side, either by passing over or under the rolls. Positioning of rolls to produce the desired cross section is simultaneously done. The basic operation in a primary slabbing or blooming mill is the gradual compression of the steel ingot between the surfaces of two rotating rolls. The physical properties of the ingot prohibit the entire reduction being accomplished in one pass. Therefore, the ingot must be rolled using a sequence of passes designed on the basis of mill capacity and capability.

Common types of primary mills include two-high reversing mills, two-high tandem mills, three-high mills, three-high billet mills, cross-country billet mills, and various combinations. Two-high reversing mills are most versatile in their capability to roll different sizes of ingot. (As the name implies, a two-high stand consists of two rolls, one above the other.) The rotation of the rolls can also be reversed. Reductions are accomplished in both directions of roll rotation. These mills are associated with low production rate. Therefore, combinations of different types of mills are used to improve the productivity, such as different size two-high mills arranged in tandem. High-lift blooming mills and slabbing mills are other variations of a two-high reversing mill that provide special rolling capabilities (Ref 50). The two-high tandem mills consist of several single stands of paired rolls, spaced such that the rolled piece is free between the stands. Normally the piece is rolled in one pass in each stand. Each stand is designed for ideal draft, and no time is lost in reversing the roll direction. These mills are limited by the size of ingot that can be rolled and are expensive to build. Two-high tandem mills are usually used for roughing the ingot for final rolling in a slab or billet mill. In three-high mills, the

top and bottom rolls rotate in the same directions while the middle roll rotates in the opposite direction. Rolling reductions are alternately taken between the top and middle roll in one direction and between the middle and bottom roll in the opposite direction. An elevating table is required to position the steel piece between the appropriate sets of rolls during rolling. These mills have a constant speed of rotation, thus initial passes are too fast and the last passes are too slow. The design of roll passes and the operating units in a primary mill are described in Ref 50.

As large size ingots are produced now for greater productivity, direct rolling of billets in the primary mill has become difficult for smaller cross-section billets. Thus, a blooming mill is followed by a billet and bar mill, which rolls the blooms into smaller cross sections, usually without a reheating step. Reheating facilities are required if the rolling temperature range is narrow for special grades of steel. Three-high billet mills operate using the same principles as the three-high blooming mill. Different parts of the rolls in the horizontal direction are used to make successive reductions in cross section through grooves along the roll length. Several sizes of billets can be produced by a single three-high billet mill. Cross-country billet mills are comprised of several stands of rolls, so arranged that the piece to be rolled is never in more than one stand at the same time. The stands can be placed side by side, and the piece is moved along the roll tables by manipulators and guides. The direction of rolling is reversed on the adjacent table after rolling through one or more stands. The roll stands along the adjacent side table are normally rotated in the reverse direction. The speed can be controlled for each stand independently, and faster rolling speeds can be used for finishing passes. In a continuous billet mill, stands are in series one after the other. The bloom enters the first stand and exits the last, taking only one pass in each stand. The rolling speed of each subsequent stand is adjusted to account for the increased length of the piece from the previous stand. Some of the stands in these mills may be vertical or could simply use vertical edgers. These mills have high output as scrap losses are low.

The product from the blooming mill is cropped by bloom-crop shears to discard the hot top (pipe) before entering the billet mill. Stationary shears are used to cut the large cross-section billets to size, whereas flying shears are used to cut smaller cross sections as the billets travel in a continuous operation.

### ***Conditioning of Semifinished Products***

Ingot defects described in the sub-section "Major Casting Defects" and some additional defects arising during heating and rolling are carried through primary rolling, and they appear on the surface of the semifinished product. These defects require removal before finish rolling is performed. Figure 22 shows the surface defects that originate from ingot defects or during heating and rolling. A cinder patch defect refers to the scabby bottom of the ingot where material is picked up from the soaking-pit bottom. The ingot is placed in the pit so the cinder patch is confined to the hot-top end of the ingot, which is discarded after rolling. Burning of ingots due to direct impingement of flames on the ingot corners during soaking make the steel nonsalvageable, as tearing or rupturing occurs during primary rolling. When fins or projections produced by one pass are bent over and rolled during subsequent passes, laps appear on the semifinished product surface. Deep laps are difficult to repair. Several nondestructive methods are employed to inspect the material and to determine the conditioning requirements. Often all the defects do not have to be removed depending on the application or the steel grade being processed. Milling and chipping machines are used to remove the surface imperfections on blooms or slabs. Scarfing in the steel mill consists of surface removal by the use of oxygen torches. The oxygen rapidly oxidizes the steel surface generating elevated temperatures that cause the oxidized product to become liquid. Scarfing can be carried out manually or mechanically. Grinding is also commonly used to remove surface defects.

**Fig. 22** Surface defects on semifinished products made by primary rolling of ingots. (a) Scabby surface of a bloom. (b) Deep seam originating with an ingot crack. (c) Clustered seams. (d) Burned steel bloom. (e) Lap on a rolled steel product

Semifinished products are rolled at temperatures well above the critical temperature range of the steel and thus, during cooling after rolling, must pass through transformation range. Depending on the size and chemical composition of the steel grade rolled, it might be necessary to control the cooling rate of the semifinished product to discourage the formation of flakes or small internal ruptures and to minimize the generation of internal thermal stresses. Flakes normally occur some distance away from the end of a rolled piece and often midway from the surface at the center of the section. Flakes are generally attributed to the dissolved hydrogen in molten steel and proper retardation of cooling from the rolling temperature is effective in prevention of flaking. Before the advent of controlled-cooling practices, steels were buried in sand or ashes (insulators) to retard the cooling process, which helped minimize the development of internal stress and lowered the hardness. Newer controlled-cooling processes involve automatically controlled furnaces, which can slow cool the steel at desired cycle times through predetermined temperature ranges. Cooling cycles are shorter when using controlled cooling as rapid cooling and holding at desired temperatures have become possible. When the steel is out of the thermally sensitive range, steels can be air cooled. These cooling profiles can be determined by judicious use of isothermal transformation diagrams specific to the grade of steel (Ref 51). In general, the higher holding temperatures followed by air cooling can be used for the carbon and lower alloy steels, and lower holding temperatures followed by reheating to temperatures just below the critical temperature range can be applied to high-alloy deep-hardening grades of steel.

### ***Finish Rolling***

After an ingot is converted into a semifinished shape (bloom, billet, slab, or a round), it is ready to join the products made by continuous casting. The process steps of conditioning and controlled cooling are more applicable to ingot products, because controlled cooling is adopted in continuous casting during solidification if the product is not finish rolled directly. Also, surface defects in continuously cast products are minimal. Beyond this point, steel is plastically worked, either hot, cold, or both, to attain the desired finished shapes. Rolling is followed by heat treatment, if required, to obtain the desired microstructure. Separate rolling mills are used to obtain the final regular shapes of plates, sheets, strips, rounds, bars, tubes, wires, and rods and medium-to-heavy sections for wheels, axles, rails, beams, channels, and angles. Other special mills are used to forge, press, or roll nonconventional sections. These mills vary in capacity, layout, and design worldwide. The function of finish rolling is to permanently deform the metal using mechanical forces to achieve a specific shape and to improve certain properties. The forces required to deform the metal are very sensitive to the rate of load application and to temperature variations in hot working, but the basic strength of the metal is unchanged after

deformation. On the other hand, the forces are relatively insensitive to the rate of load application and to temperature variations in cold working, but the basic strength of the steel is permanently changed after working. In addition to rolling, hot or cold working can take the forms of hammering, pressing, extrusion, piercing, upsetting, and drawing. In finish rolling, the number and type of stands depend on the shape being rolled and the relationship between percent reduction and rolling temperature per pass. Some of the finishing mills have facilities to coil the product, such as a strip mill or a wire mill. A plate, sheet, or a tube mill usually has facilities to clean the surface of superficial defects and scales by pickling and to apply corrosion-resistant coatings. Mills that roll concrete reinforcing bars also are capable of cold twisting the bar for strength. Ribs on the reinforcing bars are created by specially designed grooved rolls.

**Direct rolling** refers to finish rolling the continuously cast product with minimal or no reheating. The products are sent from the caster through a reheating furnace directly to finish rolling mills, such as a hot-strip mill, to conserve the heat of the as-cast product. Excellent surface quality is important because extensive conditioning of the material is not possible. Reheating for finish rolling is performed in either batch or continuous type of furnaces.

### ***Continuous Hot-Strip Rolling***

The term "strip mill" refers to a mill that continuously rolls sheet or strip. In a modern wide hot-strip mill, slabs are heated in two or more continuous reheating furnaces. A typical rolling mill train consists of a roughing scale breaker, followed by four four-high roughing stands, a finishing scale breaker, and six four-high finishing stands. In some recent installations, five roughing and seven finishing stands are used, in addition to the two scale breakers. Driven table rolls convey the material from the furnace to the mill and from stand to stand. As the steel proceeds from the mill, it is carried over a long table, called a runout table, where water is applied to the top and bottom surfaces of the strip by water sprays or laminar jets to reduce the strip temperature to a controlled value. Two or more coilers are located at the end of the runout table. Additional tables may be installed parallel to the central table with suitable mechanisms for moving material to them.

The hot-mill arrangement described previously employs continuous roughing and finishing trains and provides very high rolling capacity and rapid steel travel with little heat loss. However, it entails high installation costs and a fixed number of passes, with some loss of flexibility in making rapid changes in the mill setup when the size of the product to be rolled is changed. An alternative arrangement employs a reversing roughing mill and continuous finishing train; this arrangement has a lower installation cost and is flexible with regard to the number of passes available. If slabs are rolled directly from primary blooming operations and proceed for strip rolling using retained heat (direct rolling), slab reheating may be bypassed.

Quality aspects of finished strips include uniform reheating of slabs to produce a uniform scale jacket that can be dislodged readily during rolling. Insufficient soaking in reheating furnaces gives rise to scale which is difficult to remove. Other quality measures required to meet product standards are the consistency in surface, condition, gage, rolling width, finishing temperature, and cross-sectional contour. The water sprays play a vital roll in keeping the temperature at the desired value and in keeping the surfaces scalefree. It should be noted that metallurgical requirements dictate a definite finishing temperature. This temperature is affected by the holding time prior to coiling, the number of descaling sprays, the speed of the finishing train, and the method of drafting.

### ***Coiling***

Wide hot-rolled coils from a hot-strip mill can be used in the as-rolled condition, with or without pickling, shearing, and flattening, and are known as hot-rolled sheet. When used for cold reduction, coils are pickled and cold reduced by as much as 90%. Intermediate or post cold-work heat treatments may be done. The last hot-rolling operation at the last finishing stand should be conducted above the upper critical temperature. This practice allows the strip to pass through a phase transformation after all hot work is finished and produces a uniformly fine, equiaxed ferritic grain throughout all portions of the strip. For low-carbon steels, the finish rolling temperature is around 845 °C (1550 °F). If part of the hot rolling operation is carried out on steel below the critical temperature, the deformed ferrite grains usually recrystallize and form patches of abnormally coarse grains during the self anneal induced by coiling at the usual temperatures of 650 to 730 °C (1200 to 1345 °F). Such a structure is more likely to appear on the surface of the product, which is colder than the interior of the strip during rolling. Thus, very thin hot-rolled strips, finished far below the upper critical temperature with rolled ferrite, and coiled too cold to self anneal, may retain microstructural evidence of hot working. Such sheets or strips are not suitable for deep- or extra-deep drawing applications and may necessitate a subsequent normalizing treatment.

Steels in which the sum of the carbon plus manganese contents is below 0.10 wt% exhibit a hot-short temperature range between 900 and 1035 °C (1650 and 1900 °F). Normal hot rolling in this temperature range can produce deep cracks on the product edge. To remedy this situation, some mills complete the roughing operations above the hot-short range, to allow the steel to cool through the range by holding it on the conveyor table between the last roughing stand and the finishing train and to resume rolling by passing the product into the finishing train below the hot-short range. This practice does not allow finishing rolling above the upper critical temperature.

The runout table following the last rolling stand is long enough with sufficient cooling arrangement to lower the temperature by up to 350 °C (630 °F) below the finishing temperature before coiling. The cooling practice used at this stage largely determines the metallurgical properties of the final rolled product. These practices are referred to as the controlled rolling and accelerated cooling processes. A uniform microstructure with characteristic carbide morphology and ferrite grain size is established during this holding period before coiling. If the steel is coiled at around 730 °C (1345 °F), the self-annealing produces considerable and undesirable carbide agglomeration, a coarse ferrite grain, and a soft ductile sheet. Coiling around 650 °C (1200 °F) produces a fine, dispersed spheroidal carbide in a finer ferrite matrix, resulting in a harder steel with sufficient ductility. Because a coil has different cooling rates at the edge and center of the strip as well as the center and outer portions of the coil, uniformity in cooling is achieved by using forced cooling with fans or water sprays. Even coiling temperatures lower than 650 °C (1200 °F) can be used when martensitic or bainite microstructures are desired (see the sub-section "High-Strength Low-Alloy Steels").

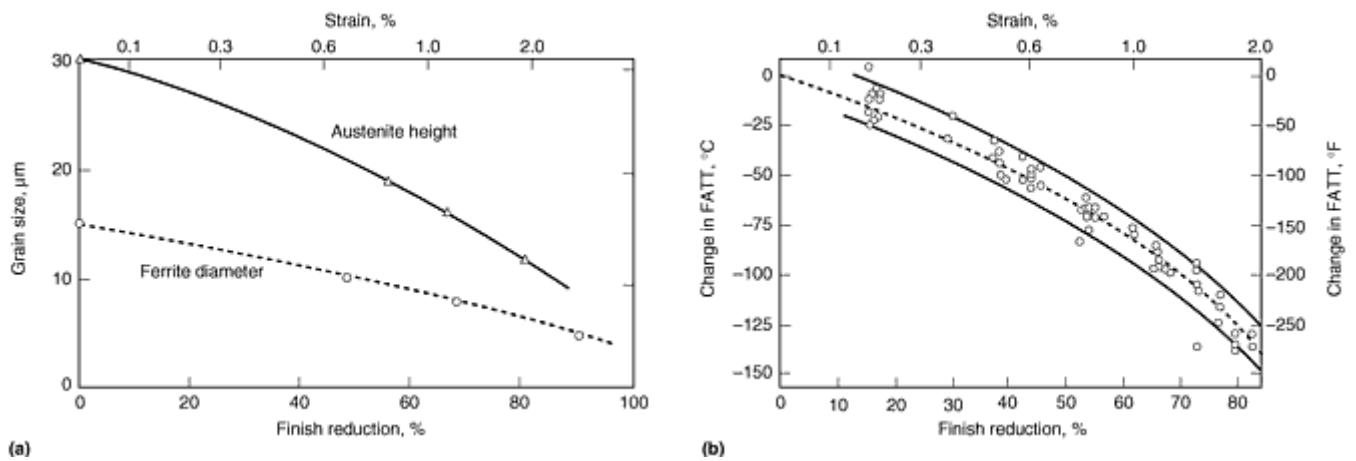

### ***Thermomechanical Processing***

The improvements in steelmaking, ladle metallurgy/refining, and continuous casting practices have been matched with other advances in the science and technology of microstructural control in the final product. It is this ability to control microstructure during processing that has allowed significant and cost-effective improvements in the final properties of steel to be achieved. Central to the concept of controlled processing is thermomechanical processing.

It is now possible to produce as-rolled steels with final properties tailored to the requirements of the final application. The concept of tailored final properties is possible primarily through the ability of the steelmaker to control the final microstructure in a predictable manner. This control of the final microstructure is based on an understanding of the way that steels respond to hot processing and how that response can be altered through alloying (Ref 52).

It is well known that the control (that is, refinement) of final microstructure begins during solidification and proceeds during reheating, hot rolling, and final transformation. Because the final transformed microstructure reflects the microstructure and composition of the austenite prior to transformation, it is obvious that the refinement of this final austenite is critical to obtaining the optimal final microstructure and properties. One of the key processing elements used to obtain the proper austenite microstructure is known as thermomechanical processing. As discussed in the following paragraphs, the most common form of thermomechanical processing in use today is called controlled rolling. During controlled rolling, it is the as-rolled austenite microstructure that is being controlled.

Because the goal of thermomechanical processing is the refinement of the austenite grain structure, the control of recrystallization and/or grain coarsening during processing are among the metallurgical techniques available. The presence of minute quantities of elements such as niobium, titanium, and vanadium have been shown to be particularly useful during thermomechanical processing because of the change in the solubilities of their carbides/carbonitrides/nitrides in austenite as a function of temperature. These elements are known as microalloying elements because they are generally present at levels at or below 0.1 wt%. Hence, the use of these microalloying elements enables the goal of thermomechanical processing to be easily achieved because these elements permit forces retarding recrystallization and grain coarsening to be governed by controlled precipitation during processing. It is, therefore, normal to have microalloyed steel mentioned in discussions of thermomechanical processing. The role of finish reduction on the refinement of ferrite grain size and the resultant improvement in toughness of microalloyed steels is shown in Fig. 23.

**Fig. 23** Effect of percent finish reduction on the (a) austenite and ferrite grain size and (b) fracture toughness (fracture appearance transition temperature, or FATT) for a general class of microalloyed steels

**Controlled Rolling.** The hot-rolling process has gradually become a much more closely controlled operation, and controlled rolling is now being increasingly applied to microalloyed steels with compositions carefully chosen to provide optimal mechanical properties at room temperature. Controlled rolling is a procedure whereby the various stages of rolling are temperature controlled, with the amount of reduction in each pass predetermined and the finishing temperature precisely defined. This process is widely used to obtain reliable mechanical properties in steels for pipelines, bridges, offshore platforms, and many other engineering applications. The use of controlled rolling has resulted in improved combinations of strength and toughness and further reductions in the carbon content of microalloyed high-strength low-alloy (HSLA) steels. This reduction in carbon content improves not only toughness but also weldability.

As mentioned previously, the basic objective of controlled rolling is to refine and/or deform austenite grains during the rolling process so that fine ferrite grains are produced during cooling. Controlled rolling can be performed on carbon steels but is most beneficial in steels with vanadium and/or niobium additions. During hot rolling, the undissolved carbonitrides of vanadium and niobium pin austenite grain boundaries and thus retard austenite grain growth. In carbon steels, however, the temperatures involved in hot rolling lead to marked austenite grain growth, which basically limits any benefit of grain refinement by controlled rolling. Controlled rolling is performed on strip, plate, and bar mills but not on continuous hot strip mills. On a hot strip mill, the water cooling on the runout table ensures a fine grain size.

The three methods of controlled rolling are:

- Conventional controlled rolling
- Recrystallization controlled rolling
- Dynamic recrystallization controlled rolling

These three methods use different techniques for grain refinement, but they are all preceded by a roughing operation to refine grain size by repeated recrystallization. In the roughing stage, stable carbonitride precipitates are desirable because they pin the grain boundaries of the recrystallized austenite and thus prevent their growth. Niobium is more effective than vanadium in preventing austenite grain growth during rolling because niobium forms precipitates that are less soluble than vanadium carbide in austenite. Roughing can achieve austenite grain sizes on the order of 20  $\mu\text{m}$ . The austenite grains are then either deformed or further refined by controlled rolling during finishing operations.

**Conventional controlled rolling** is based on the deformation, or flattening (pancaking), of austenite grains so that a large number of nucleation sites exist on the deformed austenite grain boundaries and on the deformation bands with the austenite grains. These nucleation sites allow the formation of very fine-grain ferrite during transformation cooling. This process requires a total reduction of up to 80% in a temperature range where the austenite deforms but does not recrystallize.

Niobium is the most effective alloying element for grain refinement by conventional controlled rolling. During the rolling reductions at temperatures below 1040 °C (1900 °F), the niobium in solution suppresses recrystallization by solute drag or by strain-induced Nb(C,N) precipitation on the deformed austenite and slip planes. The strain-induced precipitates are too large to affect precipitation strengthening but are beneficial for two reasons: They allow additional suppression of recrystallization by preventing migration of austenite grain subboundaries, and they provide a large number of nuclei in the deformed austenite for the formation of fine ferrite particles during cooling. The strain-induced precipitates in the austenite detract from the precipitation-hardening potential of the ferrite by removing the available niobium from austenite solid solution. Nevertheless, a useful measure of precipitation strengthening is possible in controlled-rolled niobium steels.

The controlled rolling of niobium steels can lead to ferrite grain sizes in the range of 5 to 10  $\mu\text{m}$  (ASTM grain size numbers 10 to 12). Because the precipitation of Nb(C,N) in the austenite during hot rolling retards recrystallization and raises the temperature at which recrystallization of austenite ceases (the recrystallization stop temperature), a broader temperature range is possible for hot working the steel to produce highly deformed austenite. The optimal amount of niobium to suppress recrystallization between passes can be as little as 0.02%. Titanium, zirconium, and vanadium are not as effective as niobium in raising the recrystallization stop temperature. Titanium and zirconium nitride formed during solidification and upon cooling of the slab do not readily dissolve upon reheating to hot-rolling temperatures. Although these nitrides can prevent grain coarsening upon reheating, they are not effective in preventing recrystallization because insufficient titanium or zirconium remains in solution at the rolling temperature to precipitate on deformed austenite grain boundaries during hot rolling and thus suppress austenite recrystallization. Vanadium, on the other hand, is so soluble that precipitation does not readily occur in the austenite at normal hot-rolling temperatures. The concentrations of niobium, titanium, vanadium, carbon, and nitrogen; the degree of strain; the time between passes; the strain rate; and the temperature of deformation all influence recrystallization during hot working.

**Recrystallization Controlled Rolling.** Although conventional controlled rolling can lead to very fine ferrite grain sizes, the low finishing temperature (750 to 900 °C, or 1400 to 1650 °F) of this method leads to increased rolling loads for heavy plate and thick-walled seamless tube. For thicker sections, recrystallization controlled rolling is used to refine austenite grain size. This process can result in ferrite grain sizes on the order of 8 to 10  $\mu\text{m}$ .

Recrystallization controlled rolling involves the recrystallization of austenite at successively lower temperatures below roughing temperatures, but still above 900 °C (1650 °F). Recrystallization should not be sluggish for this method to succeed, and thus vanadium can be beneficial because vanadium carbide is readily dissolved at rolling temperature and therefore unavailable for suppressing recrystallization. However, vanadium steels require stable carbonitrides, such as titanium nitride, to retard grain growth after recrystallization. Niobium steels, on the other hand, can undergo recrystallization controlled rolling at higher temperatures with Nb(C,N) precipitates eventually forming. This precipitation of Nb(C,N) will restrict austenite grain growth and may preclude the need for a titanium addition.

**Dynamic recrystallization controlled rolling** is used when there is insufficient time for recrystallization between rolling passes. This process initiates recrystallization during deformation and requires appreciable reductions (for example, 100%) to achieve an austenite grain size of 10  $\mu\text{m}$ . With low-temperature finishing, dynamic recrystallization can result in ferrite grain as fine as 3 to 6  $\mu\text{m}$ .

**Accelerated Cooling.** High-strength, control-rolled product can be obtained by low-temperature intercritical rolling combined with accelerated cooling through the transformation range. Faster cooling also retains solutes for subsequent precipitation strengthening of ferrite. If fine austenite is being transformed, fine polygonal ferrite pearlite or acicular ferrite-fine bainite with good strength and toughness can be obtained. Accelerated cooling must, therefore, be used in combination with controlled rolling, because coarse austenite can transform into upper bainite lowering the toughness considerably. Because accelerated cooling makes efficient use of both hardenability agents (such as molybdenum and boron) and microalloying additions, leaner and more economical steels with lower carbon equivalent can be used for higher strength, toughness, and weldability requirements.

The Stelmor process is another form of controlled accelerated cooling applied to wire and rod production in a continuous mill. In one form of Stelmor line applied to reinforcing bar production, the round product is passed through a water-spray box at very high speeds, causing the surface of the steel to quench and form martensite. However, as the wire is placed in the laying cone, the internal heat from the core of the product tempers the martensite producing a composite structure. The hard tempered surface provides strength and proper surface and scale characteristics while the core is tough with a predominantly ferrite-pearlite structure. Such a composite product is better suited as reinforcing bar without the need for cold twisting.

## Pickling

The oxide scale on the surface of strip, sheet, plate, or semifinished products is not acceptable when the steel is to be further processed. If the steel is to be cold rolled or coated, as in galvanized, terne coated, or painted sheet and strip, removal of surface oxide is particularly important. In drawing operations, scale removal is essential to ensure a smooth finished surface and to protect the die from abrasive oxides. The surface scales are primarily iron oxides produced during hot rolling. The nature of the scale depends on the temperature and the gaseous environment. Common practices for the removal of scale include a physical method of shot blasting or a chemical method of pickling. Pickling involves chemical removal of oxides and scale from the surface by a water solution of inorganic acids, such as sulfuric or hydrochloric acid. Pickling equipment ranges from batch types to fully continuous picklers.

The chemical reaction of pickling acids with the metal produces a sulfate or chloride salt along with hydrogen gas. When scale reacts with the acids, water is produced instead of hydrogen. Nickel, chromium, and copper retard the dissolution of iron or the scale because the scales bearing these elements resist acid attack. Silicon and aluminum themselves form refractory oxides and lower the scale solubility rate. Iron is more readily attacked by the acids than the scale. Scales containing iron in higher oxidation states are more difficult to react. The rate of pickling is also dependent on the adherence of the scale. Solution temperature and concentration, ferrous sulfate concentration, agitation, time of immersion, and presence of inhibitors affect the rate of acid attack. Temperature has more pronounced effect than concentration. Typically, pickling baths are maintained at a temperature in the range of 65 to 80 °C (150 to 175 °F) and the rate is controlled by adjusting the concentration. Such a practice helps in saving fuel for heating and maintaining the inhibitor stability. Concentration of the pickling bath varies over a wide range depending on the amount of pickling required. Continuous baths are usually stronger and held at higher temperatures because pickling is required in a shorter time. Sulfuric acid baths range from 12 to 25% while hydrochloric acid baths range from 5 to 50% in acid concentration. Buildup of ferrous sulfate has a retarding effect on the pickling rate and a level of up to 25% is allowed to build. Much higher levels of ferrous chloride are allowed. Baths are usually worked until the free acid drops to 5%. Agitating either the workpiece or the liquid is a common practice that saves time, acid, and metal loss. Other bath additives include inhibitors, wetting agents, brightening agents, etc. Inhibitors lower the metal dissolution rate, enhance the attack on the scale and prevent foaming of the bath. Good inhibitors should be cheap and effective in smaller concentrations, while producing a stain-free clean metal surface. Wetting agents serve the purpose of lowering the surface tension between the bath and the steel surface. Brightening agents, as the name suggests, add to the brightness and smoothness of the surface.

Hydrochloric acid pickling provides a faster and cleaner pickling with less acid consumption and reduced quantities of waste pickle liquor. Because lower temperatures are used in hydrochloric acid pickling, steam consumption is ~40% lower. When compared to sulfuric acid pickling, hydrochloric acid pickling is 2.5 to 3.5 times faster at comparable temperatures and acid concentration. Hydrochloric acid is also more effective in removing embedded metal and scale particles. Typical acid consumption rates for sulfuric acid and hydrochloric acid vary between 15 to 22.5 kg and 5 to 7 kg per metric ton of steel, respectively. Hydrochloric acid baths provide greater versatility as scale breaking and temper rolling are usually not required for high-speed pickling, which is often a necessity in a sulfuric acid pickling line. Pickled surfaces are generally washed and dried before subsequent processing. Pickling prepares the surface for better bonding and adhesion in cases of galvanizing, coating, or a paint application (Ref 53).

## Specialized Processing Routes

### *Ultralow Plain Carbon Steels*

The principal factors affecting the properties of the plain carbon steels are the carbon content and the microstructure. Manganese is a solid solution strengthener. The properties can be modified by the effects of residual elements other than carbon, manganese, silicon, phosphorus, and sulfur, which are usually picked up from the scrap, deoxidizers, and furnace refractories. In addition, gaseous hydrogen, nitrogen, and oxygen also affect steel properties, as has been mentioned earlier. Control of these extraneous agents is always critical during steelmaking. Steelmakers have adopted some very sophisticated processing techniques over the last two decades to achieve this end. Because carbon is the main element in plain carbon steels providing strength, carbon contents of less than 0.05% and manganese contents of the order of 0.20% are desired in steels intended for a high-level of cold formability. These steels are used for deep and extra-deep drawability and stretch formability applications, particularly in the automotive industry. The plastic strain ratio ( $r$ ) and strain hardening exponent ( $n$ ) are critical parameters along with high uniform elongation (Ref 54). Figure 24 shows the effect of carbon on some of the prominent mechanical properties reflecting high formability.

**Fig. 24** Effect of carbon content on the mechanical properties of steels. Note: 1 kg/mm<sup>2</sup> = 9.806 MPa

Figure 25 shows a typical process route for ultralow carbon steels. The steel is fully killed with aluminum and the carbon and nitrogen levels are further lowered below 0.001% by niobium or titanium treatment during secondary steelmaking. The steel can then be cast into ingots or continuously cast. Soaking temperatures in excess of 1200 °C (2190 °F) to add aluminum nitride into solution and coiling below 560 °C (1040 °F) to suppress aluminum nitride precipitation are critical steps in processing. High-temperature coiling lowers the cooling rate in a tightly wound coil and causes nitride precipitation. Favorable texturing can be obtained by subsequent cold rolling and annealing of the hot-coiled material in thin gages. Aluminum nitride precipitates during annealing give rise to {111} texturing as well as ferrite grain growth. The highest strain ratios can be obtained by maintaining aluminum and nitrogen contents in the range of 0.025 to 0.04 % and 0.005 to 0.01%, respectively. High annealing temperatures (>730 °C, or 1350 °F) are avoided to prevent carbide coarsening and sticking of coil laps. Adjustment of cooling rate during annealing is practiced to retain some of the carbon in solid solution, which imparts strength to the sheets and strips of ultralow carbon steel. Continuous annealing of low-carbon materials can be adopted for lower carbon levels of less than 0.02%, whereas batch annealing can be used to process up to 0.05% carbon steels (Ref 55).

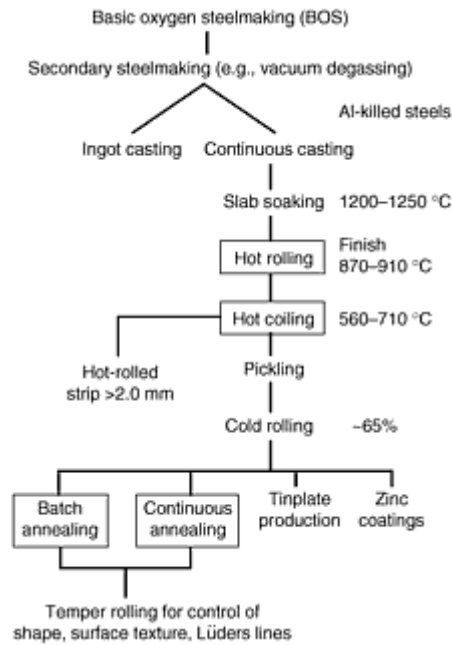

Fig. 25 Typical flow diagram for processing low-carbon strip steel

### Interstitial-Free Steels

Flat-rolled steels with carbon less than 0.003% and manganese below 0.18%, with special emphasis on low nitrogen to prevent aging effects and low hydrogen to prevent flaking, are classified as interstitial-free steel. Lowering of carbon and nitrogen is achieved by niobium, titanium, and boron treatments during secondary steelmaking. A boron-to-nitrogen ratio of 0.8 to 1.0 is beneficial in these steels, because boron has a greater affinity for nitrogen than aluminum, allowing relatively higher coiling temperature. In such steels, titanium carbides raise the recrystallization temperature. Therefore, the steels are finish rolled above 950 °C (1740 °F). Interstitial-free steels are characterized by a high strain ratio of above 2.0, where excellent forming properties can be achieved by continuous annealing. Small additions of phosphorus (rephosphorized steel: up to 0.1% P), manganese, and silicon are sometimes used to impart some strength in interstitial-free steels and are known as interstitial-free high-strength steels (IF-HSS). These steels maintain their formability without any impairment of weldability (Ref 56).

### High-Strength Low-Alloy Steels

Both the interstitial-free steels and the ultralow plain carbon steels have low strength due to low carbon and manganese levels (tensile strength below ~300 MPa, or 40 ksi) and are not suitable for high-strength applications. These grades have been specifically designed for high formability. However, there is a strong interest in weldable, formable, high-strength flat products in both hot- and cold-rolled conditions. The need to use lighter gages for weight reduction while maintaining a high strength level (yield strengths ranging from 410 to 550 MPa, or 60 to 80 ksi, are common) and structural integrity, has led to the development of a microalloyed class of steel, known as high strength low alloy (HSLA) steels. A minimum tensile strength of 480 MPa (70 ksi) is achieved in some common grades of HSLA steels. Small additions of one or more of the alloying agents, such as vanadium, niobium, titanium, boron, zirconium, chromium, silicon, nitrogen, and/or copper are made to molten steel after ladle deoxidation or during secondary steelmaking to achieve one or more of the following objectives (Ref 57):

- Precipitation strengthening
- Solid-solution strengthening
- Ferrite grain-refinement
- Transformation strengthening

In addition, corrosion resistance, excellent weldability, and high room-temperature and low-temperature notch-toughness values are also desired in HSLA steels for specific applications. The specific role of each of these additions is discussed in

Ref 58. It should be emphasized that lowering the sulfur content in steels is desired for automotive grades, line pipe steels, and corrosion-resistant products (Ref 59). The influence of very small additions of microalloying elements on the properties of HSLA steels is clearly demonstrated in Fig. 26. A good deoxidation practice is essential for HSLA grades so that a high recovery of the alloying additions can be achieved. These steels are produced as flat-rolled sheet, strip, and plate materials as well as structural shapes, for example, line pipe tubulars, gas-container steels, reinforcing bars, cold-heading steel, etc.

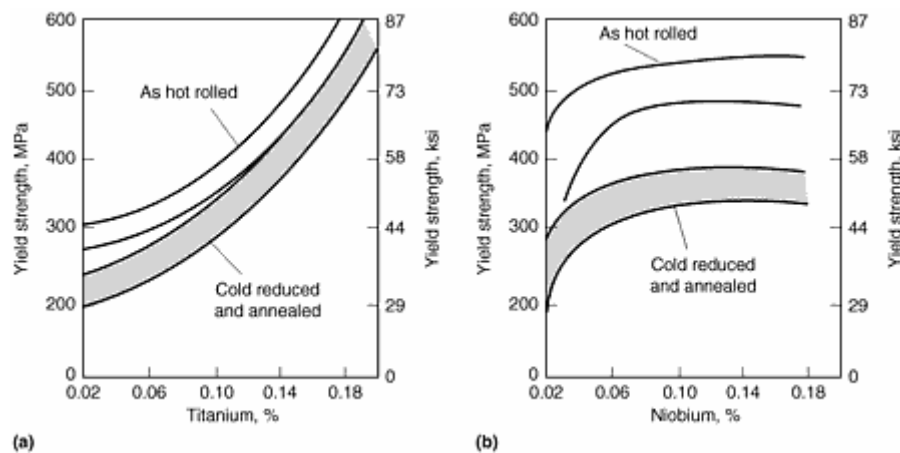

Fig. 26 Effect of microalloying on yield strength of hot- and cold-rolled steel strips

### Ultrahigh Strength Steels

Several grades of engineering steels having ultrahigh strengths (over 1000 MPa, or 145 ksi, tensile strength) have been developed either through high-alloy additions of chromium, molybdenum, nickel, vanadium, and manganese in combination with low-carbon contents or through low-to-high alloy additions in combination with medium-to-high carbon levels ( $>0.40\%$  C). The former type of high-alloy steels with low carbon are used for turbine blades, rings, bolts, and casings, whereas the latter medium-to-high, carbon-bearing steels are needed for high-strength rail steels, bearing steels, forging steels, tool steels, high-speed steels, and high-carbon wire rods. The important properties desired in these grades are high-room and elevated-temperature hardenability (through hardness or surface hardness) in combination with high toughness.

Quality of these ultrahigh strength steels has significantly improved with the introduction of vacuum degassing technology as well as inclusion shape control. Argon shrouding of the liquid stream during teeming and casting is practiced to prevent reoxidation and to reduce the non-metallic inclusion content while vacuum induction melting and vacuum arc remelting are common practices for producing exceptionally clean steels (Ref 60). Slag-free tapping, ladle stirring, and the use of high-alumina ladle refractories are some other integral aspects of clean steel production. Inclusion shape control is administered through lead, selenium, tellurium, calcium, bismuth, or rare-earths addition. Niobium, vanadium, or titanium are also added as microadditions for similar property enhancement similar to HSLA steels. Low-sulfur petroleum coke is usually the source for increasing carbon level. The recent commercialization of iron carbide can provide a better source for carburization of steel melts due to its low tramp element level and higher density than petroleum coke.

### Cold-Rolled Products

Cold-rolled finished products include flat bars, cold-rolled strips and sheets, and black plate, which are made from plain carbon steels and alloyed steels, including stainless steels. Tempering, annealing, and edging are associated steps in cold rolling. The chosen processing scheme is dictated entirely by the application. Cold rolling implies passing unheated metal through rolls for thickness reduction, surface finish improvement, and controlled mechanical properties. The metal for cold rolling is generally produced in coiled form in a hot-strip mill. Prior to cold reduction, the hot-rolled coils are uncoiled, pickled, dried, oiled, and recoiled. The coils are reduced at very high speeds by looping the metal from one coil to the other. Heavy reductions of up to 90% may be taken in a single strand reversing mill or a tandem mill. The design of a cold-rolling process is based on the type of mill, power available, steel width, total reduction, steel hardness and tension,

lubrication, and desired surface finish. On multiple-strand mills or a reversing mill, the last pass is primarily used for control of gage thickness, flatness, and surface finish and not for the purpose of reduction (Ref 61).

Cold-rolled material is sometimes used in the as-rolled condition to make use of its cold-worked high strength depending on the application. Generally, the metal requires heat treatment to control the mechanical properties. A surface cleaning step, either chemical, electrochemical, or mechanical, is taken before heat treatment. The low-carbon, deep-drawing type steels are usually annealed in a box furnace or a continuous furnace at a low temperature of  $\sim 675^{\circ}\text{C}$  ( $1250^{\circ}\text{F}$ ) to encourage recovery and recrystallization while preventing any grain growth. Other types of heat treatments can be performed after cold reduction, for example, to solutionize chromium carbides in stainless steel strips or to form a passive oxide on transformer-grade, silicon-steel sheets.

Subsequent to heat treatment, a temper rolling may be necessary to achieve certain features in the product, such as suppression of yield-point elongation that causes Lüder lines (Ref 62), a bright surface finish, and surface flatness and shape improvements. Usually, the reduction achieved during temper rolling is restricted to below 2% to prevent a decrease in ductility. Shearing, side trimming, slitting, and leveling follow temper rolling of cold-rolled products.

Some prominent surface defects of cold-rolled products are seams and slivers that have their origin in the inclusions trapped during steel casting. When the steel gage is heavily reduced, nonmetallic inclusions appear on the surface and spall off. In addition, a critical aluminum to nickel balance is required in cold-rolled products for the development of favorable texturing. Thus, it can be readily seen that deoxidation, inclusion control, and nitrogen balance are key steelmaking factors in cold-rolled materials. Fully aluminum-killed steels, cast in wide-end-up molds after argon rinsing and under complete inert shrouding are known to possess enhanced mechanical and surface properties for cold-rolling application.

## ***Stainless Steels***

Iron-chromium steels, with possible additions of nickel and molybdenum, in combination with low carbon contents, are designated as "stainless steels" when a minimum of 12% Cr is present to provide a passive layer of chromium oxide on the surface. This passive layer is responsible for the high corrosion resistance realized in stainless steels. Stainless steel was traditionally made in small EAFs by melting steel scrap, nickel, and ferrochrome before the advent of oxygen refining. The modern practice of making stainless steel is based on a two-stage process. The first stage employs a conventional EAF for the rapid melting of scrap and ferroalloys but uses cheap high-carbon ferrochrome as the main source of chromium. Because stainless steel manufacturing involves more scrap melting and alloying and less refining, EAFs are preferred over the oxygen-based converter processes due to high external energy loads. The high-carbon melt prepared in an EAF is then refined in a second stage, using either AOD or by blowing with oxygen under VOD (see the section "Secondary Steelmaking" ). The AOD process currently produces over 80% of the stainless steel tonnage worldwide. Special desulfurizing slags are used in AOD where intimate metal-slag mixing can be achieved using argon stirring. Oxygen is capable of decarburizing the melt to less than 0.01% C, and hydrogen levels are below 2 to 3 ppm. Sensitization in austenitic stainless steels leading to intergranular corrosion is markedly influenced by the presence of elongated particles or clusters of second phases, such as sulfides or other inclusions. The presence of nitrogen in some niobium-bearing stainless grades leads to carbonitride formation, which also deleteriously influences sensitization. Control of gaseous inclusions as well as sulfur are important in refining of stainless steels.

Stainless steels require expensive alloying additions of chromium, nickel, and molybdenum. Therefore, recovery of these elements needs special attention. Efficient slag reduction with stoichiometric amounts of silicon or aluminum permits overall recoveries of 97 to 100% for most metallic elements. Chromium recovery averages approximately 97.5%, and nickel and molybdenum recoveries are approximately 100%. Casting is usually done in a continuous caster for better productivity, although ingot casting and primary rolling is still more common for stainless steels than carbon steels. The cost of ferrochrome production affects stainless steel prices directly.

Commercial varieties of stainless steels are classified as austenitic (work hardenable), ferritic (work hardenable), austenitic-ferritic (duplex), or martensitic (hardenable by heat treatment). Although this classification is based on microstructure, it relates to two primary roles of alloy additions: (1) the balance between austenite formers (N, C, Ni, Co, Cu, and Mn) and ferrite formers (W, Si, Mo, Cr, V, and Al) controlling the high-temperature microstructure and (2) the overall alloy content, which controls the martensite transformation range,  $M_s$ - $M_f$ , and the degree of martensite transformation at ambient temperature. Figure 27 (Ref 63) shows the effect of ferrite-forming (chromium equivalent) and austenite-forming (nickel equivalent) alloy additions on the type of stainless steel produced.

Fig. 27 Modified Schaeffler constitution diagram for stainless steels. The compositions of the ferritic, martensitic, austenitic, and duplex alloys are superimposed on this diagram.

Stainless steels have lower thermal conductivity than carbon or alloy steels below 815 °C (1500 °F) and, therefore, need special attention in heating below 815 °C (1500 °F) to avoid surface burning. In addition, hot-working temperature ranges for stainless steels are narrower than for carbon steels, requiring better temperature control during soaking and rolling. Martensitic grades are slow cooled or annealed after rolling because they are air hardening. Ferritic grades are finish rolled to lower temperatures to prevent grain growth that could lead to tearing and cracking. Austenitic grades require more rolling-mill power because they are stronger than ferritic grades and are also susceptible to grain growth. Sulfur control in reheating furnace atmospheres is important for austenitic grades due to the presence of nickel. Liquid nickel sulfide formation at the grain boundaries during rolling can lead to tears and cracks. Cold rolling of stainless steel has two primary objectives--reduction of hot-rolled gage and cold forming into components. Except the high-carbon grades, all stainless steels are amenable to cold working. Pickling is performed following hot rolling.

## Analytical Techniques for Liquid Steel

It cannot be overemphasized that properties of a steel are primarily determined by its chemical composition and that the steelmaker has no control of the composition once the metal is cast. The computerization of the primary and secondary steelmaking processes and the dramatic reduction in time required to make steel by modern methods has put tremendous pressure on the time available for liquid metal analysis. The chemist must return the chemical composition analysis of liquid steel rapidly so that corrective actions may be taken, if necessary. Unfortunately, the techniques available for rapid and accurate analysis are limited.

Chemical analysis is employed to determine whether or not material is within ordered chemical limits and sometimes to check the degree to which elements contained in the steel have segregated. Elemental analysis of carbon, silicon, sulfur, phosphorus, and manganese go hand in hand with oxygen and nitrogen gas measurements as well as the temperature monitoring. Usually, a pyrometer or an immersion thermocouple is employed to accurately measure the temperature. Consumable oxygen sensors are commonly used for on-line total oxygen analysis. However, the rapid determination of concentrations of alloying elements in steels is performed by the optical emission spectroscopy methods.

Optical emission spectroscopy can determine major as well as trace elemental constituents qualitatively and quantitatively. Free atoms emit light at a series of narrow wavelength intervals when placed in an energetic environment. These intervals, or emission lines, form a pattern, or the emission spectrum, which is characteristic of the atom producing it. The intensities of the lines are proportional to the number of atoms producing them. The presence of an element in a sample is indicated by the presence in light from the excitation source of one or more of its characteristic lines. The concentration of the element can be determined by measuring line intensities (Ref 64). The characteristic emission spectrum forms the basis for qualitative elemental analysis, whereas the measurement of intensities of the emission lines forms the basis for quantitative analysis.

The liquid sample is collected from the steelmaking furnace during the refining period or the ladle during secondary steelmaking and prior to casting. The sample is immediately cast into a form suitable for the spectroscope. Some surface grinding of the active surface may be done prior to analysis. An emission light source is used to decompose the sample into an atomic vapor and then excite the vapor with sufficient efficiency to produce a measurable emission signal. Four types of emission sources are available: arcs, high-voltage sparks, glow discharges, and flames. Each emission source has a set of physical characteristics with accompanying analytical capability and limitations.

Spark and glow-discharge emission sources are most common for rapid compositional analysis during steelmaking. Spark-source excitation is the most rapid method for analyzing an alloy sample. Analysis can be done in as little as thirty seconds and usually can be done within a couple of minutes. While flame sources are appropriate for analyzing trace levels of alkali metals down to a few ppm, glow-discharge source is more suited for carbon, phosphorus, and sulfur analysis. Detection limits are as low as 0.002% for sulfur and 0.014% for carbon.

Other analytical techniques suitable for chemical analysis of steels include atomic absorption spectroscopy, x-ray fluorescence, and inductively-coupled and direct-current plasma emission spectroscopies. Some of these techniques require the dissolution of samples in a solvent. Qualitative analysis of sulfur and phosphorus is also performed by sulfur and phosphorus prints, but these are not used for rapid analysis.

# Classifications and Designations of Carbon and Alloy Steels

---

## Introduction

WROUGHT CARBON AND ALLOY STEELS with total alloying element contents that do not exceed 5% are considered in this article. Ferrous materials that are cast or made by powder metallurgy methods are not included, but are described elsewhere in this Handbook. The same is true for tool steels, more highly alloyed stainless steels, and steels used primarily for their magnetic or electrical properties (e.g., silicon steels).

## Important Terms and Definitions

**Classification** is the systematic arrangement or division of steels into groups on the basis of some common characteristic. Steels can be classified on the basis of (1) composition, such as carbon or alloy steel; (2) manufacturing method, such as basic oxygen furnace steel or electric-arc furnace steel; (3) finishing method, such as hot-rolled or cold-rolled sheet; (4) microstructure, such as ferritic or martensitic; (5) the required strength level, as specified in ASTM standards; (6) heat treatment, such as annealed or quenched-and-tempered; (7) quality descriptors, such as forging quality or structural quality; or (8) product form, such as bar, plate, sheet, strip, tubing, or structural shape. Classification by product form is very common within the steel industry because by identifying the form of a product, the manufacturer can identify the mill equipment required for producing it and thereby schedule the use of these facilities.

Common usage has further subdivided these broad classifications. For example, carbon steels are often loosely and imprecisely classified according to carbon content as low-carbon (up to 0.30% C), medium-carbon (0.30 to 0.60% C), or high-carbon (0.60 to 1.00% C) steels. They may be classified as rimmed, capped, semikilled, or killed, depending on the deoxidation practice used in producing them. Alloy steels are often classified according to the principal alloying element (or elements) present. Thus, there are nickel steels, chromium steels, and chromium-vanadium steels, for example. Many other classification systems are in use, the names of which are usually self-explanatory.

**Grade, type, and class** are terms used to classify steel products. Within the steel industry, they have very specific uses: grade is used to denote chemical composition; type is used to indicate deoxidation practice; and class is used to describe some other attribute, such as strength level or surface smoothness.

In ASTM specifications, however, these terms are used somewhat interchangeably. In ASTM A 533, for example, type denotes chemical composition, while class indicates strength level. In ASTM A 515, grade identifies strength level; the maximum carbon content permitted by this specification depends on both plate thickness and strength level. In ASTM A 302, grade connotes requirements for both chemical composition and mechanical properties. ASTM A 514 and A 517 are specifications for high-strength plate for structural and pressure-vessel applications, respectively; each contains several compositions that can provide the required mechanical properties. A 514 type F has the identical composition limits as A 517 grade F.

**Designation** is the specific identification of each grade, type, or class of steel by a number, letter, symbol, name, or suitable combination thereof unique to a particular steel. Chemical composition is by far the most widely used basis for designation, followed by mechanical-property specifications. The most commonly used system of designation in the United States is that of SAE International (formerly the Society of Automotive Engineers) and the American Iron and Steel Institute (AISI). The Unified Numbering System (UNS) is also being used with increasing frequency. A description of each of these designation systems follows.

**Quality.** The steel industry uses the term "quality" in a product description to imply special characteristics that make the mill product particularly well suited to specific applications or subsequent fabrication operations. The term does not necessarily imply that the mill product is better material, is made from better raw materials, or is more carefully produced than other mill products.

**A specification** is a written statement of attributes that a steel must possess in order to be suitable for a particular application, as determined by processing and fabrication needs and engineering and service requirements. It generally

includes a list of the acceptable values for various attributes that the steel must possess and, possibly, restrictions on other characteristics that might be detrimental to its intended use.

**A standard specification** is a published document that describes a product acceptable for a wide range of applications and that can be produced by many manufacturers of such items. Even if there is no standard specification that completely describes the attributes required for a steel product to be used in a particular application, it may be preferable to cite the most nearly applicable standard specification and those exceptions necessitated by the particular application. By doing so, the familiarity of both producer and user with the standard specification is retained, while an individualized product can be obtained.

A specification can be advantageously used in purchasing steel (or any other product) by incorporating it into the purchase agreement. The specification clearly states which attributes the product must possess. The use of a designation alone as the basis for purchase indicates that the buyer is specifying only those attributes described in the designation and permitting the supplier the latitude to produce the item according to his usual practice. The distinction between specifications and standard practices follows.

### Quality Descriptors

The need for communication among producers and between producers and users has resulted in the development of a group of terms known as fundamental quality descriptors. These are names applied to various steel products to imply that the particular products possess certain characteristics that make them especially well suited for specific applications or fabrication processes. The fundamental quality descriptors in common use are listed in Table 1.

**Table 1 Quality descriptions of carbon and alloy steels**

Carbon steels
Semifinished for forging
Forging quality
Special hardenability
Special internal soundness
Nonmetallic inclusion requirement
Special surface
Carbon steel structural sections
Structural quality
Carbon steel plates
Regular quality
Structural quality
Cold-drawing quality
Cold-pressing quality
Cold-flanging quality
Forging quality
Pressure vessel quality
Hot-rolled carbon steel bars
Merchant quality
Special quality
Special hardenability
Special internal soundness
Nonmetallic inclusion requirement

<p>Special surface</p> <p>Scrapless nut quality  Axle shaft quality  Cold extrusion quality  Cold-heading and cold-forging quality</p>
<p>Cold-finished carbon steel bars</p> <p>Standard quality</p> <p>Special hardenability  Special internal soundness  Nonmetallic inclusion requirement  Special surface</p> <p>Cold-heading and cold-forging quality  Cold extrusion quality</p>
<p>Hot-rolled sheets</p> <p>Commercial quality  Drawing quality  Drawing quality special killed  Structural quality</p>
<p>Cold-rolled sheets</p> <p>Commercial quality  Drawing quality  Drawing quality special killed  Structural quality</p>
<p>Porcelain enameling sheets</p> <p>Commercial quality  Drawing quality  Drawing quality special killed</p>
<p>Long terme sheets</p> <p>Commercial quality  Drawing quality  Drawing quality special killed  Structural quality</p>
<p>Galvanized sheets</p> <p>Commercial quality  Drawing quality  Drawing quality special killed  Lock-forming quality</p>
<p>Electrolytic zinc coated sheets</p> <p>Commercial quality  Drawing quality  Drawing quality special killed</p>

Structural quality
Hot-rolled strip <div> Commercial quality Drawing quality Drawing quality special killed Structural quality </div>
Cold-rolled strip <div> Specific quality descriptions are not provided in cold-rolled strip because this product is largely produced for specific end use </div>

<b>Alloy steels</b> <b>Alloy steel plates</b> <p> Drawing quality  Pressure vessel quality  Structural quality  Aircraft physical quality </p>
<b>Hot-rolled alloy steel bars</b> <p> Regular quality  Aircraft quality or steel subject to magnetic particle inspection  Axle shaft quality  Bearing quality  Cold-heading quality  Special cold-heading quality  Rifle barrel quality, gun quality, shell or armor-piercing shot quality </p>
<b>Alloy steel wire</b> <p> Aircraft quality  Bearing quality  Special surface quality </p>
<b>Cold-finished alloy steel bars</b> <p> Regular quality  Aircraft quality or steel subject to magnetic particle inspection  Axle shaft quality  Bearing shaft quality  Cold-heading quality  Special cold-heading quality  Rifle barrel quality, gun quality, shell or armor-piercing shot quality </p>
<b>Line pipe</b>
<b>Oil country tubular goods</b>
<b>Steel specialty tubular goods</b> <p> Pressure tubing  Mechanical tubing  Stainless and head-resisting pipe, pressure tubing, and mechanical tubing  Aircraft tubing  Pipe </p>

Some of the quality descriptors listed in Table 1, such as forging quality or cold extrusion quality, are self-explanatory. The meaning of others is less obvious: for example, merchant quality hot-rolled carbon steel bars are made for noncritical applications requiring modest strength and mild bending or forming, but not requiring forging or heat treating. The descriptor for one particular steel commodity is not necessarily carried over to subsequent products made from that commodity, for example, standard quality cold-finished bars are made from special quality hot-rolled bars.

The various mechanical and physical attributes implied by a quality descriptor arise from the combined effects of several factors, including: (1) the degree of internal soundness; (2) the relative uniformity of chemical composition; (3) the relative freedom from surface imperfections; (4) the size of the discard cropped from the ingot; (5) extensive testing during manufacture; (6) the number, size, and distribution of nonmetallic inclusions; and (7) hardenability requirements. Control of these factors during manufacture is necessary to achieve mill products having the desired characteristics. The extent of the control over these and other related factors is also conveyed by the quality descriptor.

Some, but not all, of the fundamental descriptors can be modified by one or more additional requirements as appropriate: special discard, macroetch test, restricted chemical composition, maximum incidental (residual) alloy, special hardenability, or austenitic grain size. These restrictions could be applied to forging quality alloy steel bars, but not to merchant quality bars.

Understanding the various quality descriptors is complicated by the fact that most of the requirements that qualify a steel for a particular descriptor are subjective. Only nonmetallic inclusion count, restrictions on chemical composition ranges and incidental alloying elements, austenitic grain size, and special hardenability are quantified. The subjective evaluation of the other characteristics depends on the skill and experience of those who make the evaluation. Although these subjective quality descriptors might seem imprecise and unworkable, steel products made to meet the requirements of a particular quality descriptor have those characteristics necessary for use in the indicated application or fabrication operation.

## Specifications

A specification is a written statement of the requirements, both technical and commercial, that a product must meet; it is a document that controls procurement. There are nearly as many formats for specifications as there are groups writing them, but any reasonably adequate specification will provide information about:

- *Scope*, which can cover product classification (including size range when necessary), condition, and any comments on product processing deemed helpful to either the supplier or user. An informative title plus a statement of the required form can be used instead of a scope clause.
- *Chemical composition*, which can be detailed or indicated by a well-recognized designation based on chemical composition. The SAE-AISI designations are frequently used.
- *The quality statement*, which includes any appropriate quality descriptor and whichever additional requirements are necessary. It can also include the type of steel and the steelmaking processes permitted.
- *Quantitative requirements*, which identify allowable ranges of the composition and all physical and mechanical properties necessary to characterize the material. Test methods used to determine these properties should also be included, at least by reference to standard test methods. For reasons of economy, this section should be limited to properties that are germane to the intended application.
- *Additional requirements*, which can include special tolerances, surface preparation, and edge finish on flat-rolled products, as well as special identification, packaging, and loading instructions.

Engineering societies, associations, and institutes whose members make, specify, or purchase steel products publish standard specifications, many of which have become well known and highly respected. Some of the important specification-writing groups are listed below. It is obvious from the names of some of these that the specifications prepared by a particular group may be limited to its own specialized field:

Organization	Acronym
Association of American Railroads	AAR

American Bureau of Shipbuilding	ABS
American Petroleum Institute	API
American Railway Engineering Association	AREA
American Society of Mechanical Engineers	ASME
American Society for Testing and Materials	ASTM
Society of Automotive Engineers	SAE
Aerospace Material Specification (of SAE)	AMS

The most comprehensive and widely used specifications are those published by ASTM. ASTM specifications pertaining to steel products exist at three distinct levels. ASTM A 6 contains the general requirements for most carbon steel structural products. ASTM A 588, for example, incorporates the general requirements of A 6 and describes the more specific requirements of a family of high-strength low-alloy (HSLA) steels. Other specifications, such as A 231 for alloy steel spring wire, refer to a particular product intended for a specific application.

Other specifications for steel products have been prepared by various corporations and United States government agencies to serve their own special needs. They are used primarily for procurement by that corporation or agency, and they receive only limited distribution or use beyond these channels.

There is an important difference between specifications and standard practices. As indicated above, a specification is a statement of the requirements that a product must meet. When it is cited by a purchaser and accepted by a supplier, it becomes part of the purchase agreement. Many manufacturers of steel mill products publish compilations of their standard manufacturing practices. These data represent the dimensions, tolerances, and properties that might be expected in the absence of specific requirements that indicate otherwise. The *AISI Steel Products Manuals* are compilations of the AISI designations for carbon and alloy steels, the standard practices of many steelmakers, and related scientific and technical information that has been reported to the institute. AISI states that the *Steel Products Manuals* are not specifications; however, they are a good indication of what restrictions and tolerances many producers of steel mill products will accept. Commercial tolerances and practices described in these manuals should, whenever possible, be incorporated into a proprietary specification in order to minimize the additional cost incurred by ordering "nonstandard" steel products.

## Chemical Analysis

Chemical composition is often used as the basis for classifying steels or assigning standard designations to steels. Such designations are often incorporated into specifications for steel products. Users and specifiers of steel products should be familiar with methods of sampling and analysis.

Chemical analyses of steels are usually performed by wet chemical analysis methods or spectrochemical methods. Wet analysis is most often used to determine the composition of small numbers of specimens or of specimens composed of machine tool chips. Spectrochemical analysis is well-suited to the routine determination of the chemical composition of a large number of specimens, as may be necessary in a steel mill environment. Both classical wet chemical and spectrochemical methods for analyzing steel samples are described in detail in *Materials Characterization*, Volume 10, *ASM Handbook*.

**Heat and Product Analysis.** During the steelmaking process, a small sample of molten metal is removed from the ladle or steelmaking furnace, allowed to solidify, and then analyzed for alloy content. In most steel mills, these heat

analyses are performed using spectrochemical methods; as many as 14 different elements can be determined simultaneously. The heat analysis furnished to the customer, however, may include only those elements for which a range or a maximum or minimum limit exists in the appropriate designation or specification.

A heat analysis is generally considered to be an accurate representation of the composition of the entire heat of metal. Producers of steel have found that heat analyses for carbon and alloy steels can be consistently held within ranges that depend on the amount of the particular alloying element desired for the steel, the product form, and the method of making the steel. These ranges have been published as commercial practice, then incorporated into standard specifications. Standard ranges and limits of heat analyses of carbon and alloy steels are given in Tables 2, 3, 4, and 5.

**Table 2 Carbon steel cast or heat chemical limits and ranges**

Applicable only to semifinished products for forging, hot-rolled and cold-finished bars, wire rods, and seamless tubing

Element	Maximum specified element, %	of Range, %
Carbon <sup>(a)</sup>	$\leq 0.12$	...
	>0.12-0.25 incl	0.05
	>0.25-0.40 incl	0.06
	>0.40-0.55 incl	0.07
	>0.55-0.80 incl	0.10
	>0.80	0.13
Manganese	$\leq 0.40$	0.15
	>0.40-0.50 incl	0.20
	>0.50-1.65 incl	0.30
Phosphorus	>0.40-0.08 incl	0.03
	>0.08-0.13 incl	0.05
Sulfur	>0.050-0.09 incl	0.03
	>0.09-0.15 incl	0.05
	>0.15-0.23 incl	0.07
	>0.23-0.35 incl	0.09

Silicon (for bars) <sup>(b)(c)</sup>	$\leq 0.15$	0.08
	>0.15-0.20 incl	0.10
	>0.20-0.30 incl	0.15
	>0.30-0.60 incl	0.20
Copper	When copper is required, 0.20 minimum is commonly used	
Lead <sup>(d)</sup>	When lead is required, a range of 0.15-0.35 is generally used	

Incl, inclusive. Boron-treated fine-grain steels are produced to a range of 0.0005-0.003% B.

- (a) The carbon ranges shown customarily apply when the specified maximum limit for manganese does not exceed 1.10%. When the maximum manganese limit exceeds 1.10%, it is customary to add 0.01 to the carbon range shown.
- (b) It is not common practice to produce a rephosphorized and resulfurized carbon steel to specified limits for silicon because of its adverse effect on machinability.
- (c) When silicon is required for rods the following ranges and limits are commonly used: 0.10 max; 0.07-0.15, 0.10-0.20, 0.15-0.35, 0.20-0.40, or 0.30-0.60.
- (d) Lead is reported only as a range of 0.15-0.35% because it is usually added to the mold or ladle stream as the steel is poured

### Table 3 Carbon steel cast or heat chemical limits and ranges

Applicable only to structural shapes, plates, strip, sheets, and welding tubing

Element	Maximum specified element, %	of Range, %
Carbon <sup>(a)(b)</sup>	$\leq 0.15$	0.05
	>0.15-0.30 incl	0.06
	>0.30-0.40 incl	0.07
	>0.40-0.60 incl	0.08
	>0.60-0.80 incl	0.11
	>0.80-1.35 incl	0.14

Manganese	$\leq 0.50$	0.20
	>0.050-1.15 incl	0.30
	>1.15-1.65 incl	0.35
Phosphorus	$\leq 0.08$	0.03
	>0.08-0.15 incl	0.05
Sulfur	$\leq 0.08$	0.03
	>0.08-0.15 incl	0.05
	>0.15-0.23 incl	0.07
	>0.23-0.33 incl	0.10
Silicon	$\leq 0.15$	0.08
	>0.15-0.30 incl	0.15
	>0.30-0.60 incl	0.30
Copper	When copper is required, 0.20% minimum is commonly specified	

Incl, inclusive.

(a) The carbon ranges shown in the range column apply when the specified maximum limit for manganese does not exceed 1.00%. When the maximum manganese limit exceeds 1.00%, add 0.01 to the carbon ranges shown in the table.

(b) Maximum of 0.12% C for structural shapes and plates

**Table 4 Alloy steel heat composition ranges and limits for bars, blooms, billets, and slabs**

Element	Maximum of specified element, %	Range, %	
		Open hearth or basic oxygen steels	Electric furnace steels
Carbon	$\leq 0.55$	0.05	0.05

	>0.55-0.70 incl	0.08	0.07

	>0.80-1.30 incl	0.35	0.35
	>1.30-1.80 incl	0.45	0.45

Element	Steelmaking process	Lowest maximum <sup>(c)</sup> , %
Phosphorus	Basic open hearth, basic oxygen, or basic electric furnace steels	0.035 <sup>(d)</sup>
	Basic electric furnace E steels	0.025
	Acid open hearth or electric furnace steel	0.050
Sulfur	Basic open hearth, basic oxygen, or basic electric furnace steels	0.040 <sup>(d)</sup>
	Basic electric furnace E steels	0.025
	Acid open hearth or electric furnace steel	0.050

Incl, inclusive.

- (a) A range of sulfur content normally indicates a resulfurized steel.
- (b) Not normally produced by open hearth process.
- (c) Not applicable to rephosphorized or resulfurized steels.
- (d) Lower maximum limits on phosphorus and sulfur are required by certain quality descriptors.

	>0.25-0.50 incl	0.10	0.10

Incl, inclusive. Boron steels can be expected to contain a minimum of 0.0005% B. Alloy steels can be produced with a lead range of 0.15-0.35%. A heat analysis for lead is not determinable because lead is added to the ladle stream while each ingot is poured.

Because segregation of some alloying elements is inherent in the solidification of an ingot, different portions will have local chemical compositions that differ slightly from the average composition. Many lengths of bar stock can be made from a single ingot; therefore, some variation in composition between individual bars must be expected. The compositions of individual bars might not conform to the applicable specification, even though the heat analysis does. The chemical composition of an individual bar (or other product) taken from a large heat of steel is called the product analysis or check analysis. Ranges and limits for product analyses are generally broader and less restrictive than the corresponding ranges and limits for heat analyses. Such limits used in standard commercial practice are given in Tables 6, 7, and 8.

**Table 6 Product analysis tolerances for carbon and alloy steel plates, sheet, piling, and bars for structural applications**

Incl, inclusive. Boron is not subject to product analysis tolerances.

(a) Resulfurized steels are not subject to product analysis limits for sulfur.

(b) If the minimum range is 0.01%, the under tolerance is 0.005%.

(c) Tolerances shown apply only to 0.065 m<sup>2</sup> (100 in.<sup>2</sup>) or less.

(d) Tolerance is over and under.

**Residual elements** usually enter steel products from raw materials used to produce pig iron or from scrap steel used in steelmaking. Through careful steelmaking practices, the amounts of these residual elements are generally held to acceptable levels. Sulfur and phosphorus are usually considered deleterious to the mechanical properties of steels; therefore, restrictions are placed on the allowable amounts of these elements for most grades. The amounts of sulfur and phosphorus are invariably reported in the analyses of both carbon and alloy steels. Other residual alloying elements generally exert a lesser influence than sulfur and phosphorus on the properties of steel. For many grades of steel, limitations on the amounts of these residual elements are either optional or omitted entirely. Amounts of residual alloying elements are generally not reported in either heat or product analyses, except for special reasons.

**Silicon Content of Steels.** The composition requirements for many steels, particularly plain carbon steels, contain no specific restriction on silicon content. The lack of a silicon requirement is not an omission, but instead indicates

recognition that the amount of silicon in a steel can often be traced directly to the deoxidation practice employed in making it.

Rimmed and capped steels are not deoxidized; the only silicon present is the residual amount left from scrap or raw materials, typically less than 0.05% Si. Specifications and orders for these steels customarily indicate that the steel must be made rimmed or capped, as required by the purchaser; restrictions on silicon content are not usually given.

The extent of rimming action during the solidification of semikilled steel ingots must be carefully controlled by matching the amount of deoxidizer with the oxygen content of the molten steel. The amount of silicon required for deoxidation can vary from heat to heat. Thus, the silicon content of the solid metal can also vary slightly from heat to heat. A maximum silicon content of 0.10% is sometimes specified for semikilled steel, but this requirement is not very restrictive; for certain heats, a silicon addition sufficient to leave a residue of 0.10% can be enough of an addition to kill the steel.

Killed steels are fully deoxidized during their manufacture; deoxidation can be accomplished by additions of silicon, aluminum, or both, or by vacuum treatment of the molten steel. Because it is the least costly of these methods, silicon deoxidation is frequently used. For silicon-killed steels, a range of 0.15 to 0.30% Si is often specified, providing the manufacturer with adequate flexibility to compensate for variations in the steelmaking process and ensuring a steel acceptable for most applications. Aluminum-killed or vacuum-deoxidized steels require no silicon; a requirement for minimum silicon content in such steel is unnecessary. A maximum permissible silicon content is appropriate for all killed plain carbon steels; a minimum silicon content implies a restriction that the steel must be silicon killed. Silicon is intentionally added to some alloy steels, for which it serves as both a deoxidizer and an alloying element to modify the properties of the steel. An acceptable range of silicon content would be appropriate for these steels.

Users and specifiers of steel mill products must realize that the silicon content of these items cannot be established independently of deoxidation practice. In ordering mill products, it is often desirable to cite a standard specification (such as an ASTM specification) where the various ramifications of restrictions on silicon content have already been considered in preparing the specification. In some instances, such as the forming of low-carbon steel sheet, the choice of deoxidation practice can significantly affect the performance of the steel; in such cases, it is appropriate to specify the desired practice.

## SAE-AISI Designations

As stated above, the most widely used system for designating carbon and alloy steels is the SAE-AISI system. Technically, there are two separate systems, but they are nearly identical and have been carefully coordinated by the two groups. It should be noted, however, that AISI has discontinued the practice of designating steels. Therefore, the reader should consult Volume 1, *Materials*, of the *SAE Handbook* for the most up-to-date information.

The SAE-AISI system is applied to semi-finished forgings, hot-rolled and cold-finished bars, wire rod and seamless tubular goods, structural shapes, plates, sheet, strip, and welded tubing. Table 9 summarizes the numerical designations used in both SAE and AISI. The fact that a particular steel is listed by SAE or AISI implies only that it has been produced in appreciable quantity. It does not imply that other grades are unavailable, nor that any particular steel producer makes all of the listed grades.

**Table 9 SAE-AISI system of designations for carbon and alloy steels**

Numerals and digits	Type of steel and nominal alloy content, %
<b>Carbon steels</b>	
10xx <sup>(a)</sup>	Plain carbon (Mn 1.00 max)
11xx	Resulfurized
12xx	Resulfurized and rephosphorized

15xx	Plain carbon (max Mn range: 1.00-1.65)
<b>Manganese steels</b>	
13xx	Mn 1.75
<b>Nickel steels</b>	
23xx	Ni 3.50
25xx	Ni 5.00
<b>Nickel-chromium steels</b>	
31xx	Ni 1.25; Cr 0.65 and 0.80
32xx	Ni 1.75; Cr 1.07
33xx	Ni 3.50; Cr 1.50 and 1.57
34xx	Ni 3.00; Cr 0.77
<b>Molybdenum steels</b>	
40xx	Mo 0.20 and 0.25
44xx	Mo 0.40 and 0.52
<b>Chromium-molybdenum steels</b>	
41xx	Cr 0.50, 0.80, and 0.95; Mo 0.12, 0.20, 0.25, and 0.30
<b>Nickel-chromium-molybdenum steels</b>	
43xx	Ni 1.82; Cr 0.50 and 0.80; Mo 0.25
43BVxx	Ni 1.82; Cr 0.50; Mo 0.12 and 0.25; V 0.03 min
47xx	Ni 1.05; Cr 0.45; Mo 0.20 and 0.35
81xx	Ni 0.30; Cr 0.40; Mo 0.12

86xx	Ni 0.55; Cr 0.50; Mo 0.20
87xx	Ni 0.55; Cr 0.50; Mo 0.25
88xx	Ni 0.55; Cr 0.50; Mo 0.35
93xx	Ni 3.25; Cr 1.20; Mo 0.12
94xx	Ni 0.45; Cr 0.40; Mo 0.12
97xx	Ni 0.55; Cr 0.20; Mo 0.20
98xx	Ni 1.00; Cr 0.80; Mo 0.25
<b>Nickel-molybdenum steels</b>	
46xx	Ni 0.85 and 1.82; Mo 0.20 and 0.25
48xx	Ni 3.50; Mo 0.25
<b>Chromium steels</b>	
50xx	Cr 0.27, 0.40, 0.50, and 0.65
51xx	Cr 0.80, 0.87, 0.92, 0.95, 1.00, and 1.05
50xxx	Cr 0.50; C 1.00 min
51xxx	Cr 1.02; C 1.00 min
52xxx	Cr 1.45; C 1.00 min
<b>Chromium-vanadium steels</b>	
61xx	Cr 0.60, 0.80, and 0.95; V 0.10 and 0.15 min
<b>Tungsten-chromium steel</b>	
72xx	W 1.75; Cr 0.75
<b>Silicon-manganese steels</b>	

92xx	Si 1.40 and 2.00; Mn 0.65, 0.82, and 0.85; Cr 0 and 0.65
<b>Boron steels</b>	
xxBxx	B denotes boron steel
<b>Leaded steels</b>	
xxLxx	L denotes leaded steel
<b>Vanadium steels</b>	
xxVxx	V denotes vanadium steel

(a) The xx in the last two digits of these designations indicates that the carbon content (in hundredths of a percent) is to be inserted.

### SAE-AISI Designations for Carbon Steels

As shown in Table 9, carbon steels comprise the lxxx groups in the SAE-AISI system and are subdivided into four distinct series as a result of the differences in certain fundamental properties among them.

**Plain carbon steels (1.00% max Mn)** in the 10xx group are listed in Tables 10 and 11; note that ranges and limits of chemical composition depend on the product form. Designations for merchant quality steels, given in Table 12, include the prefix M. A carbon steel designation with the letter B inserted between the second and third digits indicates the steel contains 0.0005 to 0.003% B. Likewise, the letter L inserted between the second and third digits indicates that the steel contains 0.15 to 0.35% Pb for enhanced machinability.

**Table 10 Carbon steel compositions**

--------	------	-----------	-----------	-------	-------

- (a) When silicon ranges or limits are required for bar and semifinished products, the following ranges are commonly used: 0.10% max; 0.10 to 0.20%; 0.15 to 0.35%; 0.20 to 0.40%; or 0.30-0.60%. For rods, the following ranges are commonly used: 0.10 max; 0.07-0.15%; 0.10-0.20%; 0.15-0.35%; 0.20-0.40%; and 0.30-0.60%. Steels listed in this table can be produced with additions of lead or boron. Lead steels typically contain 0.15-0.35% Pb and are identified by inserting the letter L in the designation (10L45); boron steels can be expected to contain 0.0005-0.003% B and are identified by inserting the letter B in the designation (10B46).

(a) When silicon ranges or limits are required, the values shown in Table 11 apply.

**H-Steels.** Certain steels have hardenability requirements in addition to the limits and ranges of chemical composition. They are distinguished from similar grades that have no hardenability requirements by the use of the suffix H (Table 17). Hardenability bands for the steels listed in Table 17 can be found in SAE J1268.

(a) If electric furnace practice is specified or required, the limit for both phosphorus and sulfur is 0.025%, and the prefix E is added to the SAE or AISI number.

(b) These steels contain 0.005 to 0.003% B.

### ***SAE-AISI Designations for Alloy Steels***

Using the SAE-AISI designation system, a steel is considered an alloy steel when the maximum content range of alloying elements exceeds one or more of the following limits: 1.65% Mn, 0.60% Si, or 0.60% Cu. Also included in the recognized field of alloy steels are steels with a specified or required range or minimum quantity of the following

elements: aluminum, boron, chromium (up to 3.99%), cobalt, niobium, molybdenum, nickel, titanium, tungsten, vanadium, zirconium, or any other alloying element added to increase hardenability in order to optimize mechanical properties and toughness after heat treatment. In some cases, however, alloy additions are used to reduce environmental degradation under certain specified service conditions. In general, total alloy content for SAE-AISI constructional steels does not exceed 5%.

Alloy sheet and strip are available as hot-rolled and cold-rolled steel in coils and cut lengths. Other product forms of alloy steel covered by SAE-AISI designations include hot-rolled plate and hot-rolled, cold-rolled, and cold-drawn bar, rod, and wire.

In the SAE-AISI system of designations, the major alloying elements in an alloy steel are indicated by the first two digits of the designation (Table 9). The amount of carbon, in hundredths of a percent, is indicated by the last two (or three) digits. The chemical compositions of SAE-AISI standard grades of alloy steels are given in Tables 18 and 19. For alloy steels that have specific hardenability requirements, the suffix H is used to distinguish these steels from corresponding grades that have no hardenability requirement (Table 20). Corresponding hardenability bands for these steels is described in SAE J1268. As with carbon steels, the letter B inserted between the second and third digits indicates that the steel contains boron. The prefix E signifies that the steel was produced by the electric furnace process.

(a) Small quantities of certain elements that are not specified or required may be found in alloy steels. These elements are to be considered as incidental and are acceptable to the following maximum amount: copper to 0.35%, nickel to 0.25%, chromium to 0.20%, and molybdenum to 0.06%.

(b) Electric furnace steel.

(c) Boron content is 0.0005-0.003%.

Boron or lead can be added to these compositions. Small quantities of certain elements not required may be found. These elements are to be considered incidental and are acceptable to the following maximum amounts: copper to 0.35%, nickel to 0.25%, chromium to 0.20%, and molybdenum to 0.06%.

(a) Indicated ranges and limits apply to steels made by the open hearth or basic oxygen processes; maximum content for phosphorus is 0.035% and for sulfur 0.040%. For steels made by the electric furnace process, the ranges and limits are reduced as follows: C to 0.01%; Mn to 0.05%; Cr to 0.05% (<1.25%), 0.10% (>1.25%); maximum content for either phosphorus or sulfur is 0.025%.

(b) Other silicon ranges may be negotiated. Silicon is available in ranges of 0.10-0.20%, 0.20-0.30%, and 0.35% maximum (when carbon deoxidized) when so specified by the purchaser.

(c) Prefix "E" indicates that the steel is made by the electric furnace process.

(d) Contains 0.15% V minimum

(a) Small quantities of certain elements may be found in alloy steel that are not specified or required. These elements are to be considered incidental and acceptable to the following maximum amounts: copper to 0.35%, nickel to 0.25%, chromium to 0.20%, and molybdenum to 0.06%.

(b) For open hearth and basic oxygen steels, maximum sulfur content is to be 0.040%, and maximum phosphorus content is to be 0.035%. Maximum phosphorus and sulfur in basic electric furnace steels are to be 0.025% each.

(c) Sulfur content range is 0.035-0.050%.

(d) Electric furnace steel.

(e) These steels contain 0.0005 to 0.003% B.

### ***SAE-AISI Designations for High-Strength Steel Sheet***

Both SAE and AISI have developed designation systems for high-strength sheet steels (including both structural carbon and HSLA grades). Using these systems, a high-strength steel is defined as a sheet product having a minimum specified yield strength of 240 MPa (35 ksi), without regard to the chemical composition or processing used to achieve that strength level. Excepted from these classification systems are alloy steels and stainless steels. Table 21 compares the SAE and AISI systems.

**Table 21 Comparison of the SAE and AISI designation systems for high-strength sheet steel**

(a) SAE, complete listing of applicable yield strengths shown in ksi. AISI, list of yield strengths is representative; more may be added at producer's option.

(b) A, B, C, and S under SAE represent various combinations of C, Mn, and N, and P content. These are grouped under S in AISI. X, Y, and Z in SAE represent microalloyed steels with 10 ksi, 15 ksi, and 20 ksi respective spreads between yield and tensile strength. These are grouped under X in AISI. The W grades are equivalent. There is no SAE equivalent for the AISI D chemistry.

(c) Value of carbon levels for H and L designations vary with the grade of steel in SAE.

**SAE Sheet Designation System.** SAE recommended practice J1392 covers high-strength hot-rolled, cold-rolled, and coated sheet steels and has replaced J410c for these particular product forms. The mechanical properties for the various grades covered by practice J1392 are given in Tables 22 and 23.

**Table 22 Mechanical properties of hot-rolled high-strength sheet steel specified in SAE J1392**

080 Y	80	550	95	650	14

(a) Elongation values are dependent upon specimen geometry (cross-sectional area). Thicker and wider specimens normally result in higher percentages.

(b) Minimum tensile strength normally does not apply.

050 X	50	340	60	410	20
050 Y	50	340	65	450	20
050 Z	50	340	70	480	20

(a) Elongation values are dependent upon specimen geometry (cross-sectional area). Thicker and wider specimens normally result in higher percentages.

(b) Minimum tensile strength normally does not apply.

A six-character code is used to describe strength level, general chemical composition, general carbon level, and the deoxidation/sulfide inclusion control system. The first, second, and third characters give the minimum yield strength in ksi; for example, 035 is 35 ksi, 040 is 40 ksi, and so forth.

The fourth character describes the general chemical composition. The letter A means carbon and manganese only; B means carbon, manganese, and nitrogen; C means carbon, manganese, and phosphorus; S means carbon and manganese with nitrogen and/or phosphorus added at producer option; W refers to weathering compositions that include silicon, phosphorus, copper, nickel, and chromium in various combinations; X refers to HSLA compositions that contain niobium, chromium, copper, molybdenum, nickel, silicon, titanium, vanadium, and zirconium added singly or in combination (along with nitrogen and/or phosphorus if desired) and that exhibit a 10 ksi (70 MPa) spread between specified minimum values of yield and tensile strengths; Y refers to the same compositions as X except with a 15 ksi (100 MPa) spread between specified minimal values of yield and tensile strengths; Z refers to the same compositions as X except with a 20 ksi (40 MPa) spread between the specified minimum values of yield and tensile strengths.

The fifth character describes the general carbon level. The letter H refers to the maximum carbon level, and L means 0.13% C maximum. The sixth character describes deoxidation/sulfide inclusion control practices. The letter K means killed and made to a fine-grain practice, F means sulfide-inclusion controlled, killed, and made to a fine-grain practice; and O refers to other than K or F.

**The AISI designation system** of high-strength sheet steels contains three basic components: the minimum yield strength, the chemical composition, and the deoxidation practice. A five-character code is used to describe these components.

The first three characters give the yield strength of a given grade. Yield strength is categorized in 5 ksi (35 MPa) increments from 35 to 60 ksi (241 to 414 MPa), in 10 ksi (70 MPa) increments from 60 to 80 ksi (414 to 550 MPa), in 20 ksi (140 MPa) increments from 80 to 140 ksi (550 to 965 MPa), and in 30 ksi (207 MPa) increments from 160 to 190 ksi (1100 to 1310 MPa). Thus, the designation "050" refers to a steel with a yield strength of 50 ksi (345 MPa).

The chemical composition of each grade is designated by a letter classification: S, X, W, or D. The letter S refers to structural-quality steels that contain carbon plus manganese; carbon plus manganese and phosphorus; carbon plus manganese and nitrogen; or carbon plus manganese, phosphorus, and nitrogen. Recovery-annealed steels, except those with the designation X, are included in this category. The letter X refers to low-alloy steel grades containing niobium, chromium, copper, molybdenum, nickel, silicon, titanium, vanadium, and zirconium either singly or in combination. Weathering steels containing silicon, phosphorus, copper, nickel, and chromium in various combinations are indicated by the letter W. Dual-phase steels containing martensite or other transformation products in a ferrite matrix are designated by the letter D. Dual-phase steels exhibit very high work-hardening rates, and, as a result, formed parts have significantly higher strengths than do the original flat-rolled sheets. Consequently, the yield strength of a dual-phase steel is designated as the strength after a 5% strain; for example, an 080D grade exhibits an 80 ksi (550 MPa) yield strength after 5% strain.

Deoxidation practice is also designated by a letter classification. The letter F means killed plus sulfide-inclusion controlled, K means killed, and O means nonkilled. For example, the steel designation 040SF would mean a minimum yield strength of 40 ksi (275 MPa), structural quality, killed.

---

## UNS Designations

The Unified Numbering System (UNS) has been developed by ASTM and SAE and several other technical societies, trade associations, and United States government agencies. A UNS number, which is a designation of chemical composition and not a specification, is assigned to each chemical composition of a metallic alloy. Available UNS designations are included in the tables in this article.

The UNS designation of an alloy consists of a letter and five numerals. The letters indicate the broad class of alloys; the numerals define specific alloys within that class. Existing designation systems, such as the SAE-AISI system for steels, have been incorporated into UNS designations. For example, the UNS prefix letter for carbon and alloy steels is G, and the first four digits are the SAE-AISI designation, for example, G10400. The intermediate letters B and L of the SAE-AISI system are replaced by making the fifth digit of the UNS designation 1 and 4 respectively, while the prefix letter E for electric furnace steels is designated in UNS system by making the fifth digit 6. The SAE-AISI steels which have a hardenability requirement indicated by the suffix letter H are designated by the Hxxxxx series in the UNS system. Carbon and alloy steels not referred to in the SAE-AISI system are categorized under the prefix letter K. The UNS designation system is described in greater detail in SAE J1086 and ASTM E 527.

## AMS Designations

Aerospace Materials Specifications (AMS), published by SAE, are complete specifications that are generally adequate for procurement purposes. Most of the AMS designations pertain to materials intended for aerospace applications; the specifications can include mechanical property requirements significantly more severe than those for grades of steel having similar compositions but intended for other applications. Processing requirements, such as for consumable electrode remelting, are common in AMS steels. Chemical compositions for AMS grades of carbon and steel alloys are given in Tables 24 and 25.

**Table 24 Product descriptions and carbon contents for wrought carbon steels covered by AMS designations**

AMS designation	Product form	Carbon content	Nearest SAE-AISI grade	UNS No.

(b) MAM, metric aerospace material specifications

## ASTM (ASME) Designations

As noted previously, the most widely used standard specifications for steel products are those published by ASTM. These are complete specifications, generally adequate for procurement purposes. Many ASTM specifications apply to specific products, such as A 574, for alloy steel socket head cap screws. These specifications are generally oriented toward performance of the fabricated end product, with considerable latitude in chemical composition of the steel used to make the end product.

ASTM specifications represent a consensus among producers, specifiers, fabricators, and users of steel mill products. In many cases, the dimensions, tolerances, limits, and restrictions in the ASTM specifications are the same as the corresponding items of the standard practices in the *AISI Steel Products Manuals*. Many of the ASTM specifications have been adopted by the American Society of Mechanical Engineers (ASME) with little or no modification; ASME uses the prefix "S" and the ASTM designation for these specifications. For example, ASME SA-213 and ASTM A 213 are identical.

Steel products can be identified by the number of the ASTM specification to which they are made. The number consists of the letter "A" (for ferrous materials) and an arbitrary, serially assigned number. Citing the specification number, however, is not always adequate to completely describe a steel product. For example, A 434 is the specification for heat treated (hardened and tempered) alloy steel bars. To completely describe steel bars indicated by this specification the grade (SAE-AISI designation in this case) and class (required strength level) must also be indicated. A 434 also incorporates, by reference, two standards for test methods and A 29, the general requirements for bar products.

SAE-AISI designations for the compositions of carbon and alloy steels are normally incorporated into the ASTM specifications for bars, wires, and billets for forging. Some ASTM specifications for sheet products include SAE-AISI designations for composition. ASTM specifications for plates and structural shapes generally specify the limits and ranges of chemical composition directly, without the SAE-AISI designations. Table 26 includes a list of some of the ASTM specifications that incorporate SAE-AISI designations for compositions of the different grades of steel.

**Table 26 ASTM specifications that incorporate SAE-AISI designations**

<b>ASTM specifications</b>	<b>Subject</b>
A 29	Carbon and alloy steel bars, hot rolled and cold finished
A 108	Standard quality cold-finished carbon steel bars
A 295	High carbon-chromium ball and roller bearing steel
A 304	Alloy steel bars having hardenability requirements
A 322	Hot-rolled alloy steel bars
A 331	Cold-finished alloy steel bars
A 434	Hot-rolled or cold-finished quenched and tempered alloy steel bars
A 505	Hot-rolled and cold-rolled alloy steel sheet and strip
A 506	Regular quality hot-rolled and cold-rolled alloy steel sheet and strip
A 507	Drawing quality hot-rolled and cold-rolled alloy steel sheet and strip
A 510	Carbon steel wire rods and coarse round wire
A 534	Carburizing steels for antifriction bearings
A 535	Special quality ball and roller bearing steel
A 544	Scrapless nut quality carbon steel wire
A 545	Cold-heading quality carbon steel wire for machine screws
A 546	Cold-heading quality medium-high-carbon steel wire for hexagon-head bolts
A 547	Cold-heading quality alloy steel wire for hexagon-head bolts
A 548	Cold-heading quality carbon steel wire for tapping or sheet metal screws
A 549	Cold-heading quality carbon steel wire for wood screws

A 575	Merchant quality hot-rolled carbon steel bars
A 576	Special quality hot-rolled carbon steel bars
A 646	Premium quality alloy steel blooms and billets for aircraft and aerospace forgings
A 659	Commercial quality hot-rolled carbon steel sheet and strip
A 682	Cold-rolled spring quality carbon steel strip, generic
A 684	Untempered cold-rolled high-carbon steel strip
A 689	Carbon and alloy steel bars for springs
A 711	Carbon and alloy steel blooms, billets, and slabs for forging
A 713	High-carbon spring steel wire for heat-treated components
A 752	Alloy steel wire rods and coarse round wire
A 827	Carbon steel plates for forging and similar applications
A 829	Structural quality alloy steel plates
A 830	Structural quality carbon steel plates

**Generic Specifications.** Several ASTM specifications, such as A 29, contain the general requirements common to each member of a broad family of steel products. Table 27 lists several of these generic specifications, which generally must be supplemented by another specification describing a specific mill form or intermediate fabricated product.

**Table 27 Generic ASTM specifications**

ASTM specification <sup>(a)</sup>	Title
A 6/A 6M	General requirements for rolled steel plates, shapes, sheet piling, and bars for structural purposes
A 20/A 20M	General requirements for steel plates for pressure vessels
A 29/A 29M	General requirements for hot-rolled and cold-finished carbon and alloy steel bars
A 450/A 450M	General requirements for carbon, ferritic-alloy, and austenitic alloy tubes

A 505	General requirements for hot-rolled and cold-rolled alloy steel sheet and strip
A 530/A 530M	General requirements for specialized carbon and alloy steel pipe
A 682	General requirements for cold-rolled spring quality high-carbon steel strip

(a) The suffix "M" indicates that a metric version of the specification is available

**Sheet Products.** Limits and ranges of chemical compositions for carbon steel sheet products with ASTM specifications that do not incorporate SAE-AISI designations are listed in Table 28. ASTM specifications for sheet products that do include SAE-AISI designations are listed in Table 26.

**Table 28 Composition ranges and limits for plain carbon sheet and strip (ASTM specifications)**

ASTM specification	Description <sup>(a)</sup>	Composition <sup>(b)</sup> , %				
		C	Mn	P	S	Other
A 611	CR SQ grades A, B, C, E	0.20	0.60	0.04	0.04	(c)

	Grades 45, 50, and 55	0.25	1.35	0.04	0.05	(c)
A 569	HR CQ	0.15	0.60	0.035	0.040	(c)
A 621	HR DQ	0.10	0.50	0.025	0.035	...

A 622	HR DQSK	0.10	0.50	0.025	0.035	(d)
A 414	Pressure vessel grade A	0.15	0.90	0.035	0.040	(c)
	Grade B	0.22	0.90	0.035	0.040	(c)
	Grade C	0.25	0.90	0.035	0.040	(c)
	Grade D	0.25	1.20	0.035	0.040	(c)(e)
	Grade E	0.27	1.20	0.035	0.040	(c)(e)
	Grade F	0.31	1.20	0.035	0.040	(c)(e)
	Grade G	0.31	1.35	0.035	0.040	(c)(e)

(a) CR, cold-rolled; HR, hot rolled; SQ, structural quality; DG, drawing quality; DQSK, drawing quality, special killed; CQ, commercial quality.

(b) All values are maximum.

(c) Copper when specified as copper-bearing steel: 0.20% min.

(d) Aluminum as deoxidizer usually exceeds 0.010% in the product.

(e) Killed steel can be supplied upon request to the manufacturer for grades D through G. When silicon-killed steel is specified, a range of 0.15-0.30% Si shall be supplied.

**Plate and Structural Shapes.** ASTM specifications for plate and structural shapes generally do not incorporate SAE-AISI designations. Limits and ranges of chemical composition in ASTM specifications for carbon and alloy structural plate are listed in Table 29.

**Table 29 ASTM specifications of chemical composition for structural plate made of alloy steel or carbon steel**

ASTM specification	Material grade or type	Composition <sup>(a)</sup> , %

(a) When a single value is shown, it is a maximum limit, except for copper, for which a single value denotes a minimum limit.

(b) Vanadium can be substituted for part or all of the titanium on a one-for-one basis.

(c) Titanium may be present in levels up to 0.06% to protect the boron additions.

(d) Limiting values vary with plate thickness.

(e) Minimum value applicable only if copper-bearing steel is specified.

(f) Plates over 13 mm ( $\frac{1}{2}$  in.) in thickness shall have a minimum manganese content not less than 2.5 times carbon content.

(g) The upper limit of manganese may be exceeded provided  $C + 1/6 \text{ Mn}$  does not exceed 0.40% based on heat analysis.

**Pressure-Vessel Plate.** Steel plate intended for fabrication into pressure vessels must conform to different specifications than similar plate intended for structural applications. The major differences between the two groups of specifications are that pressure-vessel plate must meet requirements for notch toughness and has more stringent limits for allowable surface and edge imperfections. Limits and ranges of chemical composition for carbon and alloy steel plate for pressure vessels are given in Table 30.

**Table 30 ASTM specifications of chemical compositions for pressure vessel plate made of carbon and alloy steel**

ASTM specification	Material grade or type	Composition <sup>(a)</sup> , %

(a) When a single value is shown, it is a maximum limit, except where specified as a minimum limit.

(b) Limiting values may vary with plate thickness.

(c) When specified

## International Designations and Specifications

Most industrialized nations have standards organizations that issue designations and specifications related to steels. Organizations that can assist engineers cross-reference steels from various countries include the American National Standards Institute (ANSI) in the United States and the European Committee for Standardization (CEN) in Brussels, Belgium. The latter is an association of the national standards organizations of 18 countries of the European Union and of the European Free Trade Association. Useful reference sources include:

- A.S. Melilli, Ed., *Comparative World Steel Standards*, ASTM, 1996
- D.L. Potts and J.G. Gensure, *International Metallic Materials Cross-Reference*, Genium Publishing, 1989
- C.W. Wegst, Ed., *Stahlschlüssel: Key to Steel*, 18th ed., Verlag Stahlschlüssel, 1998
- *Worldwide Guide to Equivalent Irons and Steels*, 3rd ed., ASM International, 1992

# Mechanical Properties of Carbon and Alloy Steels

---

## Introduction

THE PROPERTIES of carbon and alloy steels are dependent on the relationships between chemical composition, processing, and microstructure. In this article, emphasis is placed on the effect of composition (alloying). The role of processing and microstructure on the properties is described in the Section "Structure/Property Relationships in Irons and Steels" in this Handbook.

Alloying elements are added to ordinary (plain carbon) steels to modify their behavior during thermal processing (heat treatment or thermomechanical processing), which in turn results in improvement of the mechanical and physical properties of the steel. Specifically, alloying additions are made for one or more of the following reasons:

- Improve tensile strength without appreciably lowering ductility
- Improve toughness
- Increase hardenability which permits the hardening of larger sections than possible with plain carbon steels or allows successful quenching with less drastic cooling rates, reducing the hazard of distortion and quench cracking
- Retain strength at elevated temperatures
- Obtain better corrosion resistance
- Improve wear resistance
- Impart a fine grain size to the steel

A semantic distinction can be made between alloying elements and residual elements; the latter are not intentionally added to the steel, but result from the raw materials and steelmaking practices used to produce the steel. Any particular element can be either alloying or residual. For example, some nickel or chromium could come into steel through alloy steel scrap and so be considered residual; however, if either of these elements must be added to a steel to meet the desired composition range it might be considered an alloying element.

Both alloying and residual elements can profoundly affect steel production, manufacture into end products, and service performance of the end product. The effects of one alloying element on a steel may be affected by the presence of other elements; such interactive effects are complex. In addition, the effects of a particular element may be beneficial to steel in one respect but detrimental in others.

## Effects of Alloying Elements

General effects of various alloying elements commonly found in carbon and low-alloy steels are summarized below. Composition limits or ranges for these elements are tabulated in the article "Classifications and Designations of Carbon and Alloy Steels" in this Section. Additional information on the effects of alloying elements on the performance of steels can be found in a number of articles contained within this Section (see, for example, the articles "Hardenability of Carbon and Alloy Steels," "Service Characteristics of Carbon and Alloy Steels," and "Corrosion Characteristics of Carbon and Alloy Steels") and in the Sections "Tool Steels" and "Stainless Steels" in this Handbook.

**Carbon** is the most important single alloying element in steel. It is essential to the formation of cementite (and other carbides), pearlite, spheroidite (an aggregate of spherical carbides in a ferrite matrix), bainite and iron-carbon martensite. Microstructures comprising one or more of these components can provide a wide range of mechanical properties and fabrication characteristics. The relative amounts and distributions of these elements can be manipulated by heat treatment to alter the microstructure, and therefore the properties, of a particular piece of steel. Much of ferrous metallurgy is devoted to the various structures and transformations in iron-carbon alloys; many other alloying elements are considered largely on the basis of their effects on the iron-carbon system.

Assuming that the comparisons are made among steels having comparable microstructures, the strength and hardness are raised as the carbon content is increased; however, toughness and ductility are reduced by increases in carbon content (workability, weldability, and machinability are also deleteriously affected by higher carbon contents). The influence of

carbon content on mechanical properties is shown in Fig. 1. The hardness of iron-carbon martensite is increased by raising the carbon content of steel, reaching a maximum at about 0.6% C. Increasing the carbon content also increases hardenability.

**Fig. 1** Variations in average mechanical properties of as-rolled 25 mm (1 in.) diam bars of plain carbon steels as a function of carbon content

The amount of carbon required in the finished steel limits the type of steel that can be made. As the carbon content of rimmed steel increases, surface quality becomes impaired. Killed steels in approximately the 0.15 to 0.30% C content level may have poorer surface quality and require special processing to obtain surface quality comparable to steels with higher or lower carbon content. Carbon has a moderate tendency to segregate, and carbon segregation is often more significant than the segregation of other elements.

**Manganese** is normally present in all commercial steels. It is important in the manufacture of steel because it deoxidizes the melt and facilitates hot working of the steel by reducing the susceptibility to hot shortness. Manganese also combines with sulfur to form manganese sulfide stringers, which improve the machinability of steel. It contributes to strength and hardness, but to a lesser degree than does carbon; the amount of increase depends on the carbon content. Manganese has a strong effect on increasing the hardenability of a steel.

Manganese has less of a tendency toward macrosegregation than any of the common elements. Steels with more than 0.60% Mn cannot be readily rimmed. Manganese is beneficial to surface quality in all carbon ranges (with the exception of extremely low-carbon rimmed steels).

**Silicon** is one of the principal deoxidizers used in steelmaking. The amount of this element in a steel, which is not always noted in the chemical composition specifications, depends on the deoxidation practice specified for the product. Rimmed and capped steels contain minimal silicon, usually less than 0.05%. Fully killed steels usually contain 0.15 to 0.30% silicon for deoxidation; if other deoxidants are used, the amount of silicon in the steel may be reduced. Silicon has only a

slight tendency to segregate. In low-carbon steels, silicon is usually detrimental to surface quality, and this condition is more pronounced in low-carbon resulfurized grades.

Silicon slightly increases the strength of ferrite, without causing a serious loss of ductility. In larger amounts, it increases the resistance of steel to scaling in air (up to about 260 °C, or 500 °F) and decreases the magnetic hysteresis loss. Such high-silicon steels are generally difficult to process.

**Copper** has moderate tendency to segregate, and in appreciable amounts, it is detrimental to hot-working operations. Copper adversely affects forge welding, but it does not seriously affect arc or oxyacetylene welding. Detrimental to surface quality, copper exaggerates the surface defects inherent in resulfurized steels. Copper is, however, beneficial to atmospheric corrosion resistance when present in amounts exceeding 0.20%. Steels containing these levels of copper are referred to as weathering steels.

**Chromium** is generally added to steel to increase resistance to corrosion and oxidation, to increase hardenability, to improve high-temperature strength, or to improve abrasion resistance in high-carbon compositions. Chromium is a strong carbide former. Complex chromium-iron carbides go into solution in austenite slowly; therefore, a sufficient heating time before quenching is necessary.

Chromium can be used as a hardening element and is frequently used with a toughening element such as nickel to produce superior mechanical properties. At higher temperatures, chromium contributes increased strength; it is ordinarily used for applications of this nature in conjunction with molybdenum.

**Nickel**, when used as an alloying element in constructional steels, is a ferrite strengthener. Because nickel does not form any carbide compounds in steel, it remains in solution in the ferrite, thus strengthening and toughening the ferrite phase. Nickel steels are easily heat treated because nickel lowers the critical cooling rate. In combination with chromium, nickel produces alloy steels with greater hardenability, higher impact strength, and greater fatigue resistance than can be achieved in carbon steels. Nickel alloy steels also have superior low-temperature strength and toughness.

**Molybdenum** increases the hardenability of steel and is particularly useful in maintaining the hardenability between specified limits. This element, especially in amounts between 0.15 and 0.30%, minimizes the susceptibility of a steel to temper embrittlement. Hardened steels containing molybdenum must be tempered at a higher temperature to achieve the same amount of softening. Molybdenum is unique in the extent to which it increases the high-temperature tensile and creep strengths of steel. It retards the transformation of austenite to pearlite far more than it does the transformation of austenite to bainite; thus, bainite can be produced by continuous cooling of molybdenum-containing steels.

**Vanadium** is one of the strong carbide-forming elements. It dissolves to some degree in ferrite imparting strength and toughness. Vanadium steels show a much finer structure than steels of a similar composition without vanadium. Vanadium also provides increased hardenability where it is in solution in the austenite prior to quenching, a secondary hardening effect on tempering, and increased hardness at elevated temperatures.

**Niobium**. Small additions of niobium increase the yield strength and, to a lesser degree, the tensile strength of carbon steel. The addition of 0.20% Nb can increase the yield strength of medium-carbon steel by 70 to 100 MPa (10 to 15 ksi). This increased strength may be accompanied by considerably impaired notch toughness unless special measures are used to refine grain size during hot rolling. Grain refinement during hot rolling involves special thermomechanical processing techniques such as controlled-rolling practices, low finishing temperatures for final reduction passes, and accelerated cooling after rolling is completed.

**Aluminum** is widely used as a deoxidizer and for control of grain size. When added to steel in specified amounts, it controls austenite grain growth in reheated steels. Of all the alloying elements, aluminum is the most effective in controlling grain growth prior to quenching. Titanium, zirconium, and vanadium are also effective grain growth inhibitors; however, for structural grades that are heat treated (quenched and tempered), these three elements may have adverse effects on hardenability because their carbides are quite stable and difficult to dissolve in austenite prior to quenching.

**Boron** is added to fully killed steel to improve hardenability. Boron-treated steels are produced in a range of 0.0005 to 0.003%. Whenever boron is substituted in part for other alloys, it should be done only with hardenability in mind because the lowered alloy content may be harmful for some applications. Boron is most effective in lower carbon steels.

**Titanium** is primarily used as a deoxidizer and helps to limit grain growth in the fully killed steels. Titanium may be added to boron steels because it combines readily with any oxygen and nitrogen in the steel, thereby increasing the effectiveness of the boron in increasing the hardenability of the steel.

**Tungsten** increases hardness, promotes a fine-grain structure, and is excellent for resisting heat. At elevated tempering temperatures, tungsten forms tungsten carbide, which is very hard and stable. The tungsten carbide helps prevent the steel from softening during tempering. Tungsten is used extensively in high-speed tool steels.

**Zirconium** inhibits grain growth and is used as a deoxidizer in killed steels. Its primary use is to improve hot-rolled properties in high-strength low-alloy (HSLA) steels. Zirconium in solution also improves hardenability slightly.

**Calcium** is sometimes used to deoxidize steels. In HSLA steels it helps to control the shape of nonmetallic inclusions, thereby improving toughness. Steels deoxidized with calcium generally have better machinability than do steels deoxidized with silicon or aluminum.

**Lead** is sometimes added to carbon and alloy steels through mechanical dispersion during teeming for the purpose of improving the machining characteristics of the steels. These additions are generally in the range of 0.15 to 0.35%.

Lead does not dissolve in the steel during teeming but is retained in the form of microscopic globules. At temperatures near the melting point of lead, it can cause liquid-metal embrittlement.

**Nitrogen** increases the strength, hardness, and machinability of steel, but it decreases the ductility and toughness. In aluminum-killed steels, nitrogen forms aluminum nitride particles that control the grain size of the steel, thereby improving both toughness and strength. Nitrogen can reduce the effect of boron on the hardenability of steels.

## Effects of Residual Elements

Any of the alloying elements mentioned above may inadvertently appear in steel as a result of the presence in raw materials used to make the steel. As such, they would be known as "residual" elements. Because of possible undesired (though not necessarily undesirable) effects of these elements on the finished products, most steelmakers are careful to minimize the amount of these elements in the steel, primarily through separation of steel scrap by alloy content.

Several other elements, generally considered to be undesirable impurities, may be introduced into steel from pig iron. For certain specific purposes, however, they may be deliberately added; in this case, they would be considered alloying elements.

**Phosphorus** increases strength and hardness of steel, but severely decreases ductility and toughness. It increases the susceptibility of medium-carbon alloy steels, particularly straight chromium steels, to temper embrittlement. Phosphorus may be deliberately added to steel to improve its machinability or corrosion resistance.

**Sulfur.** Increased sulfur content lowers transverse ductility and notch impact toughness but has only a slight effect on longitudinal mechanical properties. Weldability decreases with increasing sulfur content. This element is very detrimental to surface quality, particularly in the lower-carbon and lower-manganese steels. For these reasons only a maximum limit is specified for most steels. The only exceptions is the group of free-machining steels, where sulfur is added to improve machinability; in this case, a range is specified. Sulfur has a greater segregation tendency than do any of the other common elements. Sulfur occurs in steel principally in the form of sulfide inclusions. Obviously a greater frequency of such inclusions can be expected in the resulfurized grades.

**Oxygen**, which is most likely to be found in rimmed steels, can slightly increase the strength of steel, but seriously reduce toughness.

**Hydrogen** dissolved in steel during manufacture can seriously embrittle it. This effect is not the same as the embrittlement that results from electroplating or pickling. Embrittlement resulting from hydrogen dissolved during manufacture can cause flaking during cooling from hot rolling temperatures. Dissolved hydrogen rarely affects finished mill products, for reheating the steel prior to hot forming bakes out nearly all of the hydrogen. More detailed information on how hydrogen influences the properties of steels can be found in the Section "Failure Analysis" in this Handbook.

**Tin** can render steel susceptible to temper embrittlement and hot shortness.

**Arsenic and antimony** also increase susceptibility of a steel to temper embrittlement.

## Properties of Carbon and Alloy Steels

**Carbon Steels.** The principal factors affecting the properties of the plain carbon steels are carbon content and microstructure. Each type of microstructure is developed to characteristic property ranges by specific processing routes that control and exploit microstructural changes. Processing technologies not only depend on microstructure but are also used to tailor final microstructures. For example, sheet steel formability depends on the single-phase ferritic microstructures of low-carbon cold-rolled and annealed steel, while high strength and wear resistance are enhanced by carefully developed microstructures of very fine carbides in fine martensite in fine-grained austenite of high-carbon hardened steels. (See the Section "Structure/Property Relationships in Irons and Steels" for further details.)

In addition to the predominant effects of carbon content and microstructure, the properties of plain carbon steels may be modified by the effects of residual elements other than the carbon, manganese, silicon, phosphorus, and sulfur that are always present. These incidental elements are usually picked up from the scrap, from the deoxidizers, or from the furnace refractories. The properties of carbon steels may also be affected by the presence of gases, especially oxygen, nitrogen, and hydrogen and their reaction products. The gas content is largely dependent upon the melting, deoxidizing, and pouring practice. The final properties of the plain carbon steels are therefore influenced by the steelmaking practice used in their production.

Thus, the factors governing the properties of a plain carbon steel are primarily its carbon content and microstructure, with the microstructure being determined largely by the composition and the final rolling, forging, or heat-treating operations, and secondarily by the residual alloy, non-metallic, and gas content of the steel, which, in turn, depend on the steelmaking practice.

Figure 1 illustrates the general effect of carbon content when the microstructure and grain size are held reasonably constant. These data are also representative for hot-rolled sheet and strip products. As this figure shows, hardness, tensile strength, and yield strength increase with increasing carbon content, while the elongation, reduction of area, and Charpy impact values decrease sharply. Tables 1 and 2 show both the effects of carbon content and heat treatment on the properties of carbon steels.

Data were obtained from specimens 12.8 mm (0.505 in.) in diameter that were machined from 25 mm (1 in.) rounds.

(a) All grades are fine-grained except for those in the 1100 series, which are coarse grained. Heat-treated specimens were oil quenched unless otherwise indicated.

(b) Water quenched

**Alloy steels** covered by SAE-AISI designations are not directly produced to specific mechanical properties, but are usually heat treated to achieve the desired properties. For lower strength applications, these steels are usually furnished in the as-rolled, normalized, or annealed condition. Higher strength values may be obtained in the normalized-and-tempered or quenched-and-tempered conditions with the latter heat treatment producing optimal results. Tables 1 and 2 show the effects of heat treatment on the properties of SAE-AISI carbon and alloy steels. Properties of steels produced to meet specific mechanical property requirements (for example ASTM specifications) are discussed in subsequent articles contained in this Section.

## Low-Carbon Steel Sheet and Strip

LOW-CARBON STEEL sheet and strip are used primarily in consumer goods. These applications require materials that are serviceable under a wide variety of conditions and that are especially adaptable to low-cost techniques of mass production into articles having good appearance. Therefore, these products must incorporate, in various degrees and combinations, ease of fabrication, adequate strength, excellent finishing characteristics to provide attractive appearance after fabrication, and compatibility with other materials and with various coatings and processes.

The steels used for these products are supplied over a wide range of chemical compositions; however, the vast majority are unalloyed, low-carbon steels selected for stamping applications, such as automobile bodies and appliances. For these major applications, typical compositions are 0.03 to 0.10% C, 0.15 to 0.50% Mn, 0.035% P (max), and 0.04% S (max).

Generally, rimmed (or capped) ingot cast steel has been used because of its lower price. More recently, these steels have been replaced by killed steels produced by the continuous casting process. This process is inherently suited to the production of killed steels. Where strain aging is to be avoided and/or when exceptional formability is required, steel killed with aluminum, regardless of the method of casting or manufacture, is preferred. Further details regarding steelmaking and deoxidation practice are given in the Section "Steelmaking Practices and Their Influence on Properties" in this Handbook.

The width differentiation between sheet and strip made of plain carbon steel depends on the rolling process. It should be noted that both sheet and strip can be purchased as either cut lengths or coils. The standard dimensional tolerances for plain carbon steel strip are more restrictive than those for sheet. Standard size ranges of plain carbon steel sheet and strip are given in Table 1. Typical characteristics of the various qualities of these products are listed in Tables 2(a) and 2(b).

**Table 1 Standard sizes of low-carbon sheet and strip**

Product	Thickness		Width		Other limitations	Specification symbol (ASTM No.)

(a) See Table 2(b) for a description of the surface finish listed.

(b) Produced in five tempers with specific hardness and bend test limits; composition subordinate to mechanical properties.

**Table 2(b) Selection and specification of surface condition for plain carbon steel sheet**

Specification symbol	Description of surface	Surface described applicable to
U <sup>(a)</sup>	Surface finish as normally used for unexposed automotive parts. Matte appearance. Normally annealed last	Cold-rolled sheet
E <sup>(b)</sup>	Surface finish as normally used for exposed automotive parts that require a good painted surface. Free from strain markings and fluting. Matte appearance. Temper rolled	Cold-rolled sheet
B	Same as above, except commercial bright appearance	Cold-rolled sheet
L	Same as above, except luster appearance	Cold-rolled sheet
1	No. 1 or dull finish (no luster). Especially suitable for lacquer or paint adhesion. Facilitates drawing by reducing the contact friction between the die and the metal	Cold-rolled strip
2	No. 2 or regular bright finish (moderately smooth). Suitable for many applications, but not generally applicable for parts to be plated, unless polished and buffed	Cold-rolled strip
3	No. 3 or best bright finish (relatively high luster). Particularly suitable for parts to be plated	Cold-rolled strip
A	As-rolled or black (oxide or scale not removed)	Hot-rolled sheet and strip
P	Pickled (scale removed), not oiled	Hot-rolled sheet and strip
O	Same as above, except oiled	Hot-rolled sheet and strip

(a) U, unexposed; also designated as class 2, cold-rolled sheet.

(b) E, exposed; also designated as class 1, cold-rolled sheet

## Production of Sheet and Strip

Most cold-rolled low-carbon steel sheet is available in two classes (Table 2(a)). Class 1 (temper rolled) is intended for applications where surface appearance is important and where specified surface and flatness requirements must be met. Class 2 is a product intended for applications where appearance is less important. Cold-rolled low-carbon steel strip is available in five hardness tempers ranging from full hard to dead soft (Table 3).

**Table 3 Mechanical properties of cold-rolled low-carbon steel strip (ASTM A 109)**

Temper	Hardness requirements, HRB	Bent test requirements <sup>(a)</sup>	Approximate tensile strength		Elongation in 50 mm (2 in.) <sup>(b)</sup> , %
			MPa	ksi	
No. 1 (hard)	90 minimum <sup>(c)</sup> , 84 minimum <sup>(d)</sup>	No bending in either direction	550-690	80-100	...
No. 2 (half-hard)	70-85 <sup>(d)</sup>	90° bend across rolling direction around a $1t$ radius	380-520	55-75	4-16
No. 3 (quarter-hard)	60-75 <sup>(e)</sup>	180° bend across rolling direction and 90° bend along rolling direction, both around a $1t$ radius	310-450	45-65	13-27
No. 4 (skin rolled)	65 maximum <sup>(e)</sup>	Bend flat on itself in any direction	290-370	42-54	24-40
No. 5 (dead)	55 maximum <sup>(e)</sup>	Bend flat on itself in any direction	260-	38-50	33-45

(a)  $t$  = thickness of strip.

(b) For strip 1.27 mm (0.050 in.) thick.

(c) For strip of thickness 1.02-1.78 mm exclusive (0.040-0.070 in. exclusive).

(d) For strip of thickness 1.78-6.35 mm exclusive (0.070-0.250 in. exclusive).

(e) For strip of thickness 1.02-6.35 mm exclusive (0.040-0.250 in. exclusive)

## Quality Descriptors for Carbon Steels

The descriptors of quality used for hot-rolled plain carbon steel sheet and strip and cold-rolled plain carbon steel sheet include structural quality, commercial quality, drawing quality, and drawing quality, special killed (Table 2(a)). Some of the as-rolled material made to these qualities is subject to surface disturbances known as coil breaks, fluting, and stretcher strains; however, fluting and stretcher strains will not be produced during subsequent forming if the material is temper rolled and/or roller leveled immediately prior to forming. It should be noted that any beneficial effects of roller leveling deteriorate rapidly in nonkilled steel. In addition to the requirements listed below for the various qualities of plain carbon steel sheet and strip, special soundness can also be specified.

**Commercial quality (CQ)** plain carbon steel sheet and strip are suitable for moderate forming; material of this quality has sufficient ductility to be bent flat on itself in any direction in a standard room-temperature bend test. Commercial

quality material is not subject to any other mechanical test requirements, and it is not expected to have exceptionally uniform chemical composition or mechanical properties. However, the hardness of cold-rolled CQ sheet is ordinarily less than 60 HRB at the time of shipment.

**Drawing Quality.** When greater ductility or more uniform properties than those afforded by commercial quality are required, drawing quality (DQ) is specified. Drawing quality material is suitable for the production of deep-drawn parts and other parts requiring severe deformation. When the deformation is particularly severe or resistance to stretcher strains is required, drawing quality, special killed (DQSK) is specified.

**Structural quality (SQ),** formerly called physical quality (PQ), is applicable when specified strength and elongation values are required in addition to bend tests (Table 4). Minimum values of tensile strength ranging up to 690 MPa (100 ksi) in hot-rolled sheet and strip and up to 1035 MPa (150 ksi) in cold-rolled sheet are available. Cold-rolled strip, which does not have a quality descriptor, is available in five tempers that conform to specified Rockwell hardness ranges and bend test requirements (Table 3).

**Table 4 Tensile requirements for structural quality low-carbon steel**

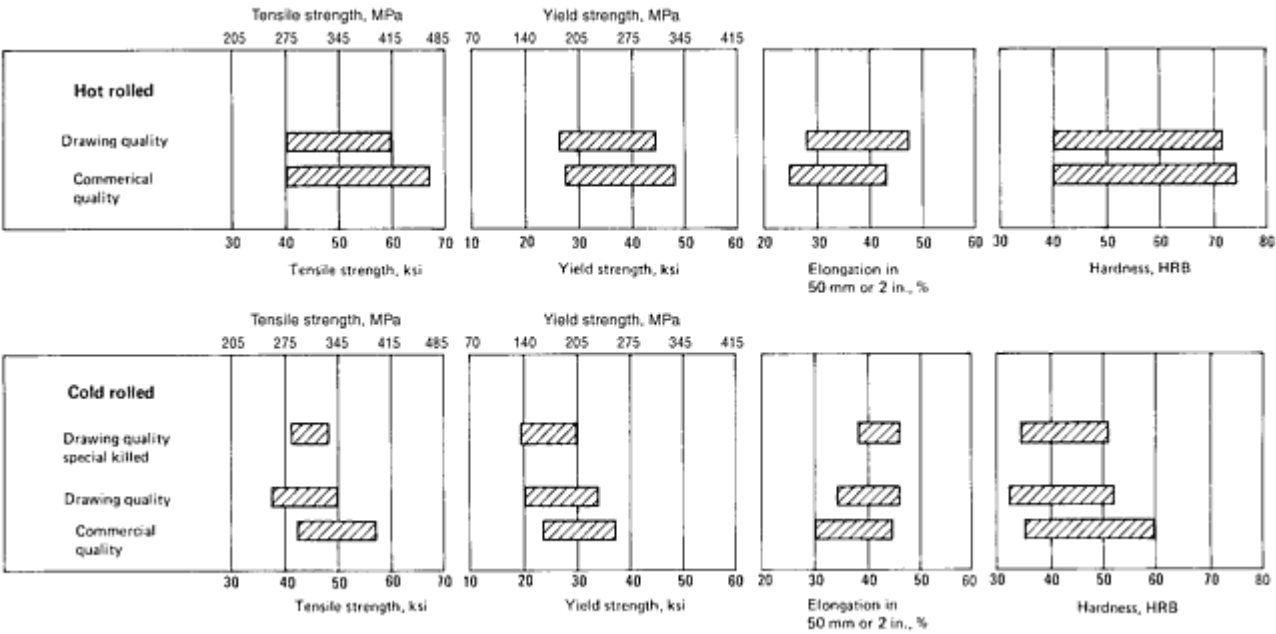

Class or grade	Yield strength, minimum		Tensile strength, minimum		Elongation in 50 mm (2 in.), minimum, %
	MPa	ksi	MPa	ksi	
Structural quality hot-rolled sheet and strip in cut lengths or coils (ASTM A 570) <sup>(a)</sup>					
30	205	30	340	49	25.0 <sup>(b)</sup>
33	230	33	360	52	23.0 <sup>(b)</sup>
36	250	36	365	53	22.0 <sup>(b)</sup>
40	275	40	380	55	21.0 <sup>(b)</sup>
45	310	45	415	60	19.0 <sup>(b)</sup>
50	345	50	450	65	17.0 <sup>(b)</sup>
55	380	55	480	70	15.0 <sup>(b)</sup>
Structural quality cold-rolled sheet in cut lengths or coils (ASTM A 611) <sup>(a)</sup>					
A	170	25	290	42	26
B	205	30	310	45	24
C	230	33	330	48	22

D, types 1 and 2	275	40	360	52	20
E	550 <sup>(c)</sup>	80 <sup>(c)</sup>	565	82	...

- (a) For coil products, testing by the producer is limited to the end of the coil. Results of such tests must comply with the specified values; however, design considerations must recognize that variation in strength levels can occur throughout the untested portions of the coil, though generally these levels will not be less than 90% of the minimum values specified.
- (b) At thickness, *t*, of 2.5-5.9 mm (0.097-0.230 in.).
- (c) On this full-hard product, the yield point approaches the tensile strength; because there is no halt in the gage or drop in the beam, the yield point shall be taken as the stress at 0.5% elongation, under load

Mechanical Properties

The commonly measured tensile properties of plain carbon steel sheet and strip are not readily related to their performance in fabrication; the relationship between formability and values of the strain-hardening exponent, *n*, and the plastic strain ratio, *r* (determined in tensile testing), is discussed in the Section "Mechanical, Wear, and Corrosion Testing" in this Handbook. The mechanical properties of commercial quality, drawing quality, and drawing quality, special killed sheet and strip are not ordinarily used in specifications unless special strength properties are required in the fabricated product. As a matter of general interest, however, the ranges of mechanical properties typical of sheet produced by three mills in these qualities are shown in Fig. 1. The bands would be wider if the product of the entire industry were represented. It should be noted that the ranges are broader and the sheet harder for the hot-rolled than for the cold-rolled materials.

**Fig. 1** Typical mechanical properties of low-carbon steel sheet shown by the range of properties in steel furnished by three mills. Hot-rolled sheet thickness from 1.519 to 3.416 mm (0.0598 to 0.1345 in., or 16 to 10 gage); cold-rolled sheet thickness from 0.759 to 1.519 mm (0.0299 to 0.0598 in., or 22 to 16 gage). All cold-rolled grades include a temper pass. All grades were rolled from rimmed steel except the one labeled special killed. See Table 4 for the mechanical properties of structural (physical) quality sheet.

Modified Low-Carbon Steel Sheet and Strip

In addition to the low-carbon steel sheet and strip products already discussed in this article, there are numerous additional products available that are designed to satisfy specific customer requirements. These products are often made with low-carbon steels having chemical compositions slightly modified from those discussed earlier. For example, in SQ steels, alloying additions of manganese and phosphorus are used to increase strength by substitutional solid-solution strengthening: approximately 3 MPa (0.4 ksi) per 0.1% Mn, and 7 MPa (1 ksi) per 0.01% P. Hot-rolled SQ steels contain from 0.90 to 1.35% max Mn and 0.035% max P. Cold-rolled SQ steels contain 0.60 to 0.90% max Mn and 0.035 to 0.20% P. Carbon contents for SQ steels are generally 0.20 to 0.25%.

**Interstitial-Free Steels.** In IF steels, which are also referred to as extra deep drawing quality (EDDQ), the elimination of interstitials (carbon and nitrogen) is accomplished by adding sufficient amounts of carbide/nitride-forming elements (generally titanium and/or niobium) to tie up carbon and nitrogen completely, the levels of which can be reduced to less than 50 ppm by modern steelmaking/casting practices, including vacuum degassing.

Steels with very low interstitial content exhibit excellent formability with low yield strength (138 to 165 MPa, or 20 to 24 ksi), high elongation (41 to 45%), and good deep drawability. With the addition of carbonitride-forming elements, the deep drawability and the nonaging properties are further improved.

**Bake-hardening (BH) steels** are characterized by their ability to exhibit an increase in yield strength due to carbon strain aging during paint-baking operations at moderate temperature (125 to 180 °C, or 260 to 355 °F). Bake hardening has little effect on tensile strength. Bake-hardening steels are finding increased usage in automotive outer-body applications (hoods, doors, fenders) to achieve an improvement in dent resistance and, in some cases, a sheet thickness reduction as well.

The bake-hardening behavior is dependent on steel chemistry and processing, in addition to the amount of forming strain and paint-baking conditions (temperature and time). Steels that exhibit bake-hardening behavior include plain low-carbon steels (continuously annealed or batch annealed), IF steels (continuously annealed), and dual-phase steels (continuously annealed).

Current automotive specifications for BH steels can be categorized according to those that specify a minimum yield strength level or a minimum bake-hardening increment, in the formed (strained) plus baked condition. The conventional test for determining bake-hardenability characteristics involves a 2% tensile prestrain, followed by baking at  $175 \pm 5$  °C ( $345 \pm 10$  °F). The resulting increase in yield strength measures the bake hardenability of the material.

While all the specifications call for a minimum yield strength level in the as-received (that is, prior to forming) condition, some also require a minimum yield strength after baking the as-received material in the absence of any tensile prestrain. The as-received yield strength is in the range 210 to 310 MPa (30 to 45 ksi) (compared with about 175 MPa, or 25 ksi, for DQSK), while the final yield strength, that is, after 2% prestrain plus bake, ranges between 280 and 365 MPa (40 to 53 ksi) (compared with about 225 MPa, or 33 ksi, for DQSK).

## Alloy Steel Sheet and Strip

---

ALLOY STEEL sheet and strip are used primarily for those special applications that require the mechanical properties normally obtained by heat treatment. A sizable selection of the standard alloy steels is available as sheet and strip, either hot rolled or cold rolled. The most commonly available alloys are listed in Table 5. In addition to standard low-alloy steels, high-strength low-alloy (HSLA) and dual-phase steels are available as sheet or strip for applications requiring tensile strengths in the range of 290 to 760 MPa (42 to 110 ksi). These steels are discussed in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Section.

**Table 5 Standard alloy steels available as sheet and strip**

SAE or AISI designation	Chemical composition ranges and limits (heat analysis) <sup>(a)</sup> , %							
	C	Mn	P	S	Si <sup>(b)</sup>	Ni	Cr	Mo
4118	0.18-0.23	0.70-0.90	0.035	0.040	0.15-0.30	...	0.40-0.60	0.08-0.15

8615	0.13-0.18	0.70-0.90	0.035	0.040	0.15-0.30	0.40-0.70	0.40-0.60	0.15-0.25

(a) The chemical ranges and limits shown are subject to product analysis tolerances. See ASTM A 505.

(b) Other silicon ranges are available. Consult the producer.

## Quality Descriptors

As it is used for steel mill products, the term "quality" relates to the general suitability of the mill product to make a given class of parts. For alloy steel sheet and strip, the various quality descriptors imply certain inherent characteristics, such as degree of internal soundness and relative freedom from harmful surface imperfections.

The quality descriptors used for alloy steel sheet and plate include regular quality, drawing quality, and aircraft quality, which are covered by ASTM specifications. The general requirements for these qualities are covered by ASTM A 505. Additional qualities include bearing quality and aircraft structural quality. Aircraft quality requirements are also covered in AMS specifications.

## Mill Heat Treatment

Hot-rolled regular-quality alloy steel sheet and strip normally are available from the producer either as rolled or as heat treated. Standard mill heat treated conditions are: annealed, normalized, and normalized and tempered. Cold-rolled regular-quality product normally is available only in the annealed condition.

## Precoated Steel Sheet

---

STEEL SHEET frequently is coated in coil form before fabrication either by the steel mills or by specialists called coil coaters.

The basic types of precoating include metallic, conversion, preprimed, and prepainted finishing. Metallic coating may be done with zinc, aluminum, tin, terne metal, or combinations of metals such as aluminum and zinc. Conversion coatings are completed with phosphates, and preprimed finishes are done with zinc chromate and zinc-rich coatings. Prepainting consists of applying an organic paint system to steel sheet on a coil coating line either at a mill or at a coil coater.

## Zinc Coatings

Metallic zinc is applied to iron and steel by one of three processes: hot dip galvanizing, electrogalvanizing, or zinc spraying. Most galvanized steel sheet is coated by the hot dip process.

Coating thickness is a key factor in determining coated product performance. In general, thicker coatings provide greater corrosion protection, whereas thinner coatings tend to give better formability and weldability. The amount of coating can also be expressed in terms of mass per unit area. This is determined by weighing a section of the coated product, stripping the coating in an acid solution, and weighing again. Table 6 summarizes coating thickness and mass called for by ASTM specifications. The coating thickness is usually expressed in terms of the coating on one side, whereas the mass is usually given as the sum of the coating on both sides.

**Table 6 Nominal coating mass and thickness for continuous hot dip coatings on steel sheet**

Type of coating <sup>(a)</sup>	Designation	Coating mass <sup>(b)</sup> , g/m <sup>2</sup>	Coating thickness <sup>(c)</sup> , $\mu\text{m}$

(d) No minimum

**Hot dip galvanizing** is a process in which an adherent, protective coating of zinc and iron-zinc alloys is developed on the surfaces of iron and steel products by immersing them in a bath of molten zinc. Most zinc coating of steel sheet is done by this process, usually on a continuous galvanizing line.

A typical hot dip galvanized coating consists of a series of layers. Starting from the basis steel at the bottom of the coating, each successive layer contains a higher proportion of zinc until the outer layer, which is relatively pure zinc, is reached. There is, therefore, no discrete line of demarcation between the iron and zinc, but a gradual transition through the series of iron-zinc alloys that provide a powerful bond between the basis metal and the coating.

**Electrogalvanizing.** Very thin formable zinc coatings ideally suited for deep drawing or painting can be obtained on steel products by electrogalvanizing. Zinc is electrodeposited on a variety of mill products, sheet, wire and, in some instances, pipe. Electrogalvanizing of sheet and wire in coil form produces a thin, uniform coating of pure zinc.

Electrodeposited zinc coatings are simpler in structure than hot dip galvanized coatings. They are composed of pure zinc, have a homogeneous structure, and are highly adherent. These coatings are not generally as thick as those produced by hot dip galvanizing. However, they do give good corrosion-free service. Coating thicknesses/masses range from 4 to 14  $\mu\text{m}$  (30 to 100  $\text{g/m}^2$ ) per side, although the most common coating thicknesses/masses are 8 and 10  $\mu\text{m}$  (60 and 70  $\text{g/m}^2$ ). For nonautomotive applications, a thickness/mass of as low as 1.5  $\mu\text{m}$  (10  $\text{g/m}^2$ ) can be used. Electrodeposited zinc is considered to adhere to steel as well as any other metallic coating. Because of its excellent adhesion, electrogalvanized coils of steel sheet and wire have good working properties, and the coating remains intact after severe deformation. Good

adhesion depends on very close physical conformity of the coating with the basis metal. Therefore, particular care must be taken during initial cleaning. Electrodeposition also affords a means of applying zinc coatings to finished parts that cannot be predipped. It is especially useful where a high processing temperature could injure the part. One advantage of electrodeposition is that it can be done cold and thus does not change the mechanical properties of the steel.

**Zinc spraying** consists of projecting atomized particles of molten zinc onto a prepared surface. Three types of spraying pistols are in commercial use today: the molten metal pistol, the powder pistol, and the wire pistol. The sprayed coating is slightly rough and slightly porous; the specific gravity of a typical coating is approximately 6.35, compared with 7.1 for cast zinc. This slight porosity does not affect the protective value of the coating, because zinc is anodic to steel. The zinc corrosion products that form during service fill the pores of the coating, giving a solid appearance. The slight roughness of the surface makes it an ideal basis for paint, when properly pretreated.

**Chromate Passivation.** Several types of finishes can be applied to zinc-coated surfaces to provide extra corrosion resistance. The simplest type of finish applicable to fresh zinc surfaces is a chromate passivation treatment. It is equally suitable for use on hot dip galvanized, zinc-sprayed, and zinc-plated articles. Usually, the treatment consists of simply cleaning the articles and then dipping them in a chromic acid or sodium dichromate solution at about 20 to 30 °C (68 to 86 °F), followed by rinsing in cold fresh water and drying in warm air.

**Anodizing** of galvanized steel produces a surface that exhibits exceptional resistance to corrosion, wear, heat, and abrasion. The anodized film is an electrical insulator. The film is formed by immersing finished parts in a simple electrolyte and applying an increasing voltage for up to 10 min. A nonreflective functional coating, anodized zinc demonstrates superior properties when compared with chromate conversion coatings. The anodized zinc coatings range from 25 to 33  $\mu\text{m}$  (1.0 to 1.3 mils) in thickness and will not deteriorate at temperatures up to the melting point of zinc.

**Painting.** The selection of galvanized steel as a material for barns, buildings, roofs, sidings, appliances and many hardware items is based on the sacrificial protection plus the barrier coating afforded the basis metal by zinc coating. For additional protection and pleasing appearance, paint coatings are often applied to the galvanized steel.

**Weldability.** Direct spot welding is recommended for zinc-coated steel, which may be either hot dip galvanized or electroplated, because the shunting current associated with series welding, when added to the higher-than-normal current needed to weld zinc-coated steel, results in excessive electrode heating and short electrode life.

Weldability of thin sheets electroplated with zinc decreases as the coating thickness increases, in the range from 0.005 to 0.025 mm (0.0002 to 0.001 in.). However, as sheet thickness increases above 1.5 mm (0.060 in.), weldability increases regardless of coating thickness. The welding behavior of hot dip galvanized steel is affected by the thickness and uniformity of the zinc-iron alloy layer, as well as the thickness of unalloyed zinc.

## Aluminum Coatings

Aluminized (aluminum-coated) steel sheet is used for applications where heat resistance, heat reflectivity, or resistance to corrosion are required in an aesthetically pleasing, economical sheet. Aluminum coating is done on continuous lines similar to those used for hot dip galvanizing of steel sheet. Cold rolled steel sheet is hot dipped into molten aluminum or an aluminum alloy containing 5 to 11% Si. The coating consists of two interfacial layers. Between the exterior layer of aluminum-silicon alloy and the steel basis metal, an aluminum-iron-silicon alloy layer is formed. This alloy can significantly affect the ductility, adhesion, uniformity, smoothness, and appearance of the surface and is controlled for optimum properties.

**Coating Thickness.** Two kinds of aluminum coating are produced (Table 6). Type 2 is a thicker coating (typically 30 to 50  $\mu\text{m}$ ) that is applied by dipping in an unalloyed aluminum bath. This product is used for outdoor construction applications such as roofing, culverts, and silos that require resistance to atmospheric corrosion and have limited formability requirements.

Type 1 aluminum coating is a thinner, aluminum-silicon alloy coating intended primarily for applications requiring formability and resistance to high temperatures, such as automobile exhaust components. Type 1 aluminum coatings are also applied to improve appearance. For most uses, the usual thickness of a Type 1 coating (Class 40) is about 20 to 25  $\mu\text{m}$  (0.8 to 1 mil). When maximum formability is a critical requirement, a thinner 12  $\mu\text{m}$  (Class 25) coating is specified.

**Corrosion Resistance.** Aluminum's value as a protective coating for steel sheet lies principally in its inherent corrosion resistance. In most environments, the long-term corrosion rate of aluminum is only about 15 to 25% of that of zinc. Generally, the protective value of an aluminum coating on steel is a function of coating thickness. The coating tends to remain intact and thus provides long-term protection.

Aluminum coatings do not provide sacrificial protection in most environments, particularly in atmospheric exposure.

**Heat Resistance.** Aluminum-coated sheet steel has excellent resistance to high-temperature oxidation. At surface temperatures above about 510 °C (950 °F), the aluminum coating protects the steel basis metal against oxidation without discoloration. Between 510 and 675 °C (950 and 1250 °F), the coating provides protection to the steel, but some darkening may result from the formation of aluminum-iron-silicon alloy. The alloy is extremely heat resistant, but on long exposure, the coating may become brittle and spall at temperatures above 675 °C (1250 °F) due to a different coefficient of expansion from that of the steel.

**Weldability.** Aluminum-coated steel sheet can be joined by electric resistance welding (spot welding or seam welding). It also can be metal-arc welded, flash welded, or oxyacetylene welded. Thorough removal of grease, oil, paint, and dirt followed by wire brushing is recommended before joining. Special fluxes are required for metal arc and oxyacetylene welding. During spot welding, electrodes tend to pick up aluminum, and the tips must be dressed more frequently than during spot welding of uncoated steel. Also, current density should be higher.

**Tin Coatings**

Tin coatings are applied to steel sheet either by electrolytic deposition or by immersion in a molten bath of tin (hot dip process). Hot dip tin coatings are applied to provide nontoxic, protective and decorative coating of food-handling, packaging, and dairy equipment, and to facilitate soldering of components used in electronic and electrical equipment. In the United States, hot dip tin coating has been replaced by electrolytic tin coating.

Electrolytic tin-coated steel sheet is used where solderability, appearance, or corrosion resistance under certain conditions is important, such as in electronic equipment, food-handling and processing equipment, and laboratory clamps. It is generally produced with a matte finish formed by applying the coating to basis metal sheet called "black plate," which has a dull surface texture, and leaving the coating unmelted. It can also be produced with a bright finish formed by applying the coating to basis metal having a smooth surface texture and then melting the coating. Electrolytic tin-coated sheet is usually produced in nominal thicknesses from 0.38 to 0.84 mm (0.015 to 0.033 in.) and in widths from 300 to 910 mm (12 to 36 in.).

Tin coatings are of the order of 0.4 to 1.5 μm thick, although they are usually expressed in terms of coating mass. Present values range from 0.5 to 11 g/m<sup>2</sup> on each surface. In the United States, tin coatings have numbers (Table 7) that designate the total weight of tin (i.e., the weight of the tin on the two sides per base box, a measure of surface area equal to 31,360 in.<sup>2</sup>, originally defined as 112 sheets, 14 by 20 in.). Presently there is a tendency, for economical and technological reasons, to apply lower-tin coatings, most commonly No. 20 or 25 (2.2 or 2.8 g/m<sup>2</sup>).

**Table 7 Electrolytic tin coating weight and mass designations**

Designation No.	Nominal tin coating weight each surface <sup>(a)</sup> , lb/base box	Minimum average coating weight each surface test value <sup>(a)(b)</sup> , lb/base box
Coating weights per ASTM A 624		
10	0.05/0.05	0.04/0.04
20	0.10/0.10	0.08/0.08

25	0.125/0.125	0.11/0.11
35	0.175/0.175	0.16/0.16
50	0.25/0.25	0.23/0.23
75	0.375/0.375	0.35/0.35
100	0.50/0.50	0.45/0.45
D50/25 <sup>(c)</sup>	0.25/0.125	0.23/0.11
D75/25 <sup>(c)</sup>	0.375/0.125	0.35/0.11
D100/25 <sup>(c)</sup>	0.50/0.125	0.45/0.11
D100/50 <sup>(c)</sup>	0.50/0.25	0.45/0.23
D135/25 <sup>(c)</sup>	0.675/0.125	0.62/0.11

Nominal coating each surface, g/m <sup>2</sup>	tin mass each surface, g/m <sup>2</sup>	Minimum average coating mass each surface test value <sup>(d)</sup> , g/m <sup>2</sup>
Coating masses per ASTM A 624M		
1.1/1.1		0.9/0.9
2.2/2.2		1.8/1.8
2.8/2.8		2.5/2.5
3.9/3.9		3.6/3.6
5.6/5.6		5.2/5.2
8.4/8.4		7.8/7.8
11.2/11.2		10.1/10.1
D5.6/2.8 <sup>(c)</sup>		5.2/2.5

D8.4/2.8 <sup>(c)</sup>	7.8/2.5
D11.2/2.8 <sup>(c)</sup>	10.1/2.5
D11.2/5.6 <sup>(c)</sup>	10.1/5.2
D15.2/2.8 <sup>(c)</sup>	14.0/2.5

Note: Listed above are the commonly produced coating weights and masses. Upon agreement between the producer and the purchaser, other combinations of coatings may be specified and the appropriate minimum average test values will apply.

- (a) Base box is a measure of surface area equal to 31,360 in.<sup>2</sup>.
- (b) The minimum value shall be not less than 80% of the minimum average tin coating weight.
- (c) The letter D on differentially coated tin plate indicates the coated surface to be marked. For example, the examples indicate that the heavy-coated side is marked.
- (d) The minimum spot value shall be not less than 80% of the minimum average tin coating mass.

## Terne Coatings

Long terne steel sheet is carbon steel sheet continuously coated by various hot dip processes with terne metal (lead with 3 to 15% tin). This coated sheet is duller in appearance than conventional tin-coated sheet, hence the name (terne) from the French, which means "dull" or "tarnished." The smooth, dull coating gives the sheet corrosion resistance, formability, excellent solderability, and paintability. The term "long terne" is used to describe terne-coated sheet, while "short terne" is used for terne-coated plate.

Because of its unusual properties, long terne sheet has been adapted to a wide variety of applications. Its greatest use is in automotive gasoline tanks. Its excellent solderability and special corrosion resistance makes the product well suited for this application.

Long terne sheet is often produced to ASTM A 308. The coatings are designated according to total coating weight on both surfaces as shown in Table 6. For applications requiring good formability, the coating is applied over low-carbon steel sheet of commercial quality, drawing quality, or drawing quality special killed. The terne coating acts as a lubricant and facilitates forming, and the strong bond of the terne metal allows it to be formed along with the basis metal. When higher strength is required, the coating can be applied over low-carbon steel sheet of structural (physical) quality, although at some sacrifice in ductility.

## Phosphate Coatings

Phosphate coating of iron and steel consists of treatment with a dilute solution of phosphoric acid and other chemicals whereby the surface of the metal, reacting chemically with the phosphoric acid, is converted to an integral layer of insoluble crystalline phosphate compound. This layer is less reactive than the metal surface and at the same time is more absorbent of lubricants or paints. Because the coating is an integral part of the surface, it adheres to the basis metal tenaciously.

The chief application for iron phosphate coatings is as a paint base for nongalvanized carbon steel sheet; such a coating is usually applied on coil-coating lines. Manganese phosphate coatings are used chiefly as an oil base on engine parts for break-in and to prevent galling.

## Steel Sheet for Porcelain Enameling

PORCELAIN ENAMELS are glass coatings applied primarily to products or parts made of sheet steel, cast iron, or aluminum to improve appearance and to protect the metal surface. Porcelain enamels are distinguished from other ceramic coatings on metallic substrates by their predominantly vitreous nature and the types of applications for which they are used. These coatings are differentiated from paint by their inorganic composition and coating properties. They are fused to the metallic substrate at temperatures above 425 °C (800 °F) during the firing process.

Properties of the particular steel sheet should be evaluated before its selection for enameling; some steel sheet is not recommended because of problems that complicate the process of coating the sheet with porcelain enamel. The four major problems are:

- Distortion caused by sag and warpage occurring at the temperatures reached during firing of the enamel
- Improper surface preparation that causes poor adherence
- Fishscale imperfections, particularly of the delayed variety, caused by hydrogen evolution
- Carbon boiling in the enamel coating caused by surface carbides in the steel

Steels for porcelain enameling with a single cover coat (white or colored) have since been developed. These steels, in addition to possessing single-coat coverage, have good sag resistance and freedom from carbon boiling, fishscale formation and the other problems associated with carbon, and internal imperfections. These steels are highly formable and can be drawn into more complex shapes than enameling iron.

### Types of Sheet

Six types of steel sheet are available for porcelain enameling. These are described below. In most instances, a detailed review should be made with the steel supplier before ordering a particular grade or beginning production. Typical chemical analysis of the steels recommended for enameling are listed in Table 8.

**Table 8 Compositions of low-carbon steels used for porcelain enameling**

Type of steel	Composition <sup>(a)</sup> , %								
	C	Mn	P	S	Al	Ti	Nb	B	Si
Low-carbon enameling steels <sup>(b)</sup>	0.02-0.04	0.15-0.3	0.015 <sup>(c)</sup>	0.015 <sup>(c)</sup>	0.03-0.07	...	...	0.006	0.015 <sup>(c)</sup>
Decarburized	0.005	0.2-0.3	0.01	0.02	<sup>(d)</sup>	...	...	...	...
Titanium-stabilized	0.05	0.30	0.01	0.02	0.05	0.30	...	...	...
Interstitial-free	0.005-0.020	0.20	0.01	0.02	...	0.06-0.15	0.10	...	...

(a) All compositions contain balance of iron.

- (b) Aluminum-killed replacement steel for enameling iron, which was a rimmed ingot-poured product formerly used for porcelain enameling.
- (c) Maximum.
- (d) Some steels may be supplied as aluminum-killed products.

**Low-Carbon Enameling Steels (Enameling Iron Replacements).** For many years, enameling iron, a rimmed-ingot poured product with a low metalloid content, was used extensively for porcelain enameling. The enameling characteristics were excellent, with the caveat that the product required a separate ground coat before applying a cover coat. Because enameling iron is a rimmed steel, it cannot be continuously cast. The movement in the steel industry to continuous casting has resulted in the recent withdrawal of the product from the market.

A number of highly serviceable enameling iron replacement products are now available for porcelain enameling. These aluminum killed steels have low carbon (0.02 to 0.04 wt%) and low manganese (0.15 to 0.30 wt%), along with 0.015 wt% P max, 0.015 wt% S max, 0.015 wt% Si max, and 0.03 to 0.07 wt% Al. Some contain a boron addition (0.006 wt% max) to aid in grain size control and to help improve resistance to enamel fishscale. The yield strength is 172 to 221 MPa (25 to 32 ksi), the tensile strength is 303 to 338 MPa (44 to 49 ksi), and the elongation is 38 to 46%.

Unlike the old enameling iron, these products do not require normalizing; they are either box annealed or continuously annealed. These processing changes result in steels that are more formable than their predecessors. Experience to date indicates that the enameling characteristics are similar to those of enameling iron, and these steels are being used in the same applications. They perform well with both ground-coat and two-coat/two-fire systems.

**Decarburized Steels.** The manufacture of fully decarburized sheet for direct-on cover coat enameling became practical following the development of the open coil annealing process. Different melting and teeming practices may be used to produce decarburized sheets: for instance, ladle aluminum killed-ingot poured and ladle aluminum killed-continuously cast. These aluminum killed products are not subject to the return of yield point elongation following temper rolling. As killed steels, the hot coiling off the hot strip mill eliminates the possibility of having deep drawability, but in stretch and plane strain conditions, the decarburized products are excellent performers.

Enameling characteristics for decarburized steels are excellent, and these steels are being used in all types of today's enamel systems. The low carbon content eliminates primary boiling and consequent defects such as black specks, pullthrough, and dimples caused by the evolution of carbon monoxide and carbon dioxide through the porcelain enamel coating during firing.

These steels have excellent resistance to warpage. They also exhibit good resistance to defects such as fishscale and ground-coat reboiling during firing of the cover coat, both of which are caused by the evolution of hydrogen gas. If over-pickled using the acid etch/nickel deposition metal preparation method, ladle killed steels will tend to have a "gassy" enamel surface, and enamel adherence is likely to be substandard. Ladle killing with aluminum and continuously casting is becoming the predominant way to produce these steels. It is expected that all decarburized steels will soon be manufactured by this method.

**Interstitial-free steels** are products in which all of the carbon and nitrogen contained in them are combined with an alloying element. Titanium or niobium (columbium), or a combination of titanium and niobium additions, are used to fully stabilize the steel. Domestically produced IF steels contain from <0.008 to 0.020 wt% C, 0.15 to 0.25 wt% Mn, 0.06 to 0.15 wt% Ti, and 0 to 0.10 wt% Nb. Vacuum degassing is used to produce the very-low-carbon versions, whereas the higher-carbon version is controlled by the basic oxygen shop.

These highly formable steels exhibit excellent strength retention after strain and firing, as well as good base metal sag properties. They do not exhibit stretcher strain and are nonaging and nonfluting. Because titanium can effect the development of ground-coat adherence, enamel systems should be optimized to ensure satisfactory adherence with these steels.

There are many specific applications in the appliance and plumbingware sector where these steels have proved to be valuable, especially where deep drawing is required. Also, these products can be produced by either ingot pouring or continuous casting, thereby ensuring their future availability.

**Titanium-stabilized steels** are a variation of IF steels. These steels are popular for large panels where maximum flatness can be achieved because of the product's resistance to warpage. Not being vacuum degassed, these steels are somewhat higher in carbon content than IF steels.

This carbon is stabilized as titanium carbide by the addition of titanium. Stabilization provides carbon boil resistance, a high after-fire strength, and excellent deep drawability. The higher titanium carbide content increases yield strength and reduces overall ductility. These steels offer high-temperature strength and resulting warp resistance, and they are now being produced as continuous-cast products.

**Common cold-rolled steels** have been used for many years in the porcelain enamel industry. They have been typically rimmed-ingot poured steels, but they are now being produced as continuous-cast products. They typically contain 0.04 to 0.07 wt% C and 0.25 to 0.040 wt% Mn. For cold-rolled drawing-quality steels, yield strength is 193 to 220 MPa (28 to 32 ksi), tensile strength is 295 to 330 MPa (43 to 48 ksi), and elongation is 40 to 44%. Enameling of cold-rolled steels should be restricted to ground coats and to noncritical appearance components.

Cold-rolled steels may also be used for two-coat enameling, where appearance is less important than in such components as range tops and other exterior parts for major appliances. Because of the high tendency of cold-rolled steel to warp and to carbon boil during porcelain enameling, the use of this material is generally restricted to components for which appreciable distortion during firing can be tolerated, applications using a low enamel firing temperature, or parts where a greater metal thickness is provided to minimize warpage. Most authorities recommend that parts fabricated from cold-rolled steels be porcelain enameled on one side only to minimize fishscale defects.

**Common Hot-Rolled Steels.** Hot-rolled sheets have a high susceptibility to fishscaling when porcelain enameled, especially if both sides of the steel are coated. When the use of hot-rolled steels is necessitated by the thickness/strength requirements for a given application, such as for water heater tanks, porcelain enameling should be limited to only one side of the sheet. This permits hydrogen gas, which produces the fishscaling, to escape from the unenameled side of the sheet.

## Carbon and Low-Alloy Steel Plate

---

STEEL PLATE is any flat-rolled steel product more than 200 mm (8 in.) wide and more than 6.0 mm (0.230 in.) thick or more than 1220 mm (48 in.) wide and 4.6 mm (0.180 in.) thick. The majority of mills for rolling steel plate have a working-roll width between 2030 and 5600 mm (80 and 220 in.). Therefore, the width of product normally available ranges from 1520 to 5080 mm (60 to 200 in.). Most steel plate consumed in North America ranges in width from 2030 to 3050 mm (80 to 120 in.) and ranges in thickness from 5 to 200 mm ( $\frac{3}{16}$  to 8 in.). Some plate mills, however, have the capability to roll steel more than 640 mm (25 in.) thick.

Steel plate is usually used in the hot-finished condition, but the final rolling temperature can be controlled to improve both strength and toughness. Heat treatment is also used to improve the mechanical properties of some plate.

## Basic Requirements

Steel plate is mainly used in the construction of buildings, bridges, ships, railroad cars, storage tanks, pressure vessels, pipe, large machines, and other heavy structures, for which good formability, weldability, and machinability are required. The impairment of these desirable characteristics with increased carbon content usually limits the steel to the low-carbon and medium-carbon constructional grades, with the low-carbon grades predominating. Many alloy steels are also produced as plate. In the final structure, however, alloy steel plate is sometimes heat treated to achieve mechanical properties superior to those typical of the hot-finished product.

## Steelmaking Practices

Killed steel is fully deoxidized, and from the viewpoint of minimum chemical segregation and uniform mechanical properties, killed steel is utilized for higher quality requirements. Therefore, killed steel is generally specified when homogeneous structure and internal soundness of the plate are required.

**Vacuum degassing** is used to remove dissolved oxygen and hydrogen from steel, thus reducing the number and size of indigenous nonmetallic inclusions. It also reduces the likelihood of internal fissures or "flakes" caused when hydrogen content is higher than desired.

**Desulfurization.** Using either hot metal desulfurization or ladle desulfurizing agents immediately before teeming (e.g., calcium or rare earth additions), final plate sulfur content can be reduced to less than 0.005%. Lower sulfur content improves plate ductility and impact properties, but adds to the cost of the steel.

**Electroslag remelting** is a consumable remelting process, used to produce the highest levels of quality in plate steels, particularly in thick plates. First, an ingot is melted by conventional methods, allowed to solidify in the form of an electrode, and prepared for remelting. It is then remelted through a reactive flux using a powerful electric current and again allowed to solidify. The resultant ingot is very low in sulfur and oxygen contents and free from internal blowholes and segregation.

## Quality Descriptors

Steel quality, as the term applies to steel plate, is indicative of many conditions, such as degree of internal soundness, relative uniformity of mechanical properties and chemical composition, and relative freedom from injurious surface imperfections. The various types of steel plate quality are indicated in Table 9.

**Table 9 Available quality levels for carbon, HSLA, and low-alloy steel plate**

Carbon steel plates	HSLA steel plates	Low alloy steel plates
Regular quality	...	...
Structural quality	Structural quality	Structural quality
Drawing quality	Drawing quality	Drawing quality
Cold-drawing quality	Cold-drawing quality	Cold-drawing quality
Cold-pressing quality	...	...
Cold-flanging quality	Cold-flanging quality	Cold-flanging quality
Forging quality	Forging quality	...
Pressure vessel quality	Pressure vessel quality	Pressure vessel quality
...	...	Aircraft quality

Regular quality carbon steel is produced with a maximum carbon content of 0.33%. Plates of this quality are not expected to have the same degree of chemical uniformity, internal soundness, or freedom from surface imperfections associated with structural quality or pressure-vessel quality plate.

Structural quality and pressure-vessel quality steel plates usually are produced to meet specific standard specifications prepared by one of several specification-writing bodies. ASTM A 6 covers the general requirements for the structural quality steel plate products described in the individual ASTM specifications, while ASTM A 20 covers general requirements for pressure-vessel quality products.

## Types of Steel

The three general categories of steel plate are carbon steel, alloy steel, and high-strength low-alloy (HSLA) steels. These three categories of steel plate are available in the steel plate quality levels given in Table 9. The various ASTM specifications for structural quality steel plate are given in Table 10. Chemical compositions of standard grades (SAE-AISI) and ASTM grades of carbon and alloy steels are given in the article "Classifications and Designations of Carbon and Alloy Steels" in this Section. Compositions, properties, and applications of HSLA steels are described in the article "High-Strength Structural and High-Strength Low-Alloy Steels." Plate steels used for elevated-temperature applications, for example, chromium-molybdenum alloy steels, are reviewed in the article "Service Characteristics of Carbon and Alloy Steels." some plate steels are also produced in more highly alloyed specialized grades, for example, high-fracture toughness steels and maraging steels. These materials are discussed in the article "Ultrahigh-Strength Steels."

**Table 10 ASTM specifications for structural quality steel plate**

ASTM specification <sup>(a)</sup>	Steel type and condition
<b>Carbon steel</b>	
A 36 <sup>(b)</sup>	Carbon steel shapes, plates, and bars of structural quality
A 131 <sup>(c)</sup>	Structural steel shapes, plates, bars, and rivets for use in ship construction (ordinary strength)
A 283 <sup>(b)</sup>	Low and intermediate tensile strength carbon steel plates
A 284	Low and intermediate tensile strength carbon-silicon steel plates for machine parts and general construction
A 529 <sup>(d)</sup>	Structural steel with 290 MPa (42 ksi) minimum yield point
A 573	Structural quality carbon-manganese-silicon steel plates with improved toughness
A 678	Quenched and tempered carbon and HSLA plates for structural applications
A 709	Carbon and HSLA steel structural shapes, plates, and bars, and quenched and tempered alloy steel for use in bridges
A 827 <sup>(e)</sup>	Carbon steel plates for forging applications
A 830 <sup>(e)</sup>	Structural quality carbon steel plates furnished to chemical requirements
<b>Alloy steel</b>	
A 514	Structural quality quenched and tempered alloy steel plates for use in welded bridges and other structures

A 709	See above under "Carbon steel"
A 710	Low-carbon age-hardening Ni-Cu-Cr-Mo-Nb, Ni-Cu-Nb, and Ni-Cu-Mn-Mo-Nb alloy steel plates, shapes, and bars for general applications
A 829 <sup>(e)(f)</sup>	Structural quality alloy steel plates specified to chemical composition requirements
<b>HSLA steel</b>	
A 131 <sup>(c)</sup>	Structural steel shapes, plates, bars, and rivets for use in ship construction (higher strength)
A 242	HSLA structural steel shapes, plates, and bars for welded, riveted, or bolted construction
A 441 <sup>(g)</sup>	Mn-V HSLA steel plates, bars, and shapes
A 572	HSLA structural Nb-V steel shapes, plates, sheet piling, and bars for riveted, bolted, or welded construction of bridges, buildings, and other structures
A 588 <sup>(h)</sup>	HSLA structural steel shapes, plates, and bars for welded, riveted, or bolted construction for use in bridges and buildings with atmospheric corrosion resistance approximately two times that of carbon steel with copper
A 633	Normalized HSLA structural steel for welded, riveted, or bolted construction suited for service at low ambient temperatures of -45 °C (-50 °F) or higher
A 656	Hot-rolled HSLA structural steel with improved formability for use in truck frames, brackets, crane booms, rail cars, and similar applications
A 678	See above under "Carbon steel"
A 709	See above under "Carbon steel"
A 808	Hot-rolled HSLA Mn-V-Nb structural steel plate with improved notch toughness
A 852	Quenched and tempered HSLA structural steel plate for welded, riveted, or bolted construction for use in bridges and buildings with atmospheric corrosion resistance approximately two times that of carbon steel with copper
A 871	HSLA structural steel plate in the as-rolled, normalized, or quenched and tempered condition with atmospheric corrosion resistance approximately two times that of carbon steel with copper

General requirements for structural plate are covered in ASTM A 6.

(a) Also designated with the suffix "M" when the specification covers metric equivalents.

- (b) This specification is also published by the American Society of Mechanical Engineers, which uses the prefix "S" (for example, SA36).
- (c) See also Section 43 of the American Bureau of Shipping specifications and MIL-S-22698 (SH).
- (d) 13 mm ( $\frac{1}{2}$  in.) maximum thickness.
- (e) See also the *AISI Steel Products Manual*.
- (f) Tensile properties may also be specified when compatible.
- (g) Discontinued in 1989 and replaced by A 572.
- (h) Minimum yield point 345 MPa (50 ksi) to 100 mm (4 in.). Lower minimum yield points for thicker sections

## Mechanical Properties

Of the various mechanical properties normally determined for steel plate, yield strength is an important design criterion in structural applications. Tensile strength is also an important design consideration in many design codes in the United States, but is useful primarily as an indication of fatigue properties. Yield strength is a design criterion in most design codes when the ratio of yield to tensile strength is less than 0.5. Ductility, as measured by tensile elongation and reduction in area, is seldom in itself a valuable design criterion, but is sometimes used as an indication of toughness and suitability for certain applications.

The mechanical properties of steel plate in the hot-finished condition are influenced by several variables, of which chemical composition is the most influential. Other factors include deoxidation practice, finishing temperature, plate thickness, and the presence of residual elements. For steels used in the hot-finished condition (such as plate), carbon content is the single most important factor in determining mechanical properties. The static tensile properties of the various grades, types, and classes of steel plate covered by ASTM specifications are listed in Table 11. It should be noted that some of these values vary with plate thickness/width.

ASTM specification	Material grade or type	Tensile strength <sup>(a)</sup>		Yield strength <sup>(a)</sup>		Minimum elongation <sup>(b)</sup> in 200 mm (8 in.), %	Minimum elongation <sup>(b)</sup> in 50 mm (2 in.), %
		MPa	ksi	MPa	ksi

## Steel Bar, Rod, and Wire

### Hot-Rolled Steel Bar and Shapes

HOT-ROLLED STEEL BARS and other hot-rolled steel shapes are produced from ingots, blooms, or billets converted from ingots, or from strand cast blooms and billets, and comprise a variety of sizes and cross sections. These bars and shapes are most often produced in straight lengths, but bars in some sizes and cross sections are also produced in coils.

The term "bar" includes: rounds, squares, hexagons, and similar cross sections 9.52 mm ( $\frac{3}{8}$  in.) and greater across; flats greater than 5.16 mm (0.203 in.) in thickness and 152.4 mm (6 in.) and less in width, or 5.84 mm (0.230 in.) and greater in thickness and 203.2 mm (8 in.) and less in width; small angles, channels, tees, and other standard shapes less than 76 mm (3 in.) across; and concrete-reinforcing bars. The term "shapes" includes structural shapes and special shapes. Structural shapes are flanged, are 76 mm (3 in.) or greater in at least one cross-sectional dimension, and are used in structures such as bridges, buildings, ships, and railroad cars. Special shapes are those designed by users for specific applications.

### Dimensions and Tolerances

The nominal dimensions of hot rolled steel bars and shapes are designated in inches or millimeters with applicable tolerances, as shown in ASTM specifications A 6 and A 29.

### Surface Imperfections

**Surface seams or laps** are the most common imperfections in hot rolled bars and shapes; they appear as longitudinal fissures. Seams are crevices in the steel that have been closed, but not welded. Laps are somewhat similar imperfections that result from rolling fins or protrusions into the surface of the bar,

**Allowance for Surface Imperfections.** Experience has shown that when purchasers order hot-rolled or heat-treated bars that are to be machined, it is advisable for the purchaser to make adequate allowances for the removal of surface imperfections and to specify the sizes accordingly. These allowances depend on the way the surface metal is removed, the length and size of the bars, the straightness, the size tolerance, and the out-of-round tolerance. Bars are generally straightened before machining. For special quality carbon steel bars and regular quality alloy steel bars, either resulfurized or nonresulfurized, it is advisable that allowances for centerless-turned or centerless-ground bars be adequate to permit stock removal of not less than the amount shown below:

Bar diameter		Recommended minimum machining allowance per side, % of specific size	
mm	in.	Nonresulfurized	Resulfurized
$\leq 51$	$\leq 2$	2.6	3.4
$> 51$	$> 2$	1.6	2.4

Note that these allowances are based on bars within straightness tolerance. Also, because straightness is a function of length, additional machining allowance may be required for turning long bars on centers. For steel bars subject to magnetic particle inspection, additional stock removal is recommended, as indicated in Table 1.

**Table 1 Recommended minimum stock removal for steel bars subject to magnetic particle inspection**

Hot-rolled size		Minimum stock removal from the surface <sup>(a)</sup>	
mm	in.	mm	in.
Up to 12.7	Up to $\frac{1}{2}$	0.76	0.030
$> 12.7$ -19	$> \frac{1}{2}$ - $\frac{3}{4}$	1.14	0.045
$> 19$ -25	$> \frac{3}{4}$ - 1	1.52	0.060
$> 25$ -38	$> 1$ - $1\frac{1}{2}$	1.90	0.075

>38-51	$>1\frac{1}{2}-2$	2.29	0.090
>51-64	$>2-2\frac{1}{2}$	3.18	0.125
>64-89	$>2\frac{1}{2}-3\frac{1}{2}$	3.96	0.156
>89-114	$>3\frac{1}{2}-4\frac{1}{2}$	4.75	0.187
>114-152	$>4\frac{1}{2}-6$	6.35	0.250
>152-191	$>6-7\frac{1}{2}$	7.92	0.312
>191-229	$>7\frac{1}{2}-9$	9.52	0.375
>229-254	>9-10	11.10	0.437

(a) The minimum reduction in diameter of rounds is twice the minimum stock removal from the surface.

## Product Requirements

Hot-rolled steel bars and shapes can be produced to chemical composition ranges or limits, mechanical property requirements, or both. The mechanical testing of hot-rolled steel bars and shapes can include tensile, Brinell or Rockwell hardness, bend, Charpy impact, fracture toughness, and short-time elevated-temperature tests, as well as tests for elastic limit, proportional limit, and offset yield strength, which require the use of an extensometer or plotting of a stress-strain curve. These tests are covered by ASTM A 370 and other ASTM standards.

Other tests sometimes required include the measurement of grain size and hardenability. Austenitic grain size is determined by the McQuaid-Ehn test, which is described in ASTM E 112. This test involves metallographic examination of a carburized specimen to observe prior austenitic grain boundaries. Hardenability can be measured by several methods, the most common being the Jominy end-quench test, as described in ASTM A 255 (see the article "Hardenability of Carbon and Alloy Steels" in this Section).

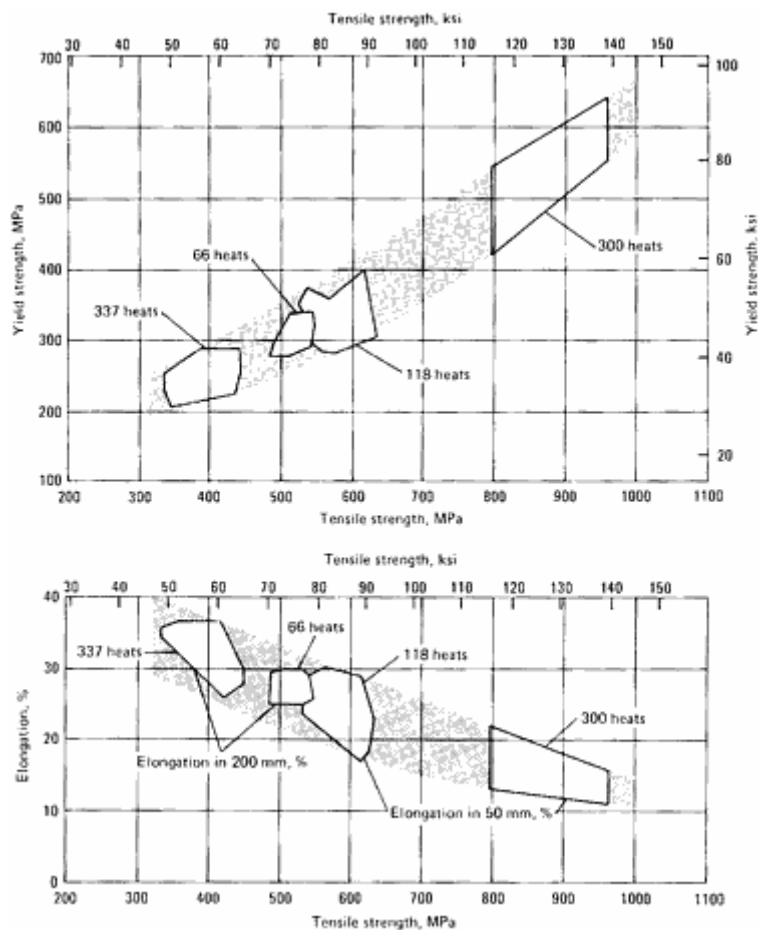

Soundness and homogeneity can be evaluated by fracturing. The fracture test is commonly applied only to high-carbon bearing quality steel. Location of samples, number of tests, details of testing technique, and acceptance limits based on the test should be established in each instance.

Testing for nonmetallic inclusions consists of careful microscopic examination (at 100×) of prepared and polished specimens. The specimens should be taken on a longitudinal plane midway between the center and surface of the product. Location of specimens, number of tests, and interpretation of results should be established in each instance. Typical testing procedures are described in ASTM E 45.

Tensile and hardness tests are the most common mechanical tests performed on hot-rolled steel bars and shapes. Hardness is a relatively simple property to measure, and it is closely related to tensile strength, as shown in Fig. 1. When Fig. 2 is used together with Fig. 1, a simple hardness test can give an estimate of yield strength and elongation, as well as tensile strength.

**Fig. 1** Relationship between hardness and tensile strength of steel. Range up to 300 HB is applicable to the hot-finished steel discussed in this article.

**Fig. 2** Relation of tensile properties for hot-rolled carbon steel

It is not practicable to set definite limitations on tensile strength or hardness for carbon or alloy steel bars in the as-rolled condition. For mill-annealed steel bars, there is a maximum tensile strength or a maximum hardness (Table 2) that can be expected for each grade of steel. For steel bars in the normalized condition, maximum hardness, maximum tensile strength, minimum hardness, or minimum tensile strength can be specified. For normalized and tempered bars and for quenched and tempered bars, either maximum and minimum hardness or maximum and minimum tensile strength can be

specified; for either property, the range that can be specified varies with tensile strength and is equivalent to a 0.4 mm range of Brinell indentation diameters at any specified location for normalized and tempered bars and to a 0.3 mm range for quenched and tempered bars.

**Table 2 Lowest maximum hardness that can be expected for hot-rolled steel bars, billets, and slabs with ordinary mill annealing**

## Product Categories

Hot-rolled carbon steel bars are produced to two primary quality levels: merchant quality and special quality. Merchant quality is the lower quality level and is not suitable for any operation in which internal soundness or freedom from surface imperfections is of primary importance. Special quality includes all bar categories with end-use-related and restrictive quality requirements.

### Merchant Quality Bars

Merchant quality is the least restrictive descriptor for hot-rolled carbon steel bars. Merchant quality bars are used in the production of noncritical parts of bridges, buildings, ships, agricultural implements, road-building equipment, railway equipment, and general machinery. These applications require only mild cold bending, mild hot forming, punching, and welding. Mild cold bending is bending in which a generous bend radius is used and in which the axis of the bend is at right angles to the direction of rolling.

**Grades.** Merchant quality bars can be produced to meet both chemical composition (heat analysis only) and mechanical properties. These steels can be supplied to chemical compositions within the ranges of 0.50% C (max), 0.60% Mn (max), 0.04% P (max), and 0.05% S (max), but are not produced to meet any specific silicon content, grain size, or any other requirement that would dictate the type of steel produced.

Merchant quality steel bars do not require the chemical ranges typical of standard steels. They are produced to wider carbon and manganese ranges and are designated by the prefix "M."

**Mechanical Properties.** When ordering merchant quality bars to meet mechanical properties, the following strength ranges are to be used up to a maximum of 655 MPa (95 ksi):

- 70 MPa (10 ksi) for minimums up to but not including 415 MPa (60 ksi)
- 80 MPa (12 ksi) for minimums from 415 MPa (60 ksi) up to but not including 460 MPa (67 ksi)
- 100 MPa (15 ksi) for minimums from 460 to 550 MPa (67 to 80 ksi)

Specification ASTM A 663 defines the requirements for hot-wrought merchant quality carbon steel bars and bar-size shapes intended for noncritical constructional applications.

**Sizes.** Merchant quality steel rounds are not produced in diameters greater than 76 mm (3 in.).

### Special Quality Bars

Special quality steel bars are employed when end use, method of fabrication, or subsequent processing treatment requires characteristics not available in merchant quality bars. Typical applications, including many structural uses, require hot forging, heat treating, cold drawing, cold forming and machining.

Special quality bars are required to be free from visible pipe and excessive chemical segregation. Also, they are rolled from blooms and billets that have been inspected and conditioned, as necessary, to minimize surface imperfections.

**Table 3 Typical ASTM specifications for structural quality steel bars and steel structural shapes. Covered in ASTM A6**

Specification	Steel type and condition
<b>Carbon Steels</b>

A 242	HSLA steel plates, bars, and shapes
A 572	Nb-V HSLA steel plates, bars, shapes, and sheet piling
A 588	HSLA steel plates, bars, and shapes with minimum yield point of 345 MPa (50 ksi)
A 633	Normalized HSLA steel plates, bars, and shapes
A 690	HSLA steel H-piles and sheet piling for use in marine environments

(a) This ASTM specification is also published by the American Society of Mechanical Engineers, which adds an S in front of the A.

(b) See also Canadian Standards Association (CSA) specification G40.8.

(c) See also Section 39 of the ABS specifications.

**Mechanical Properties.** Some special quality steel bars are produced to specified mechanical properties, Tensile properties are identical to those of the merchant quality bars described above.

**Sizes.** Special quality steel bars are commonly produced in the following sizes:

- *Rounds:* 6.4 to 254 mm ( $\frac{1}{4}$  to 10 in.)
- *Squares:* 6.4 to 154 mm ( $\frac{1}{4}$  to  $6\frac{1}{16}$  in.)
- *Round-cornered squares:* 9.5 to 203 mm ( $\frac{3}{8}$  to 8 in.)
- *Hexagons:* 9.5 to 103 mm ( $\frac{3}{8}$  to  $4\frac{1}{16}$  in.)
- *Flats:* greater than 5.16 mm (0.203 in.) in thickness and 152 mm (6 in.) and less in width, or 5.84 mm (0.230 in.) and greater in thickness and 203 mm (8 in.) and less in width

## Alloy Steel Bars

Hot-rolled alloy steel bars are commonly produced in the same size ranges as special quality steel bars. Both hot-rolled alloy and high-strength low-alloy steel bars are covered by ASTM specifications (Tables 3, 4). Many of the alloys covered in these specifications are standard SAE-AISI grades. Hot-rolled alloy steel bars are also produced for bearing applications and aircraft parts. Bearing-quality steels are described in the article "Bearing Steels" in this Section. Aircraft quality grades are often made to Aerospace Material Specifications (AMS).

**Table 4 Typical ASTM specification for hot-rolled steel bars**

Specification	Steel type and condition
<b>Carbon steels</b>

A 434 <sup>(a)</sup>	Quenched and tempered alloy steel bars, hot rolled or cold finished
A 485	Bearing quality high-carbon chromium steel billets, tube rounds, bars, and tubes modified for high hardenability

A 534	Carburizing alloy steel billets, tube rounds, bars, rods, wire, and tubes of bearing quality
A 535	Special quality alloy steel billets, bars, tube rounds, rods, and tubes for the manufacture of antifriction bearings

See Table 3 for ASTM specifications for structural quality bars and structural shapes.

(a) Covered in ASTM A 29

## Cold-Finished Steel Bars

**COLD-FINISHED STEEL BARS** are carbon and alloy steel bar products (round, square, hexagonal, flat, or special shapes) that are produced by cold finishing previous hot-wrought bars by means of cold drawing, cold forming, turning, grinding, or polishing (singly or in combination) to yield straight lengths or coils that are uniform throughout their length. Not covered here are flat-rolled products such as sheet, strip, or plate, which are normally cold finished by cold rolling, or cold-drawn tubular products.

Cold-finished bars fall into five classifications: cold-drawn bars; turned and polished (after cold draw or hot roll) bars; cold-drawn, ground, and polished (after cold draw) bars; turned, ground, and polished bars; and cold-drawn, turned, ground, and polished bars.

Cold-drawn bars represent the largest tonnage production and are widely used in the mass production of machined and other parts. They have attractive combinations of mechanical and dimensional properties.

Turned and polished bars have the mechanical properties of hot-rolled products but have greatly improved surface finish and dimensional accuracy. These bars are available in sizes larger than those that can be cold drawn. Turned bars are defect and decarb free.

Cold-drawn, ground, and polished bars have the increased machinability, tensile strength, and yield strength of cold-drawn bars together with very close size tolerances. However, cold-drawn, ground, and polished bars are not guaranteed to be defect free.

Turned, ground, and polished bars have superior surface finish, dimensional accuracy, and straightness. These bars find application in precision shafting and in plating, where such factors are of primary importance.

Cold-drawn, turned, ground, and polished bars have improved mechanical properties, close size tolerances, and a surface free of imperfections.

## Bar Sizes

Cold-finished steel bars are available in a wide variety of sizes and cross-sectional shapes. Normally, they are furnished in straight lengths, but in some sizes and cross sections they may be furnished in coils. Cold-finished steel bars are available with nominal dimensions designated in either inches or millimeters. Cold-finished product is available in standard size increments, which vary by size range. Special sizes can be negotiated depending on hot mill increments and cold-finish tooling. The sizes in which they are commonly available in bar form are given in Table 5.

**Table 5 Commercially available sizes of cold-finished steel bars**

Configuration	Minimum thickness or diameter		Maximum thickness or diameter		Size increments		Normal length	
	mm	in.	mm	in.	mm	in.	m	ft
Round	3.2	0.125	305	12	0.8-25	32nds to 1 in.	3.0-3.7 or 6.1-7.3	10-12 or 20-24
					1.6-75	16ths to 3 in.		
					3.2-152	8ths to 6 in.		
Square	3.2	0.125	152	6	1.6-38	16ths to $1\frac{1}{2}$ in.	3.0-3.7	10-12
					3.2-70	8ths to $2\frac{3}{4}$ in.		
Hexagonal	3.2	0.125	102	4	1.6-50	16ths to 2 in.	3.0-3.7	10-12
					6.4-102	4ths to 4 in.		
Flat	3.2 thick × 6.4 wide	0.125 thick × 0.25 wide	76 × 371	3 thick × $14\frac{5}{8}$ wide	1.6-17	16ths to $\frac{11}{16}$ in.	3.0-3.7	10-12
					3.2-44	8ths to $1\frac{3}{4}$ in.		

## Product Types

In the manufacture of cold-finished bars, the steel is first hot rolled oversize to appropriate shape and is then subjected to mechanical operations (other than those intended primarily for scale removal) that affect its machinability, straightness, and end-cut properties. As indicated above, the two common methods of cold finishing bars are (a) removal of surface material by turning or grinding, singly or in combination, and (b) drawing the material through a die of suitable configuration.

**Commercial Grades.** Any grade of carbon or alloy steel that can be hot rolled can also be cold finished. The choice of grade is based on the attainable cold-finished and/or hardenability and tempering characteristics necessary to obtain the required mechanical properties.

Cold drawn carbon steels are most common in grades with less than 0.55% carbon. Grades above this carbon level must be annealed before cold drawing, which increases cost, and their ultimate mechanical properties after annealing and cold drawing may be lower than those of lower-carbon grades cold drawn directly from hot rolled stock. Some improvement in machining characteristics of the higher-carbon grades can be obtained by annealing.

Alloy steels containing more than 0.38% carbon must be annealed before cold drawing.

**Machined Bars.** Bar products that are cold finished by stock removal can be: turned and polished; turned, ground, and polished; cold drawn, ground and polished; cold drawn, turned and polished; and cold drawn, turned, ground, and polished. Turning is done in special machines with cutting tools mounted in rotating heads, thus eliminating the problem of having to support long bars as in a lathe. Grinding is done in centerless machines. Polishing can be done in a roll straightener of the crossed-axis (Medart) type with polished rolls to provide a smooth finish. Polishing by grinding with an organic wheel or with a belt is also employed.

The published range of diameters both for turned and for turned and ground bars is 13 to 229 mm ( $\frac{1}{2}$  to 9 in.) inclusive; for cold-drawn and ground bars, it is 3.2 to 102 mm ( $\frac{1}{8}$  to 4 in.) inclusive. These are composites of size ranges throughout the industry; an individual producer may be unable to furnish a full range of sizes. For example, one well-known producer supplies turned rounds from 13 to 229 mm ( $\frac{1}{2}$  to 9 in.), another from 29 to 203 mm ( $1\frac{1}{8}$  to 8 in.)--all finished sizes.

Stock removal in turning, or turning and grinding, measured on the diameter, is normally 1.6 mm ( $\frac{1}{16}$  in.) for sizes up to 38 mm ( $1\frac{1}{2}$  in.), 3.2 mm ( $\frac{1}{8}$  in.) for the 38 to 76 mm ( $1\frac{1}{2}$  to 3 in.) range, 4.8 mm ( $\frac{3}{16}$  in.) for the 76 to 127 mm (3 to 5 in.) range, and 6.4 mm ( $\frac{1}{4}$  in.) for 127 mm (5 in.) diameter and larger.

**Cold-drawn round bars** are available in a range of diameters from 3.2 to 152 mm ( $\frac{1}{8}$  to 6 in.). The maximum diameters available from individual producers, however, may vary from 76 to 152 mm (3 to 6 in.). The reduction in diameter in cold drawing, called draft, is commonly 0.79 mm ( $\frac{1}{32}$  in.) for finished sizes up to 9.5 mm ( $\frac{3}{8}$  in.) and 1.6 mm ( $\frac{1}{16}$  in.) for sizes over 9.5 mm ( $\frac{3}{8}$  in.). Some special processes use heavier drafts followed by stress relieving. One producer employs heavy drafting at elevated temperature. With this exception, drawing operations are begun with the material at room temperature, and the only elevated temperature involved is that developed in the bar as a result of drawing; this temperature rise is small and of little significance.

Originally, cold finishing, whether by turning or by cold rolling, was employed only for sizing to produce a bar with closer dimensional tolerances and a smoother surface. As cold-finished bar products were developed and improved, increased attention was paid to the substantial enhancement of mechanical properties that could be obtained by cold working. This additional advantage is now more fully appreciated, as evidenced by the fact that increased mechanical properties are an important consideration in about 40% of the applications. In approximately half of these applications, or 20% of the total, cold drawing is used only to increase strength; in the other 20%, close tolerances and better surface finish are desired in addition to increased strength.

As-rolled microalloyed high-strength low-alloy (HSLA) steels or microalloyed HSLA steels in various combinations of controlled drafting and furnace treatment provide an extension of property attainment. A high percentage of free-machining steels are cold drawn for the combination of size accuracy and improved machinability. Recent developments in microalloyed steels provide hot-rolled turned bars, under certain circumstances, having mechanical properties similar to cold-drawn nonmicroalloyed steels.

**Turning Versus Cold Drawing.** Basic differences exist between bars finished by turning and those finished by cold drawing. First, it is obvious that turning and centerless grinding are applicable only to round bars, while drawing can be applied to a variety of shapes. Drawing, therefore, is more versatile than turning.

Second, there is a difference in the number and severity of the surface imperfections that may be present. Because stock is removed in turning and grinding, shallow surface imperfections and decarburization may be completely eliminated. When material is drawn, stock is only displaced, and surface imperfections are only reduced in depth.

Different size tolerances are applicable to cold-finished products, depending on shape, carbon content and heat treatment. Listed in Tables 6, 7, and 8 are the tolerances for cold-finished carbon and alloy steel bars published in ASTM A 29. These tables include cold-drawn bars; turned and polished rounds; cold-drawn, ground, and polished rounds; and turned, ground, and polished rounds. From the data in Tables 6, 7, and 8, certain generalizations can be stated. The tolerances for cold-drawn and for turned and polished rounds, for example, are the same for sizes up to and including 102 mm (4 in.). There are differences, however, between the tolerances that apply to carbon steel and those that apply to alloy steels. Tolerances for several finishes also vary with certain levels of carbon content. Broader tolerances are applicable to bars that have been heat treated before cold finishing. In contrast, tolerances are closer when bars are ground, and these tolerances are independent of carbon content.

**Table 6 Size tolerances for cold-finished carbon steel bars, cold drawn or turned and polished**

Size		Size tolerance									
		Maximum carbon (C) range, %								All grades quenched and tempered or normalized before cold finishing	
		C ≤0.28		0.28 < C ≤ 0.55		C ≤0.55 including stress relief or annealed after cold finishing		C > 0.55

This table includes tolerances for bars that have been annealed, spheroidize annealed, normalized, normalized and tempered, or quenched and tempered before cold finishing. This table does not include tolerances for bars that are annealed, spheroidize annealed, normalized, normalized and tempered, or quenched and tempered after cold finishing; the producer should be consulted for tolerances for such bars.

- (a) Tolerances can be ordered all plus, or distributed plus and minus with the sum equivalent to the tolerances listed.
- (b) Width governs the tolerance for both width and thickness of flats, for example, when the maximum of carbon range is 0.28% or less for a flat 50 mm (2 in.) wide and 25 mm (1 in.) thick. The width tolerance is 0.13 mm (0.005 in.), and the thickness is the same, nearly 0.13 mm (0.005 in.).

Incl, inclusive; excl, exclusive.

- (a) For nonresulfurized steels (steels specified to maximum sulfur limits under 0.08%) or for steels thermally treated, the tolerance is increased by 0.03 mm (0.001 in.).

## Carbon Steel Quality Descriptors

**Standard quality** is the descriptor applied to the basic quality level to which cold-finished carbon steel bars are produced. Standard quality cold-finished bars are produced from hot-rolled carbon steel of special quality (the standard quality for hot-rolled bars for cold finishing). Steel bars of standard quality must be free from visible pipe and excessive chemical segregation. They may contain surface imperfections. In general, the size of surface imperfections increases with bar size.

**Restrictive requirement quality A (RRA)** incorporates all the features of standard quality carbon steel bars described above, plus any one of the following restrictive requirements.

**Special surface bars** are produced with special surface preparation to minimize the frequency and size of seams and other surface imperfections. These bars are used for applications in which machining allowances do not allow sufficient surface removal to clean up the detrimental imperfections that occur in standard quality bars.

**Special internal soundness bars** have greater freedom from chemical segregation and porosity than standard quality bars

**Special hardenability bars** are produced to hardenability requirements other than those of standard H-steels.

**Cold-finished carbon steel bars** are also produced to inclusion ratings as determined by standard nonmetallic inclusion testing.

**Restrictive requirement quality B (RRB)** incorporates all the features of standard quality carbon steel bars, plus any one of the following.

**Special discard** is specified when minimized chemical segregation, special steel cleanliness, or internal soundness requirements dictate that the product be selected from certain positions in the ingot.

**Minimized decarburization** is specified whenever decarburization is important, as in heat treating for surface hardness requirements.

**Single restrictions** other than those noted above, such as special chemical limitations, special processing techniques, and other special characteristics not previously anticipated are also covered by this quality level.

**Multiple restrictive requirement quality (MRR)** applies when two or more of the above-described restrictive requirements are involved.

**Cold-forging quality A and cold-extrusion quality A** apply to cold-finished carbon steel bars used in the production of solid or hollow shapes by means of cold plastic deformation involving the movement of metal by compression with no expansion of the surface and not requiring special inspection standards.

**Cold-heading quality, cold-extrusion quality B, cold-upsetting quality, and cold-expansion quality** apply to cold-finished carbon steel bars used in production of solid or hollow shapes by means of severe cold plastic deformation by cold heading, cold extrusion, cold upsetting, or cold expansion involving movement of metal by expansion and/or compression. Such bars are obtained from steel produced by closely controlled steelmaking practices and are subject to special inspection standards for internal soundness and surface quality and uniform chemical composition. For grades of steel with a maximum specified carbon content of 0.30% or more, an anneal or spheroidize anneal heat treatment may be required to obtain the proper hardness and microstructure for cold working.

**Restrictive cold-working quality** applies to cold-finished carbon steel bars used in the production of solid or hollow shapes by means of very severe cold plastic deformation involving cold working by expansion and/or compression.

**Other Carbon Steel Qualities.** The quality descriptors listed below are some of those that apply to cold-finished carbon steel bars intended for specific requirements and applications. They may have requirements for surface quality, amount of discard, macroetch tests, mechanical properties, or chemical uniformity as indicated in product specifications:

- Axle shaft quality
- Shell steel quality A
- Shell steel quality C
- Rifle barrel quality
- Spark plug quality

## **Alloy Steel Quality Descriptors**

**Regular quality** is the descriptor applied to the basic, or standard, quality level to which cold-finished alloy steel bars are produced. Steels for this quality are killed and are usually produced to a fine grain size. They are melted to chemical ranges and limits and are inspected and tested to meet normal requirements for regular constructional alloy steel applications. Regular quality cold-finished alloy steel bars may contain surface imperfections. In general, the size of detrimental surface imperfections increases with bar size.

**Cold-heading quality** applies to cold-finished alloy steel bars intended for applications involving cold plastic deformation by such operations as upsetting, heading, or forging. Bars are supplied from steel produced by closely controlled steelmaking practices and are subject to mill testing and inspection designed to ensure internal soundness, uniformity of chemical composition, and freedom from detrimental surface imperfections. Proper control of hardness and microstructure by heat treatment and cold working is important for cold forming. Most cold-heading quality alloy steels are low- and medium-carbon grades.

**Special cold-heading quality** applies to cold-finished alloy steel bars for applications involving severe cold plastic deformation when slight surface imperfections may cause splitting of a part. Bars of this quality are produced by closely

controlled steelmaking practices to provide uniform chemical composition and internal soundness. Also, special processing (such as grinding) is applied at intermediate stages to remove detrimental surface imperfections. Proper control of hardness and microstructure by heat treatment and cold working is important for cold forming.

**Axle shaft quality** applies to cold-finished alloy steel bars intended for the manufacture of automotive or truck-type, power-driven axle shafts, which by their design or method of manufacture are either not machined all over or undergo less than the recommended amount of stock removal for proper cleanup of normal surface imperfections.

**Ball and roller bearing quality and bearing quality** apply to cold-finished alloy steel bars used for the manufacture of antifriction bearings. Such bars are usually produced from alloy steels of the SAE-AISI standard alloy carburizing grades and the SAE-AISI high-carbon chromium series. These steels can be produced in accordance with ASTM A 534, A 295, and A 485 (see the article "Bearing Steels" in this Section for details).

**Aircraft quality and magnaflux quality** apply to cold-finished alloy steel bars for important or highly stressed parts of aircraft and for other similar or corresponding purposes involving additional stringent requirements, such as magnetic particle inspection, additional discard, macroetch tests, and hardenability control.

**Other Alloy Steel Qualities.** The quality descriptors listed below apply to cold-finished alloy steel bars intended for rifles, guns, shell, shot, and similar applications. They may have requirements for amount of discard, macroetch testing, surface requirements, or magnetic particle testing as indicated in the product specifications:

- Armor-piercing (AP) shot quality
- AP shot magnaflux quality
- Gun quality
- Rifle barrel quality
- Shell quality
- Shell magnaflux quality

## Mechanical Properties

A major difference between machined and cold-drawn round bars is the improvement in tensile and yield strengths that results from the cold work of drawing. Cold work also changes the shape of the stress-strain diagram, as shown in Fig. 3. Within the range of commercial drafts, cold work markedly affects certain mechanical properties (Fig. 4). The variations in percentage of reduction of cross section for bars drawn with normal commercial drafts of 0.8 and 1.6 mm ( $\frac{1}{32}$  and  $\frac{1}{16}$  in.) and with heavy drafts of 3.2 and 4.8 mm ( $\frac{1}{8}$  and  $\frac{3}{16}$  in.) are shown in Fig. 5. Normal reductions seldom exceed 20% and are usually less than 12%. According to Fig. 4, the more pronounced changes in significant tensile properties occur within this range of reductions (up to about 15%).

**Fig. 3** Effect of cold work on the tensile stress-strain curve for low-carbon steel bars

**Fig. 4** Effect of cold drawing on the tensile properties of steel bars. Data are for bars up to 25 mm (1 in.) in cross section having a tensile strength of 690 MPa (100 ksi) or less before cold drawing.

**Fig. 5** Effect of draft on reduction of cross section of steel bars

## Steel Wire Rod

WIRE ROD is a semifinished product rolled from billet on a rod mill and is used primarily for the manufacture of wire. The steel for wire rod is produced by all the steelmaking processes, including the basic oxygen, basic open hearth, and electric furnace processes. Steel wire rod is usually cold drawn into wire suitable for further drawing; for cold rolling, cold heading, cold upsetting, cold extrusion, or cold forging; or for hot forging.

Although wire rod may be produced in several regular shapes, most is round in cross section. Round rod is usually produced in nominal diameters of 5.6 to 18.7 mm ( $\frac{7}{32}$  to  $\frac{47}{64}$  in.), advancing in increments of 0.4 mm ( $\frac{1}{64}$  in.). As the rod comes off the rolling mill, it is formed into coils. These coils are usually about 760 mm (30 in.) in inside diameter and weigh up to 2000 kg (4400 lb). The dimensions and maximum weight of a single coil are determined by the capabilities of the rolling mill. Coil weights that exceed the capabilities of the rolling mill sometimes can be obtained by welding two or more coils together. The standard tolerances are  $\pm 0.4$  mm ( $\pm \frac{1}{64}$  in.) on the diameter and 0.64 mm (0.025 in.) maximum out-of-roundness.

Producers of wire rod may market their product as rolled, as cleaned and coated, or as heat treated, although users generally prefer to do such preparations themselves. These operations are explained in the following sections, along with the several recognized quality and commodity classifications applicable to steel wire rods.

## Processing

**Cleaning and Coating.** Mill scale is cleaned from steel wire rods by pickling or caustic cleaning followed by water rinsing, or by mechanical means such as shot blasting with abrasive particles or reverse bending over sheaves. The chemical cleaning of steel wire rods is always followed by a supplementary coating operation. Lime, borax, or phosphate coating is applied to provide a carrier for the lubricant necessary for subsequent processing into wire. In lime coating, practices may be varied in order to apply differing amounts of lime on the rods depending on the customer requirements. Phosphate-coated rods may have a supplementary coating of lime, borax, or water-soluble soap. Mechanically descaled rods may be drawn without coating using only wire drawing soaps, or may be coated in a fashion similar to that used for chemically cleaned rods.

**Heat treatments commonly applied to steel wire rod**, either before or during processing into wire, include annealing, spheroidize annealing, patenting, and controlled cooling. Annealing commonly involves heating steel wire rod to a temperature near or below the lower critical temperature and holding it at that temperature for a sufficient period of time, followed by slow cooling. This process softens the steel for further processing, but not to the same degree as does spheroidize annealing. Spheroidize annealing involves prolonged heating at a temperature near or slightly below the lower critical temperature (or thermal cycling at about the lower critical temperature), followed by slow cooling, in order to change the shape of carbides in the microstructure to globular (spheroidal), which produces maximum softness.

Patenting is a heat treatment usually confined to medium-high-carbon and high-carbon steels. In this process, individual strands of rod or wire are heated well above the upper critical temperature and then are cooled comparatively rapidly in air, molten salt, molten lead, or a fluidized bed. The object of patenting is to develop a microstructure of homogeneous, fine pearlite. This treatment generally is employed to prepare the material for subsequent wire drawing.

Controlled cooling is a heat treatment performed in modern rod mills in which the rate of cooling after hot rolling is carefully controlled. The process imparts uniformity of properties and some degree of control over scale, grain size, and microstructure.

## Carbon Steel Rod

**Compositions.** Carbon steel rods are produced in various grades, or compositions:

- Low-carbon steel wire rods (maximum carbon content  $\leq 0.15\%$ )
- Medium-low-carbon steel wire rods (maximum carbon content  $>0.15\%$  but  $\leq 0.23\%$ )
- Medium-high-carbon steel wire rods (maximum carbon content  $>0.23\%$  but  $\leq 0.44\%$ )
- High-carbon steel wire rods (maximum carbon content  $>0.44\%$ )

Ordinarily, sulfur and phosphorus contents are kept within the usual limits for each grade of steel, while carbon, manganese, and silicon contents are varied according to the mechanical properties desired. Occasionally, sulfur and/or phosphorus may be added to the steel to improve the machinability.

**Qualities and Commodities.** Rod for the manufacture of carbon steel wire is produced with manufacturing controls and inspection procedures intended to ensure the degree of soundness and freedom from injurious surface imperfections necessary for specific applications. The quality descriptors and commodities applicable to carbon steel wire rod are:

- Industrial quality rod
- Chain quality rod
- Fine wire quality rod
- Cold finishing quality rod
- Heading, cold extrusion, or cold rolling quality rod
- Wood screw quality rod
- Scrapless nut quality rod
- Severe cold heading, severe cold extrusion, or severe scrapless nut quality rod
- Welding quality rod
- Medium-high-carbon and high-carbon quality rod
- Special quality rod (e.g., rod for music wire, valve spring wire, and tire cord wire)

**Mechanical Properties.** In the older mills, where rod was coiled hot, there was considerable variation within each coil because of the effect of varying cooling rates from the center to the periphery of the coil. Therefore, as-hot-rolled rod was seldom sold to specific mechanical properties because of the inherent variations of such properties. These properties for a given grade of steel varied from mill to mill and were influenced by both the type of mill and the source of steel being rolled.

In newer rod mills, which are equipped with controlled cooling facilities, this intracoil variation is kept to a minimum. In such mills, finishing temperature, cooling of water, cooling air, and conveyor speed all are balanced to produce rod with the desired scale and microstructure. This structure, in turn, is reflected in the mechanical properties of the rod and permits the rod to be drawn directly for all but the most demanding applications. The primary source of intracoil variation on these new mills is the overlapping of the coiled rings on the conveyor. These overlapped areas cool at a slower rate than the majority of the ring.

Table 9 lists typical values of tensile strength for 5.6 mm ( $\frac{7}{32}$  in.) low-carbon steel rod rolled on a modern rod mill equipped with controlled cooling facilities. The values shown are for rods rolled with full air cooling. Tensile strength values for larger-diameter rod are lower, decreasing by approximately 1.9 MPa (270 psi) for each 0.4 mm ( $\frac{1}{64}$  in.) increment by which rod diameter exceeds 5.6 mm ( $\frac{7}{32}$  in.). Similar analyses of rods rolled without full air cooling or rods rolled on an older mill, where the steel is coiled hot, would be expected to reveal lower tensile strength.

**Table 9 Tensile strength of 5.6 mm ( $\frac{7}{32}$  in.) diam hot-rolled low-carbon steel rod**

Steel grade	Rimmed		Capped		Aluminum killed fine-grain steel		Silicon killed fine- or coarse-grain steel

Data obtained from rod produced with controlled cooling

## Alloy Steel Rod

Alloy steels are those steels for which maximum specified manganese content exceeds 1.65% or maximum specified silicon or copper content exceeds 0.60%; or for which a definite range or definite minimum quantity of any other element is specified in order to obtain desired effects on properties. For detailed information on composition ranges and limits of alloy steels, see the article "Classifications and Designations of Carbon and Alloy Steels," at the beginning of this Section.

## Steel Wire

---

WIRE may be cold drawn from any of the types of carbon steel or alloy steel rod described in the preceding subsection on steel wire rod. For convenience in describing the various grades of carbon steel wire, they may be divided into the same four classes used for carbon steel wire rod. Based on carbon content, these classes are: low-carbon steel wire (0.15% carbon max), medium-low-carbon steel wire (>0.15 to 0.23% carbon), medium-high-carbon steel wire (>0.23 to 0.44% carbon), and high-carbon steel wire (>0.44% carbon). The conventional four-digit or five-digit SAE-AISI designation is used to specify the carbon or alloy steel used to make the wire. Carbon and alloy steel wire can be produced in qualities suitable for cold rolling, cold drawing, cold heading, cold upsetting, cold extrusion, cold forging, hot forging, cold coiling, heat treatment or carburizing, and for a wide variety of fabricated products.

## Wire Shapes and Sizes

**Shapes of Wires.** Although wire ordinarily is thought of as being only round, it may have any one of an infinite number of sectional shapes, as required by end use. After ordinary round wire, the most common shapes are square, hexagonal, octagonal, oval, half-oval, half-round, triangular, and flat. Besides these regular (symmetrical) shapes, wire also is made in various odd and irregular shapes for specific purposes.

**Sizes of Wire.** The size limits for the product commonly known as wire range from approximately 0.13 mm (0.005 in.) to (but not including) 25.4 mm (1 in.) for round sections, and from a few tenths of a millimeter (a few thousandths of an inch) to approximately 13 mm ( $\frac{1}{2}$  in.) for square sections. Larger rounds and squares, and all sizes of hexagonal and octagonal sections, are commonly known as bars.

## Wiremaking Practices

**Wiredrawing.** Steel wire is produced from coils of wire rod after removal of scale by one or more cold reduction processes intended primarily for the purpose of obtaining the desired size. Wiredrawing, which improves surface finish and dimensional accuracy, is the most common cold reduction process. Cold drawing naturally results in mechanical and physical properties different from those of hot rolled steel of like composition. By varying the amount of cold reduction and other wire mill practices (including heat treatment) a wide diversity of properties and finishes can be obtained.

Mechanical characteristics of steel wire (e.g., strength, stiffness, hardness) result from wire mill treatment as well as from chemical composition, and thus mechanical properties of wire are less dependent on chemical composition than those of other steel mill forms. In most instances, the purchaser of wire is interested in suitability for a given application rather than in chemical composition.

Before drawing, the scale is removed from the material by acid pickling or mechanical descaling. If acid pickled, the coil is rinsed with water, dipped in a vat containing hydrated lime in suspension or other material in solution, and baked to dry the coating and to liberate any hydrogen that may have been absorbed by the steel during pickling.

In cold drawing of wire, coiled rod is drawn through the tapered hole of a die or through a series of dies, the number of dies employed depending on the finished diameter required. To begin drawing, one end of the rod is pointed, inserted through the die and attached to a power-driven reel (block); the block then pulls the material through the die and coils the drawn wire.

The common design of wiredrawing die (see Fig. 6) consists of a supporting ring of steel encasing a hard, wear-resistant nib. The nib consists of one or more carbides (such as tungsten, tantalum, or titanium) mixed with a bonding agent, such as cobalt, pressed into the desired shape and sintered into its hardened rough form, after which it is mounted, sized, and polished. For certain types of fine wire, diamond dies sometimes are used instead of carbide dies.

**Fig. 6** Typical wiredrawing die: schematic cross section (not to scale) of a single-hole wiredrawing die employing a nib of sintered carbide mounted in a circular steel holder

The amount of reduction during drawing is expressed as a percent of the original cross-sectional area and is known as draft. As soon as a wire rod has been reduced by drawing, it is called a wire, even though many more reductions (drafts) may be necessary to reduce it to final size.

**Cleaning and Coating.** Whenever necessary, scale and other surface contaminants are cleaned from steel wire by acid pickling followed by water rinsing. Cleaning is always followed by a supplementary coating operation.

Lime, borax, or phosphate coating is performed to provide a carrier for the lubricant necessary for subsequent processing. In lime coating, practices may be varied to apply differing amounts of lime, depending on the end use. Phosphate-coated wire may have a supplementary coating of lime, borax, or a water-soluble soap.

**Heat treatments** for steel wire include annealing, patenting, and oil tempering.

Annealing-in-process is performed on dry drawn low-carbon or medium-low-carbon steel wire. The product is sometimes called "processed wire" or "bright soft wire." In producing annealed-in-process wire, an annealing heat treatment (followed by a separate cleaning and coating operation) is performed at an intermediate stage of wiredrawing to produce a softer wire for applications in which direct drawn wire would be too hard or too stiff.

Patenting is a thermal treatment usually confined to medium-high-carbon and high-carbon steels. In this process, individual strands of rod or wire are heated well above the upper critical temperature and then cooled comparatively rapidly in air, molten salt, or molten lead. This treatment is generally employed to prepare the material for subsequent wiredrawing.

Oil tempering is a heat treatment for high-carbon steel wire in which strands of the wire at finish size are continuously heated to an appropriate temperature above the critical temperature range, oil quenched, and finally passed through a

tempering bath. Oil tempering is used in the production of such commodities as oil-tempered spring wire, which is used in certain types of mechanical springs that are not subjected to a final heat treatment after forming.

### Specification Wire

There are some applications for low-carbon and medium-low-carbon steel wire that involve special requirements, such as specific tensile strength ranges or hardness limitations, the attainment of which involves special selection of steel and modification of conventional wire mill practices and/or thermal treatment (for example, annealed in-process wire). Such wire is commonly designated specification wire.

A standard specification that covers the general requirements for coarse, carbon steel round wire is ASTM A 510 (Table 11). Specification wire can be furnished with special finishes for subsequent processing, such as spot welding, electroplating, and tinning.

**Table 11 Common tensile strength ranges for coarse, round specification wire**

Wire diameter		Tensile strength range <sup>(a)</sup>	
mm	in.	MPa	ksi
0.889 to <2.69	0.035 to <0.106	207	30
2.69 to 4.50	0.106 to 0.177	172	25
>4.50	>0.177	138	20

(a) Difference between specified minimum and maximum values

### Metal-Coated Wire

Metallic coatings can be applied to wire by various methods, including both hot dip processes' and electrolytic processes.

**Aluminized wire** (aluminum-coated wire) is produced by passing strands of wire through a bath of molten aluminum or aluminum alloy.

**Brass-plated wire** is produced by passing strands of wire through an electrolytic cell containing a solution of both copper and zinc salts. Generally, such wire is used when rubber adhesion is required or when pleasing appearance is important. Brass-plated wire is not intended for applications requiring corrosion resistance.

**Galvanized wire** (zinc-coated wire) is produced by passing strands of wire through a bath of molten zinc (hot dip galvanized) or through an electrolytic cell containing a solution of a zinc salt (electrogalvanized). The wire usually is annealed in the same operation by being passed through molten lead, molten salt, or a furnace, followed by cleaning or pickling, prior to galvanizing. The general requirements for galvanized carbon steel wire are given in ASTM A 641.

The term "temper" as applied to galvanized wire is a reference to stiffness or resistance to bending, not to heat treatment. It customarily is expressed as soft, medium, or hard. Tensile strengths corresponding to these three tempers are given in Table 12.

**Table 12 Tensile strength ranges and limits of galvanized wire**

Wire diameter		Tensile strength					
		Soft temper (maximum) <sup>(a)</sup>		Medium temper		Hard temper	
mm	in.	MPa	ksi	MPa	ksi	MPa	ksi
0.889 to <2.03	0.035 to <0.080	515	75	483-690	70-100	620-825	90-120
2.03 to <2.69	0.080 to <0.106	515	75	483-655	70-95	585-795	85-115
2.69 to 4.47	0.106 to 0.176	483	70	448-620	65-90	550-760	80-110
>4.47	>0.176	483	70	414-585	60-85	515-720	75-105

(a) Generally produced from maximum 0.13% C grades

**Tinned wire** is produced by passing strands of wire continuously through a molten tin bath and then through tightly compressed wipes as the strands emerge from the bath. Tinned wire is commonly manufactured in three tempers: soft, medium hard, and hard. Soft tinned wire is tinned after being annealed at or near finish size. Medium-hard tinned wire is produced from heat treated wire. Hard tinned wire is obtained by tinning wire that has been cold drawn to final size, usually without intermediate heat treatment.

## Quality Descriptors and Commodities

Many kinds of steel wire have been developed for specific components of machines and equipment and for particular end uses. The unique properties of each of these types of wire are obtained by employing a specific combination of steel composition, steel quality, process heat treatment, and cold drawing practice.

These wires normally are grouped into broad usage categories including:

- Low-carbon steel wire for general usage
- Wire for packaging and container applications (includes bailing wire and strapping wire)
- Wire for structural applications (includes galvanized bridge wire, zinc- and aluminum-coated strand wire, and concrete reinforcing wire)
- Wire for prestressed concrete
- Wire for electrical or conductor applications (includes aluminum conductor steel reinforced wire and telephone and telegraph wire)
- Rope wire

## Wire for Fasteners

Wire for fasteners includes wire intended for such applications as bolts and cap screws, rivets, wood and self-tapping screws, and scrapless nuts. Depending on the application, such wire must be able to be forged, extruded, cold upset, roll or cut threaded, drilled, and hardened by suitable heat treatment.

The type and grade of steel used in wire for fasteners depend on the requirements of the finished product and the nature of the required forming operations. Compositions range from that of 1006 steel, which is used for such items as common rivets, to that of a 0.55 to 0.65% carbon steel intended for lockwashers or screwdrivers. The wire may be drawn from hot rolled or annealed wire rod, and it may be either annealed or spheroidized in process.

The coating on the wire must provide sufficient lubrication in the header dies and must have the necessary lubricating qualities to prevent galling or undesirable die wear. Although lime-soap coatings are common, phosphate coatings are frequently used for more demanding applications. Producing phosphated wire may involve coating the cleaned rod or process wire with zinc phosphate and then coating with lime or borax to carry the lubricant during subsequent drawing.

It is important that the wire be internally sound and free from seams and other surface imperfections. Decarburization must be held to a minimum for those products that are to be hardened by heat treatment.

## **Mechanical Spring Wire for General Use**

The several types of steel wire used for mechanical springs are produced in a variety of chemical compositions, but the primary consideration is that the wire have the specific properties necessary for the application. The required properties vary with the intended use of the spring and with problems involved in its fabrication. Among the factors governing the selection of spring wire are: (a) the load range through which the spring must operate; (b) the corresponding stress range for the wire; (c) weight and space limitations; (d) expected life of the spring; (e) temperatures and other environmental conditions to be encountered in service; and (f) severity of deformation to be encountered in fabrication.

As stress on the wire is increased, wire with higher strength is required. Because the surface of the wire is the most highly stressed part of a spring, freedom from surface imperfections becomes increasingly important as maximum stress or required service life is increased. Surface condition is very important in music spring steel wire and is even more important in valve spring quality wire.

There are three types of spring wire for general use: hard drawn spring wire (covered in ASTM A 227 and A 679), oil tempered spring wire (ASTM A 229) and spring steel wire for heat treated components (ASTM A 713).

**Music spring steel wire** is used in springs subject to high stresses and requiring good fatigue properties. Final cold drawing commonly is performed by the wet white liquor method to develop a characteristic smooth bright luster. Manufacturers employ specialized coiling tests, twist tests, torsion tests and bend tests to verify that the exacting requirements of this type of wire are met. ASTM A 228 describes music spring steel wire in detail.

## **Fine Wire**

Fine wire is considered to include all wire less than 0.89 mm (0.035 in.) in diameter, as well as some coarser wire up to 1.57 mm (0.062 in.) in diameter when so designated. Fine wire commonly is produced with bright, liquor, coppered, or phosphate finishes; with galvanized, tin, or cadmium coatings; and in the hard drawn, annealed, or oil-tempered conditions. Aircraft cords, brooms, brushes, fishhooks, florist wire, hose reinforcement, paper clips, insect screens, and safety pins are examples of products produced entirely or in part from various kinds of fine wire.

**Aircraft cord wire** is a hard drawn, high-tensile-strength, high-carbon steel wire designed for manufacture of flexible cords and multiple-wire strands for aircraft controls.

## **Alloy Wire**

Chemical compositions and quality descriptions, as well as requirements and tests, applicable to alloy wire are described in the preceding article on steel wire rod. Many alloy steel wires have been developed for specific applications which include wires for bearings, chains and springs, and for cold heading and cold forging applications.

**Alloy steel spring wire** is used for the manufacture of springs intended for operation at moderately elevated temperatures. Three grades in common use are 6150 chromium-vanadium steel, SAE 9260 silicon manganese, and 9254 chromium-silicon steel, which are covered in ASTM A 231, A 232, and A 401, respectively. ASTM A 877/A 877M also covers chromium-silicon grades; ASTM A 878/A 878M covers a grade of modified chromium-vanadium steel valve spring quality wire.

The wire is commonly produced in one of four conditions: oil tempered, spheroidize annealed, annealed in-process, and patented in-process. Oil-tempered alloy spring wire, commonly produced in diameters up to 12.7 mm (0.500 in.) to tensile strength or hardness requirements, is intended for very light forming and is generally used for coiling into common types of springs. Table 13 lists tensile strength ranges for several oil-tempered wires.

**Table 13 Tensile strength ranges for oil-tempered alloy steel spring wires**

Wire diameter <sup>(a)</sup>		Chromium-vanadium spring wire, aircraft quality spring wire, and valve-spring quality wire		Chromium-silicon spring wire	
mm	in.	MPa	ksi	MPa	ksi

# Steel Tubular Products

---

## Introduction

STEEL TUBULAR PRODUCTS is the term used to cover all hollow steel products. Although these products are usually produced in cylindrical form, they are often subsequently altered by various processing methods to produce square, oval, rectangular, and other symmetrical shapes. Such products have applications that are almost innumerable, but they are most commonly used as conveyors of fluids and as structural members.

## Product Classification

The two simplest and broadest commercial classifications of steel tubular products are tube and pipe. (Although the application of the terms pipe and tube is not always consistent, the term pipe is commonly used to describe cylindrical tubular products made to standard combinations of outside diameter and wall thickness.) These two broad classifications are subdivided into several named use groups. For example, the term tube covers three such groups: pressure tubes, structural tubing, and mechanical tubing.

The term pipe covers five such groups: standard pipe, line pipe, oil country tubular goods, water well pipe, and pressure pipe. There is also pipe for special applications, such as conduit pipe and tubular piling, that do not fit any of these classifications. Each of these use groups, in turn, has a number of uses or named-use subdivisions. These are shown in Table 1.

**Table 1 Major types and uses of pipe**

Type of pipe	Uses
Standard	Industrial or residential water steam, oil, or gas transmission; distribution or service lines; structural uses
Special	Conduit, piling, pipe for nipples, and other
Line	Oil- or gas-transmission pipe, water-main pipe
Oil country tubular goods	Drill pipe, casing, tubing
Water well	Drive pipe, driven-well pipe, casing, reamed pipe, and drifted pipe
Pressure	Pipe for elevated-temperature or pressure service

The named uses in Table 1 have been developed without regard to method of manufacture, size range, wall thickness, or degree of finish. For example, the names do not distinguish between those products commonly called pipe that have size and wall thicknesses the same as standard pipe, and those having different basic dimensions; all are termed pipe.

On a use basis, pressure pipe is distinguished from pressure tubes in that the latter are suitable for those applications in which heat is applied externally. The principal use groups and types of pressure tubes are shown in Table 2.

**Table 2 Principal uses and types of pressure tubes**

Use groups	Types
Water tube boilers	Generating tubes, superheater tubes, economizer tubes, circulator tubes, furnace wall tubes
Fire tube boilers	Boiler flues, superheater flues, superheater tubes, arch tubes, stay tubes, safe ends
Others	Feedwater heater tubes, oil still tubes

Structural and mechanical tubing do not follow this system of nomenclature. Instead, their names are derived from the method of fabrication and degree of finish, such as cold formed welded or seamless hot finished.

Steel tubular products can be made by forming a flat skelp, sheet, strip, or plate into a hollow cylinder and welding the resulting longitudinal seam together or by generating an opening in a solid cylinder by piercing and elongating the resultant hollow cylinder. The first group of products is called welded and the second group, seamless.

## Welding Processes

In producing welded steel tubular products, flat-rolled skelp, strip, sheet or plate is formed into cylinders that are then joined at the longitudinal or spiral seam by one of the processes described below.

**Electric resistance welding** employs a series of operations, in the first of which the flat-rolled steel is cold shaped into tubular form. Welding is effected by the application of pressure and heat generated by induction or by an electric current through the seam. The welding pressure is generated by constricting rolls and the electromagnetic effects of the high welding current. Electric resistance welded tubular products having longitudinal seams are usually made in sizes ranging from 3.2 mm ( $\frac{1}{8}$  in.) nominal to 0.6 m (24 in.) actual outside diameter, but larger sizes are also available. Electric resistance methods are also sometimes used for making tubular products by spiral welding. This method is frequently used for large-diameter products.

**Continuous Welding.** In continuous (or furnace butt) welding, skelp with square or slightly beveled edges is furnace heated to the welding temperature. The heated stock is roll formed into cylindrical shape as it emerges from the furnace; additional heat is usually provided by an oxygen or air jet impinging on the seam edges, and the tube passes through constricting rolls where the seam edges are welded by the pressure of the rolls. Continuous welded products are available in nominal diameters from 3.2 to 100 mm ( $\frac{1}{8}$  to 4 in.).

**Fusion Welding.** In fusion welding, the flat-rolled steel, with edges suitably prepared, is formed into tubular shape by either hot or cold shaping. The flat-rolled steel may be shaped longitudinally (straight seam) or bent into helical form (spiral welded). The edges are welded with or without simultaneously depositing filler metal in a molten or molten-and-vapor state. Mechanical pressure is not required to effect welding. Fusion may be accomplished by either electric arc or gas heating, or a combination of both. The upper limit of outside diameter is determined mainly by the forming method and the fusion welding process used.

**Double submerged arc welding** is a special method of shielded-arc welding in which the seam is submerged under a solid flux while being welded. The weld is made in two passes, one from inside the pipe and the other from outside the pipe, with approximately half the wall thickness being welded in each pass. The maximum diameter is limited only by the capability of the forming equipment, and double submerged-arc welded pipe is currently available in outside diameters of up to 3 m (120 in.).

## Seamless Processes

Steel tubular products produced by the seamless processes are made in diameters up to 0.67 m (26 in.) by the rotary piercing method and up to 1.2 m (48 in.) by hot extrusion.

**Rotary Piercing.** In rotary piercing, rounds of the necessary diameter and length are first heated to rolling temperature. Each hot round is fed into a set of rolls having crossed axes and surface contours that pull it through the rolls, thus rupturing it longitudinally. The force of the rolls then causes the metal to flow around a piercing point, enlarging the axial hole, smoothing the inside surface, and forming a tube. After being pierced, the rough tube is usually hot rolled to final dimensions by means of plug mills or mandrel mills, which may be followed by stretch reducing mills.

**Hot extrusion** is a hot working process for making hollows, suitable for processing into finished tubing of regular and irregular form, by forcing hot, prepierced billets through a suitably shaped orifice formed by an external die and internal mandrel. The outside of the hollow acquires the size and contour imposed by the die; the inside conforms to the size and contour of the mandrel. Extruded hollows may be further worked into tubular products by cold-finishing methods.

**Cupping and Drawing.** In the cupping and drawing method of making seamless tubing, a circular sheet or plate is hot cupped in a press through several pairs of conical dies, each successive pair being deeper and more nearly cylindrical than the previous set. The rough tube then is drawn to finished size.

## Cold Finishing

Pipe in suitable sizes and most products classified as tubing, both seamless and welded, may be cold finished. The process may be used to increase or decrease the diameter, to produce shapes other than round, to produce a smoother surface or closer dimensional tolerances, or to modify mechanical properties. The process most commonly used is cold drawing, in which the descaled hot-worked tube is plastically deformed by drawing it through a die and over a mandrel (mandrel drawing) to work both exterior and interior surfaces. Cold drawing through the die only (without a mandrel) is called sink drawing or sinking.

**Tube Reducing and Swaging.** In tube reducing by rotorolling or pilgering and in swaging, a reducing die works the tube hollow over a mandrel; swaging may, however, be done without a mandrel. The commercial importance of tube reducing is, first, that very heavy reductions (up to 85%) can be applied to mill length tubes, and second, that the process can be applied to the refractory alloys that are difficult to cold draw because of high power requirements.

**Cold Finishing.** Tubular products of circular cross section may be cold finished on the outside by turning, grinding, or polishing, or by any combination of these processes. They may be bored, skived, or honed on the inside diameter. Because these operations involve stock removal only, with negligible plastic deformation, there is no enhancement of mechanical properties.

Many of the standard specifications involving strength are based on the properties of hot-rolled or cold-worked material. Some high-strength oil country goods are heat treated to achieve the combination of high strength, ductility, and sulfide stress corrosion cracking resistance required by the intended application.

Cold drawing may be employed to improve surface finish and dimensional accuracy and to increase the strength of tubular products. Some customer specifications prescribe strength levels that can best be attained by cold working.

## Pipe Sizes and Specifications

Pipe is distinguished from tubing by the fact that it is produced in relatively few sizes and, therefore, in comparatively large quantities of each size. For a reasonably complete list of the standardized sizes and weights of pipe for the major named uses, the AISI Steel Products Manual should be consulted. For oil country tubular goods, the specifications of the American Petroleum Institute (API) govern. Table 3 lists the current ASTM, API, and Canadian Standards Association (CSA) specifications covering pipe. Some of these involve several grades. The specifications listed cover carbon high-strength low-alloy (HSLA), and alloy steels other than stainless, all methods of manufacture, and a wide range of service temperature. Steels are produced with yield strengths ranging from 170 MPa to 930 MPa (25 to 135 ksi).

**Table 3 ASTM, API, and CSA specifications for carbon, HSLA, and alloy steel pipe**

Specification	Product
ASTM specifications	
A 53 <sup>(a)</sup>	Welded and seamless steel pipe, black and hot dipped, zinc coated
A 106 <sup>(a)</sup>	Seamless carbon steel pipe for high-temperature service
A 134 <sup>(a)</sup>	Arc-welded steel-plate pipe (sizes 400 mm, or 16 in., and over)
A 135 <sup>(a)</sup>	Resistance-welded steel pipe
A 139	Arc-welded steel pipe (sizes 100 mm, or 4 in., and over)

A 211	Spiral-welded steel or iron pipe
A 252	Welded and seamless steel pipe piles
A 333 <sup>(a)</sup>	Welded and seamless steel pipe for low-temperature service
A 335 <sup>(a)</sup>	Seamless ferritic alloy steel pipe for high-temperature service
A 381	Double submerged-arc welded steel pipe for high-pressure transmission systems
A 405	Seamless ferritic alloy steel pipe, specially heat treated for high-temperature service
A 523	Resistance-welded or seamless steel pipe (plain end) for high-pressure electric cable conduit
A 524 <sup>(a)</sup>	Seamless carbon steel pipe for atmospheric service and lower temperatures
A 587 <sup>(a)</sup>	Resistance-welded low-carbon steel pipe for the chemical industry
A 589	Welded and seamless carbon steel water well pipe
A 671 <sup>(a)</sup>	Arc-welded steel pipe for atmospheric service and lower temperatures
A 672 <sup>(a)</sup>	Arc-welded steel pipe for high-pressure service at moderate temperatures
A 691	Arc-welded carbon or alloy steel pipe for high-pressure service at high temperatures
A 714	Welded and seamless HSLA steel pipe
A 795	Black and hot-dipped zinc-coated (galvanized) welded and seamless steel pipe for fire protection use
<b>API specifications</b>	
2B	Specification for fabricated structural steel and pipe
5CT	Specification for casing and tubing
5D	Specification for drill pipe
5L	Specification for line pipe
<b>CSA standard</b>	

CAN3-Z245.1-M86	Steel line pipe
-----------------	-----------------

(a) This ASTM specification is also published by ASME, which adds an "S" in front of the "A" (for example, SA 53).

## Common Types of Pipe

The following brief descriptions concern the end uses of some of the more common types of pipe.

**Standard pipe** is standard weight, extra strong, and double extra strong welded, or seamless pipe of ordinary finish and dimensional tolerances, produced in sizes up to 660 mm (26 in.) in nominal diameter, inclusive. This pipe is used for fluid conveyance and some structural purposes.

**Conduit pipe** is welded or seamless pipe intended especially for fabrication into rigid conduit, a product used for the protection of electrical wiring systems.

**Piling pipe** is welded or seamless pipe for use as piles, with the cylinder section acting as a permanent load-carrying member or as a shell to form cast-in-place concrete piles.

**Pipe for nipples** is standard weight, extra strong, or double extra strong welded or seamless pipe, produced for the manufacture of pipe nipples.

**Transmission or line pipe** is welded or seamless pipe currently produced in sizes ranging from 3 mm ( $\frac{1}{8}$  in.) nominal to 1.2 m (48 in.) actual outside diameter and is used principally for conveying gas or oil. Transmission pipe, which is covered by API Specification 5L and CSA specification Z245.1 is being increasingly manufactured from microalloyed HSLA steels with yield strengths as high as 550 MPa (80 ksi).

**Water main pipe** is welded or seamless steel pipe used for conveying water for municipal and industrial purposes. Pipe lines for such purposes are commonly designated as flow mains, transmission mains, force mains, water mains, or distribution mains. The mains are generally laid underground.

**Oil country tubular goods** is a collective term applied in the oil and gas industries to three kinds of pipe used in oil wells: drill pipe, casing, and tubing. These products conform to API specifications 5CT (casing and tubing) and 5D (drill pipe).

Drill pipe is used to transmit power by rotary motion from ground level to a rotary drilling tool below the surface and to convey flushing media to the cutting face of the tool. Drill pipe is produced in sizes ranging from 60 to 170 mm ( $2\frac{3}{8}$  to  $6\frac{5}{8}$  in.) in outside diameter. Size designations refer to actual outside diameter and weight per foot. Drill pipe is usually upset, either internally or externally, or both, and is prepared to accommodate welded-on types of joints.

Casing is used as a structural retainer for the walls of oil or gas wells, to exclude undesirable fluids, and to confine and conduct oil or gas from productive subsurface strata to ground level. Casing is produced in sizes from 115 to 500 mm ( $4\frac{1}{2}$  to 20 in.) in outside diameter.

Tubing is used within the casing of oil wells to conduct oil and gas to ground level. It is produced in sizes from 26 to 114 mm (1.05 to 4.50 in.) in outside diameter, in several weights per foot. Ends are threaded for special integral-type joints or fitted with couplings and may or may not be upset externally.

**Water well pipe** is a collective term applied to four types of pipe that are used in water wells and that conform to ASTM A 589: type I, drive pipe; type II, reamed and drifted pipe; type III, driven well pipe; and type IV, casing pipe.

Drive pipe is used to transmit power from ground level to a rotary drill tool below the surface and to convey flushing media to the cutting face of the tool. The lengths of pipe have specially threaded ends that permit the lengths to butt inside

the coupling. Drive pipe is produced in nominal sizes of 150, 200, 300, 350, and 400 mm (6, 8, 12, 14, and 16 in.) in outside diameter.

Driven well pipe is threaded pipe in short lengths used for the manual driving of a drill tool or for use with short rigs. It may be furnished in random lengths ranging from 0.9 to 1.8 m (3 to 6 ft) or in random lengths ranging from 1.8 to 3.0 m (6 to 10 ft).

Casing is used both to confine and conduct water to ground level and as a structural retainer for the walls of water wells. It is produced as threaded pipe in random lengths from 4.9 to 6.7 m (16 to 22 ft) and in sizes from 90 to 220 mm ( $3\frac{1}{2}$  to  $8\frac{5}{8}$  in.) in outside diameter. In western water well practice, welded strings are sometimes used.

Reamed and drifted pipe is similar to casing, but is manufactured and inspected in a manner that assures the well driller that the pipe string will have a predetermined minimum diameter sufficient to permit unrestricted passage of pumps or other equipment through the string.

**Pressure pipe**, as distinguished from pressure tubes, is a commercial term for pipe that is used to convey fluids at elevated temperature or pressure, or both, but that is not subjected to the external application of heat. This commodity is not differentiated from other types of pipe by ASTM, and the applicable specifications are listed with the other types in Table 3. Pressure pipe ranges in size from 3 mm ( $\frac{1}{8}$  in.) nominal to 660 mm (26 in.) actual outside diameter in various wall thicknesses.

## Pressure Tubes

Pressure tubes are given a separate classification by both ASTM and the producers. Pressure tubes are distinguished from pressure pipe in that they are suitable for application of external heat while conveying pressurized fluids.

The principal named uses of pressure tubing are given in Table 2. These tubings are produced to actual outside diameter and minimum or average wall thickness (as specified by the purchaser) and may be hot finished or cold finished, as specified.

**Double-wall brazed tubing** is a specialty tubing confined to small sizes (refer to ASTM A 254) It is used in large quantities by the automotive industry for brake lines and fuel lines, and by the refrigeration industry for refrigerant lines. It is made by forming copper-coated strip into a tubular section with double walls, using either single-strip or double strip construction. The tubing is then heated in a reducing atmosphere to join all mating surfaces completely. The resulting product is thus copper coated both inside and outside. When required by the intended service, a tin coating may be supplied. Available sizes range from 3 to 15 mm ( $\frac{1}{8}$  to  $\frac{5}{8}$  in.) in outside diameter (OD) with wall thickness from 0.64 mm (0.025 in.) for 3 mm ( $\frac{1}{8}$  in.) OD to 0.9 mm (0.035 in.) for 15 mm ( $\frac{5}{8}$  in.) OD.

## Structural Tubing

Structural tubing is used for the welded, riveted, or bolted construction of bridges and building and for general structural purposes. It is available in round, square, rectangular, or special-shape tubing, as well as tapered tubing. These products are covered by ASTM specifications.

## Mechanical Tubing

Mechanical tubing includes welded and seamless tubing used for wide variety of mechanical purposes. It is usually produced to meet specific end-use requirements and therefore is produced in many shapes, to a variety of chemical compositions and mechanical properties, and with hot-rolled or cold-finished surfaces. Most mechanical tubing is ordered to ASTM specifications. Even when customer specifications are used, they usually reference portions of the ASTM standard.

Mechanical tubing is not produced to specified standard sizes: instead, it is produced to specified dimensions, which may be anything the customer requires within the limits of production equipment or processes.

Welded mechanical tubing is usually made by electric resistance welding, but some is made by the various fusion welding processes. In all instances, the exterior welding flash may be removed (if necessary) by cutting, grinding, or hammering.

Electric resistance welded (ERW) mechanical tubing is made from hot-rolled or cold-rolled carbon steel or from alloy steel strip. The welded tubing can be supplied as-welded, hot finished, or cold finished. Sizes produced by ERW range in outside diameters from 6.4 to 400 mm ( $\frac{1}{4}$  to 16 in.) and in wall thickness from 1.65 to 17 mm (0.065 to 0.680 in.) for hot-rolled steel and 0.65 to 4.2 mm (0.025 to 0.165 in.) for cold-rolled steel.

**Continuous-welded cold-finished mechanical tubing**, as its name implies, is tubing that has been hot formed by furnace butt welding and cold finished. It is furnished sink drawn or mandrel drawn and is available in outside diameters up to 90 mm ( $3\frac{1}{2}$  in.) and wall thicknesses from 0.9 to 13 mm (0.035 to 0.500 in.). The material is low-carbon steel, and the product is, in effect, a form of cold-drawn pipe. Although furnished in a narrower size range than electric resistance welded tubing, it has two advantages: within the available size range, heavier walls are available, and there is no problem with flash.

**Seamless mechanical tubing**, both hot and cold finished, is available in a wide variety of finishes and mechanical properties. It is made from carbon and alloy steels in sizes up to and including 325 mm ( $12\frac{3}{4}$  in.) OD.

## Closed-Die Steel Forgings

### Introduction

FORGING is the process of working hot metal between dies, usually under successive blows and sometimes by continuous squeezing. Closed-die forgings, hot upset parts, and extrusions are shaped within a cavity formed by the closed dies.

Justification for selecting forging in preference to other and sometimes more economical methods of producing useful shapes is based on several considerations. Mechanical properties in wrought materials are maximized in the direction of major metal flow during working.

### Types of Forgings

Forgings are classified in several ways, beginning with the general classifications "open-die" and "closed-die." They are also classified in terms of the "close-to-finish" factor, or the amount of stock (cover) that must be removed from the forging by machining to satisfy the dimensional and detail requirements of the finished part (Fig. 1). Finally, forgings are classified in terms of the forging equipment required for their manufacture: for example, hammer upset forgings, ring-rolled forgings and multiple-ram press forgings (see the Section "Forging" in this Handbook for more detailed information on such equipment).

Fig. 1 Schematic composite of cross sections of blocker-type, conventional, and precision forgings

Of the various classifications, those based on the close-to-finish factor are most closely related to the inherent properties of the forging, such as strength and resistance to stress corrosion. In general, the type of forging that requires the least machining to satisfy finished-part requirements has the best properties. For this reason, a finished part that is machined from a blocker-type forging usually exhibits mechanical properties and corrosion characteristics that are inferior to those of a part produced from a close-tolerance, no-draft forging.

## Selection of Steel

Selection of a steel for a forged component is an integral part of the design process, and acceptable performance is dependent on this choice. A thorough understanding of the end use of the finished part will serve to define the required mechanical properties, surface-finish requirements, tolerance to nonmetallic inclusions, and the attendant inspection methods and criteria.

Forging-quality steels are produced to a wide range of chemical compositions by electric furnace, open hearth, or pneumatic steelmaking processes.

**Forgeability** describes the relative ability of a steel to flow under compressive loading without fracturing. Except for resulfurized and rephosphorized grades, most carbon and low-alloy steels are usually considered to have good forgeability. Differences in forging behavior among the various grades of steel are small enough that selection of the steel is seldom affected by forging behavior. However, the choice of a resulfurized or rephosphorized steel for a forging is usually justified only if the forging must be extensively machined; because one of the principal reasons for considering manufacture by forging is the avoidance of subsequent machining operations, this situation is uncommon.

**Design Requirements.** Selection of a steel for a forged part usually requires some compromise between opposing factors; for instance, strength versus toughness, stress-corrosion resistance versus weight, manufacturing cost versus useful load-carrying ability, production cost versus maintenance cost, and the cost of the steel.

Material selection also involves consideration of melting practices, forming methods, machining operations, heat-treating procedures, and deterioration of properties with time in service, as well as the conventional mechanical and chemical properties of the steel to be forged.

An efficient forging design obtains maximum performance from the minimum amount of material consistent with the loads to be applied, producibility, and desired life expectancy. To match a steel to its design component, the steel is first appraised for strength and toughness and then qualified for stability to temperature and environment. Optimum steels are then analyzed for producibility and finally for economy.

**Cost.** The cost of steel as a percentage of the total manufacturing cost of forgings is shown in Fig. 2. These curves are based on an average of many actual forgings that are different in number of forging and heat treating operations required, cost of steel, quantity, and setup cost. It should not be inferred from these data that an average 14 kg (30 lb) stainless steel forging will cost 34% more than an average carbon steel forging of the same weight.

Fig. 2 Cost of steel as a percentage of total cost of forgings

## Material Control

After completion of a forging design, there remains the responsibility of ensuring and verifying that the delivered forging will have all of the properties and characteristics specified on the forging drawing.

Responsibility for material control is subject to agreement between the purchaser and forging supplier. In many such agreements, the purchaser is responsible for design, material selection, and controls during manufacture; the forging supplier is responsible for performing raw-material inspection as well as maintaining adequate process control and product inspection.

**Tests and Test Coupons.** Tests contained in the material specifications are intended to provide correlation with, and interpretation of, the behavior of material in actual use. The dynamic behavior of a full-size structural component seldom can be accurately predicted from simple room-temperature tests on small specimens. Analytical studies coupled with model or full-scale testing can augment simple tests in interpreting the complex behavior of materials.

The kinds of test specimens and tests specified for quality assurance depend on the conditions imposed on the final component in service. If, for example, a critical forging is to be subjected to large tensile loads, the designer would specify tests to measure fracture toughness and tensile yield strength. For components for elevated-temperature service, tests measuring strength, ductility, and creep at appropriate temperatures would be specified.

**Test Plans.** Frequently, specifications are prepared from the results of tests on laboratory specimens because the cost and time required for full-scale testing are usually prohibitive. Test plans for evaluation of the mechanical properties of two high-strength 9Ni-4Co steels used in aircraft service at temperatures ranging from -45 to greater than 205 °C (-50 to greater than 400 °F) are shown in Table 1. This table illustrates the range and number of tests required for a very extensive type of evaluation.

**Table 1 Testing plan for determining mechanical properties of forging material**

Temperature and test	Number of tests for <sup>(a)</sup> :							
	9Ni-4Co-0.30C steel (1520-1660 MPa, or 220-240 ksi) <sup>(b)</sup>				9Ni-4Co-0.45C steel (1790-1930 MPa, or 260-280 ksi) <sup>(c)</sup>			
	L	LT	ST	Total	L	LT	ST	Total
At -80 °C (-110 °F)								
Tension	2	3	2	7	2	4	2	8
Compression	1	3	1	5	1	4	...	5
Shear	1	3	1	5	1	3	1	5
Bearing $e/D = 1.5^{(d)}$	1	2	1	4	1	1	1	3
Bearing $e/D = 2.0^{(d)}$	1	2	1	4	1	4	1	6
At room temperature								
Tension	12	12	12	36	18	17	18	53

Bearing $e/D = 2.0^{(d)}$	...	...	...	0	1	4	1	6
At 260 °C (500 °F)								
Tension	2	3	2	7	...	...	...	0
Compression	1	3	1	5	...	...	...	0
Shear	1	3	1	5	...	...	...	0
Bearing $e/D = 1.5^{(d)}$	1	2	1	4	...	...	...	0
Bearing $e/D = 2.0^{(d)}$	2	2	1	5	...	...	...	0
Total number of tests	42	57	40	139	42	65	39	146

(a) L, longitudinal; LT, long transverse; ST, short transverse.

(b) Three heats.

(c) Four heats.

(d)  $D$ , hole diameter;  $e$ , edge distance measured from the hole center to the edge of the material in direction of applied stress

As shown in Table 1, test plans for mechanical properties include tension, compression, shear, and bearing strength tests; the effect of grain orientation is evaluated by testing specimens representative of the longitudinal, long-transverse, and short-transverse directions, as required. In addition to room-temperature tests, specimens are tested at -80, 150, and 260 °C (-110, 300, and 500 °F). The plan encompasses a total of 285 individual tests.

**Ductility and the Amount of Forging Reduction.** A principal objective of material control is to ensure that optimum mechanical properties will be obtained in the finished forging. The amount of reduction achieved in forging has a marked effect on ductility, as shown in Fig. 3, which compares ductility in the cast ingot, the wrought (rolled) bar or billet, and the forging. The curves in Fig. 3(a) indicate that when a wrought bar or billet is flat forged in a die, an increase in forging reduction does not affect longitudinal ductility, but does result in a gradual increase in transverse ductility. When a similar bar or billet is upset forged in a die, an increase in forging reduction results in a gradual decrease in axial ductility and a gradual increase in radial ductility.

**Fig. 3** Metal flow in forging. Effect of extent and direction of metal flow during forging on ductility. (a) Longitudinal and transverse ductility in flat-forged bars. (b) Axial and radial ductility in upset-forged bars

**Grain Flow.** Macroetching permits direct observation of grain direction and contour and also serves to detect folds, laps, and re-entrant flow. By macroetching of suitable specimens, grain flow can be examined in the longitudinal, long-transverse, and short-transverse directions. Macroetching also permits evaluation of complete sections, end to end and side to side, and a review of uniformity of macro grain size. Figure 4 illustrates grain flow in a representative forged part.

**Fig. 4** Flow lines in a closed-die forging of AISI 4340 alloy steel.  $\sim 0.75\times$

**End-Grain Exposure.** Lowered resistance to stress-corrosion cracking in the long-transverse and short-transverse directions is related to end-grain exposure. A long, narrow test specimen sectioned so that the grain is parallel to the longitudinal axis of the specimen has no exposed end grain, except at the extreme ends, which are not subjected to loading. In contrast, a corresponding specimen cut in the transverse direction has end-grain exposure at all points along its length. End grain is especially pronounced in the short-transverse direction on die forgings designed with a flash line. Consequently, forged components designed to reduce or eliminate end grain have better resistance to stress-corrosion cracking.

## Mechanical Properties

A major advantage of shaping metal parts by rolling, forging, or extrusion stems from the opportunities such processes offer the designer with respect to control of grain flow. The strength of these and similar wrought products is almost always greatest in the longitudinal direction (or equivalent) of grain flow, and the maximum load-carrying ability in the finished part is attained by providing a grain-flow pattern parallel to the direction of the major applied service loads when, in addition, sound, dense, good-quality metal of sufficiently fine grain size has been produced throughout.

**Grain Flow and Anisotropy.** Metal that is rolled, forged, or extruded develops and retains a fiber-like grain structure aligned in the principal direction of working. This characteristic becomes visible on external and sectional surfaces of wrought products when the surfaces are suitably prepared and etched. The "fibers" are the result of elongation of the microstructural constituents of the metal in the direction of working. Thus, the phrase "direction of grain flow" is commonly used to describe the dominant direction of these fibers within wrought metal products.

In wrought metal, the direction of grain flow is also evidenced by measurements of mechanical properties. Strength and ductility are almost always greater in the direction parallel to that of working. The characteristic of exhibiting different strength and ductility values with respect to the direction of working is referred to as "mechanical anisotropy" and is exploited in the design of wrought products.

Although best properties in wrought metals are most frequently the longitudinal (or equivalent), properties in other directions may yet be superior to those in products not wrought; that is, in cast ingots or in forging stock taken from only lightly worked ingot.

The square rolled section shown schematically in Fig. 5(a) is anisotropic with respect to average mechanical properties of test bars such as those shown in phantom. Average mechanical properties of the longitudinal bar 1 are superior to the average properties of the transverse bars 2 and 3. Mechanical properties are equivalent for bars 2 and 3 because the section is square, which implies equal reduction in section in both transverse directions.

**Fig. 5 Anisotropy and mechanical properties in forgings.** Schematic views of sections from (a) square rolled stock, (b) rectangular rolled stock, (c) a cylindrical extruded section, and (d) a ring-rolled section, illustrating the effect of section configuration, forging process, or both, on the longitudinal direction in a forging

Mechanical anisotropy also is found in rectangular sections such as that shown in Fig. 5(b), in cylinders as in Fig. 5(c), and in rolled rings as in Fig. 5(d). Again, best strength properties are, on the average, those of the longitudinal, as in test bar 1. Flat rolling of a section such as that shown in Fig. 5(a) to a rectangular section (Fig. 5b) enhances the average "long transverse" properties of test bar 4 when compared with "short transverse" properties of test bar 5. Thus, such rectangular sections exhibit anisotropy among all three principal directions: longitudinal, long transverse, and short transverse. A design that employs a rectangular section such as that shown in Fig. 5(b) involves the properties in all these directions, not just the longitudinal. Thus, the longitudinal, long transverse, and short transverse service loads of rectangular sections are analyzed separately. The same concept can be applied to cylinders, whether extruded or rolled; longitudinal direction changes with the forging process used, as indicated in Fig. 5(c) and 5(d).

## Fundamentals of Hammer and Press Forgings

Many small forgings are made in a die that has successive cavities to preshape the stock progressively into its final shape in the last, or "finish," cavity. Dies for large forgings are usually made to perform one operation at a time. The upper half of the die, having the deeper and more intricate cavity, is keyed or dovetailed into the hammer or press ram. The lower half is keyed to the "sow block" or bed of the hammer or press in precise alignment with the upper die. After being heated, the forging stock is placed in one cavity after another and is thus forged progressively to final shape.

**The parting line** is the plane along the periphery of the forging where the striking faces of the upper and lower dies come together. Usually, the die has a gutter or recess just outside of the parting line to receive overflow metal or flash forced out between the two dies in the finish cavity (Fig. 6). More complex forgings may have other parting lines around holes and other contours within the forging that may or may not be in the same plane as the outer parting line.

**Fig. 6** Two stages of metal flow in forging. Top diagram shows limitation on height of ribs above and below the parting line.

For greatest economy, the outer parting line should be in a single plane. When it must be along a contour, either step or locked dies may be necessary to equalize thrust, as shown in Fig. 7. This may increase costs as much as 20%, because of the increased cost of dies and cost increases from processing difficulties in forging and trimming. Sharp steps or drops in the parting line should be limited to about  $15^\circ$  from the vertical in small parts and  $25^\circ$  in large forgings, to prevent a tearing instead of a cutting action in trimming off the flash. Locked dies may sometimes be avoided by locating the parting line as shown in the lower part of Fig. 8.

**Fig. 7** Locked or stepped dies used to equalize thrust

**Fig. 8 Orientation of a forging in the die to avoid counterlocked dies and to eliminate draft**

Specification of optional parting lines on forgings to be made in different shops allows these lines to vary from shop to shop. Unless the draft has been removed, this variation may cause difficulties in locating forgings when they are being chucked for subsequent machining. However, shearing the draft is not always an adequate remedy if trimming angles vary. Forgings made in different shops are likely to be more consistent in quality and to have less variation in shape when a definite parting line is specified.

**Draft** on the sides of a forging is an angle or taper necessary for releasing the forging from the die and is desirable for long die life and economical production. Draft requirements vary with the shape and size of the forging. The effect of part size on the amount of metal needed for draft is illustrated by Fig. 9.

**Fig. 9 Effect of part size on the amount of metal needed for draft in a forging**

Inside draft is draft on surfaces that tightens on the die as the forging shrinks during cooling; examples are cavities such as narrow grooves or pockets. Outside draft is draft on surfaces such as ribs or bosses that shrink *away* from the die during cooling. Both are illustrated in Fig. 10, which shows inside draft to be greater than outside draft (the usual relation). Recommended draft angles and tolerances for steel forgings are given in Table 2.

**Table 2 Draft angles and tolerances for steel forgings**

Height or depth of draft		Commercial standard		Special standard	
mm	in.	Draft, degree	Tolerance <sup>(a)</sup> , degree	Draft, degree	Tolerance <sup>(a)</sup> , degree
<b>Outside draft</b>					
6.35-12.7	$\frac{1}{4} - \frac{1}{2}$	...	...	3	2
19-25	$\frac{3}{4} - 1$	5	3	...	...
>12.75-25	$> \frac{1}{2} - 1$	...	...	5	2

>25-76	>1-3	7	3	5	3
>76	>3	7	4	7	3
<b>Inside draft</b>					
6.35-25.4	$\frac{1}{4}-1$	7	3	5	3
>25.4	>1	10	3	10	3

(a) The minus tolerance is zero.

Fig. 10 Definition of inside and outside draft and limitations on the depth of the cavities between ribs.

Tolerances

Forging tolerances, based on area and weight, that represent good commercial practice are listed in Tables 3 and 4. These tolerances apply to the dimensions shown in the illustration accompanying Table 3. In using these tables to determine the size of the forging, the related tolerances, such as mismatch, die wear, and length, should be added to allowance for machining plus machined dimensions. On the average, tolerances listed in Tables 3 and 4 conform to the full process tolerances of actual production parts and yield more than 99% acceptance of any dimension specified from this table. In particular, instances may be found of precise accuracy or rarely as much as ±50% error in the tolerances recommended in Table 4.

Table 3 Recommended commercial tolerances on length and location

Maximum length of forging		Tolerance on length or location	
mm	in.	mm	in.

(a) The illustration in Table 3 shows locations of thickness and mismatch.

The characteristics of die wear are shown graphically in Fig. 11. The part represented was made of 4140 steel, using ten blows in a 11 kN (2500 lbf) board hammer. Tolerances were commercial standard, and the part was later coined to a thickness tolerance of +0.25 mm, -0.000 (+0.010 in., -0.000). The die block, 250 by 455 by 455 mm (10 by 18 by 18 in.), was hardened to 42 HRC. After 30,000 forgings had been produced, the die wore as indicated and the dies were resunk.

**Fig. 11** Extent of die wear in a die block hardened to 42 HRC. The block was evaluated for die wear after producing 30,000 forgings of 4140 steel at a rate of 10 blows/workpiece with an 11 kN (2500 lbf) hammer.

Ranges of mismatch tolerance are given in Table 4. The higher values are to be added to tolerances for forgings that need locked dies or involve side thrust on the dies during forging. On forgings heavier than 23 kg (50 lb), it is sometimes necessary to grind out mismatch defects up to 3.18 mm ( $\frac{1}{8}$  in.) maximum.

**Flash** is trimmed in a press with a trimming die shaped to suit the plan view, outline, and side view contour of the parting line. The forging may be trimmed with a stated amount of burr or flash left around the periphery at the parting line.

## Design of Hot Upset Forgings

Hot heading, upset forging, or more broadly, machine forging consists primarily of holding a bar of uniform cross section, usually round, between grooved dies and applying pressure on the end in the direction of the axis of the bar by using a heading tool so as to upset or enlarge the end into an impression of the die. The shapes generally produced include a variety of enlargements of the shank, or multiple enlargements of the shank and "re-entrant angle" configurations. Transmission cluster gears, pinion blanks, shell bodies and many other shaped parts are adapted to production by the upset machine forging process. This process produces a "looped" grain flow of major importance for gear teeth. Simple, headed forgings may be completed in one step, while some that have large, configured heads or multiple upsets may require as many as six steps. Upset forgings are produced weighing from less than 0.45 kg (1 lb) to about 225 kg (500 lb).

**Machining Stock Allowances.** The standard for machining stock allowance on any upset portion of the forging is 2.39 mm (0.094 in.), although allowances vary from 1.58 to 3.18 mm (0.062 to 0.125 in.), depending on size of upset, material and shape of the part (Fig. 12a).

**Fig. 12** Machining stock allowances for hot upset forgings. (a) Hot upset forging terminology and standards. (b) Probable shape of shear-cut ends. (c) Variation of corner radius with thickness of upset. These parts are the

simplest forms of upset forgings. Dimensions given in inches

Mismatch and shift of dies are each limited to 0.406 mm (0.016 in.) maximum. Mismatch is the location of the gripper dies with respect to each other.

Parting-line clearance is required in gripper dies for tangential clearance in order to avoid undercut and difficulty in removal of the forging from the dies (Fig. 12a).

Tolerances for shear-cut ends have not been established. Figure 12(b) shows a shear-cut end on a 31.8 mm ( $1\frac{1}{4}$  in.) diameter shank. Straight ends may be produced by torch cutting, hack-sawing, or abrasive wheel cutoff, at a higher cost than that of shearing.

Corner radii should follow the contours of the finished part, with a minimum radius of 1.59 mm ( $\frac{1}{16}$  in.). Radii at the outer diameter of the upset face are not required, but may be specified as desired. Variations in thickness of the upset require variations in radii, as shown in Fig. 12(c), because the source of the force is farther removed and the die cavity is more difficult to fill. When a long upset is only slightly larger than the original bar size, a taper is advisable instead of a radius.

**Tolerances** for all upset forged diameters are generally +1.59 mm, -0 ( $+\frac{1}{16}$  in., -0) except for thin sections of flanges and upsets relatively large in ratio to the stock sizes used, where they are +2.38 mm, -0 ( $+\frac{3}{32}$  in., -0). The increase of tolerances over the standard +1.59 mm, -0 is sometimes a necessity, because of variations in size of hot rolled mill bars, extreme die wear, or complexity of the part.

Draft angles may vary from 1 to 7°, depending on the characteristics of the forging design. Draft is needed to release the forging from the split dies; it also reduces the shearing of face surfaces in transfer from impression to impression.

For an upset forged part that requires several operations or passes, the dimensioning of lengths is determined on the basis of the design of each individual pass or operation.

# STEEL CASTINGS

---

## Introduction

STEEL CASTINGS can be made from any of the many types of carbon and alloy steel produced in wrought form. Such castings are produced by pouring molten steel of the desired composition into a mold of the desired configuration and allowing the steel to solidify. The mold material may be silica, zircon, chromite or olivine sand, graphite, metal, or ceramic. Choice of mold material depends on the size, intricacy, and dimensional accuracy of the casting and on cost. While the producible size, surface finish, and dimensional accuracy of castings vary widely with the type of mold, the properties of the cast steel are not affected significantly. Steel castings produced in any of the various types of molds and wrought steel of equivalent chemical composition respond similarly to heat treatment, have the same weldability, and have similar physical, mechanical, and corrosion properties. Cast steels do not exhibit the effects of directionality on mechanical properties that are typical of wrought steels.

**Table 1 Summary of specification requirements for various carbon steel castings**

Unless otherwise noted, all the grades listed in this table are restricted to a phosphorus content of 0.040% max and a sulfur content of 0.045% max.

- (a) Where a single value is shown, it is a minimum.
- (b) Where a single value is shown, it is a maximum.
- (c) For each reduction of 0.01% C below the maximum specified, an increase of 0.04% Mn above the maximum specified is permitted up to the maximums given in the applicable ASTM specifications.
- (d) Grades may also include low-alloy steels; see Table 2 for the stronger grades of ASTM A 148.
- (e) Unless specified by purchaser, the compositions of cast steels in ASTM A 148 are selected by the producer in order to achieve the specified mechanical properties.
- (f) Purchased on the basis of hardenability, with manganese and other elements added as required.
- (g) Specified residual elements include 0.30% Cu max, 0.50% Ni max, 0.50% Cr max, 0.20% Mo max, and 0.03% V max, with the total residual elements not exceeding 1.00%.
- (h) These ASTM specifications also include alloy steel castings for the general type of applications listed in the table.
- (i) Testing temperature of -32 °C (-25 °F).
- (j) Charpy V-notch impact testing at the specified test temperature with an energy value of 18 J (13 ft · lbf) min for two specimens and an average of three.
- (k) Testing temperature of -46 °C (-50 °F).
- (l) Specified residual elements of 0.03% V, 0.50% Cu, 0.50% Ni, 0.40% Cr, and 0.25% Mo, with total amount not exceeding 1.00%. Sulfur and phosphorus content, each 0.025% max

The steel castings discussed in this article are classified into four general groups according to their carbon or alloy contents. Carbon steel castings account for three of these groups: low-carbon steel castings with less than 0.20% carbon,

medium-carbon castings with 0.20 to 0.50% carbon, and high-carbon castings with more than 0.50% carbon. The fourth group, low-alloy steel castings, is generally limited to grades with a total alloy content of less than 8%.

## Specifications

Steel castings are usually purchased to meet specified mechanical properties, with some restrictions on chemical composition. Tables 1 and 2 list the requirements given in various ASTM specifications and in SAE J435c. Table 1 lists primarily carbon steel castings (with some comparable low-alloy types), while Table 2 lists several low-alloy cast steels and some cast steels with chromium content up to 10.0%.

**Table 2 Summary of specification requirements for various alloy steel castings with chromium contents up to 10%**

(a) NT, normalized and tempered; QT, quenched and tempered.

(b) When a single value is shown, it is a minimum.

(c) When a single value is shown, it is a maximum.

- (d) Unless specified by the purchaser, the compositions of cast steels in ASTM A 148 are selected by the producer and therefore may include either carbon or alloy steels; see Table 1 for the lower-grade steels specified in ASTM A 148.
- (e) 0.06% S (max), 0.05% P (max).
- (f) 0.020% S (max), 0.020% P (max).
- (g) Similar to the cast steel in ASTM A 148.
- (h) 0.045% S (max), 0.040% P (max).
- (i) When residual maximums are specified for copper, nickel, chromium, tungsten, and vanadium, their total content shall not exceed 1.00%.
- (j) 0.50% Cu (max), 0.10% W (max), 0.045% S (max), 0.04% P (max).
- (k) When residual maximums are specified for copper, nickel, chromium, tungsten, and vanadium, their total residual content shall not exceed 0.60%.
- (l) 0.35% Cu (max), 0.03% V (max), 0.015% S (max), 0.020% P (max).
- (m) 0.15-0.25% V.
- (n) The specified residuals of copper, nickel, chromium, and molybdenum (plus tungsten), shall not exceed a total content of 1.00%.
- (o) Includes the residual content of tungsten.
- (p) 0.50% Cu (max), 0.10% W (max), 0.03% V (max), 0.045% S (max), 0.04% P (max).
- (q) Material class 7A is a proprietary steel and has a maximum thickness of 63.5 mm ( $2\frac{1}{2}$  in.).
- (r) Specified elements include 0.15-0.50% Cu, 0.03-0.10% V, and 0.002-0.006% B.
- (s) When residual maximums are specified for copper, nickel, chromium, tungsten, molybdenum, and vanadium, their total content shall not exceed 0.50%.
- (t) When residual maximums are specified for copper, nickel, chromium, tungsten, and vanadium, their total content shall not exceed 0.75%.
- (u) Low-carbon grade with double austenitization.

(v) For each reduction of 0.01% C below the maximum, an increase of 0.04% Mn is permitted up to a maximum of 2.30%.

(w) 0.20% Cu (max), 0.10% W (max), 0.02% V (max), 0.02% S (max), 0.02% P (max)

In the low-strength ranges, some specifications limit carbon and manganese content, usually to ensure satisfactory weldability. In SAE J435c, carbon and manganese are specified to ensure that the minimum desired hardness and strength are obtained after heat treatment. For special applications, other elements may be specified either as maximum or minimum, depending on the characteristics desired.

If only mechanical properties are specified, the chemical composition of castings for general engineering applications is usually left to the discretion of the casting supplier. For specific applications, however, certain chemical compositions limits have been established to ensure the development of specified mechanical properties after proper heat treatment, as well as to facilitate welding, uniform response to heat treatment, or other requirements. Hardness is specified for most grades of SAE J435c to ensure machinability, ease of inspection for high production rate items, or certain characteristics pertaining to wear.

SAE J435c includes three grades, HA, HB, and HC, with specified hardenability requirements. Figure 1 plots hardenability requirements, both minimum and maximum, for these steels. Hardenability is determined by the end-quench hardenability test described in the article "Hardenability of Steels" in this Section. Other specifications require minimum hardness at one or two locations on the end-quench specimen. In general, hardenability is specified to ensure a predetermined degree of transformation from austenite to martensite during quenching, in the thickness required. This is important in critical parts requiring toughness and optimal resistance to fatigue.

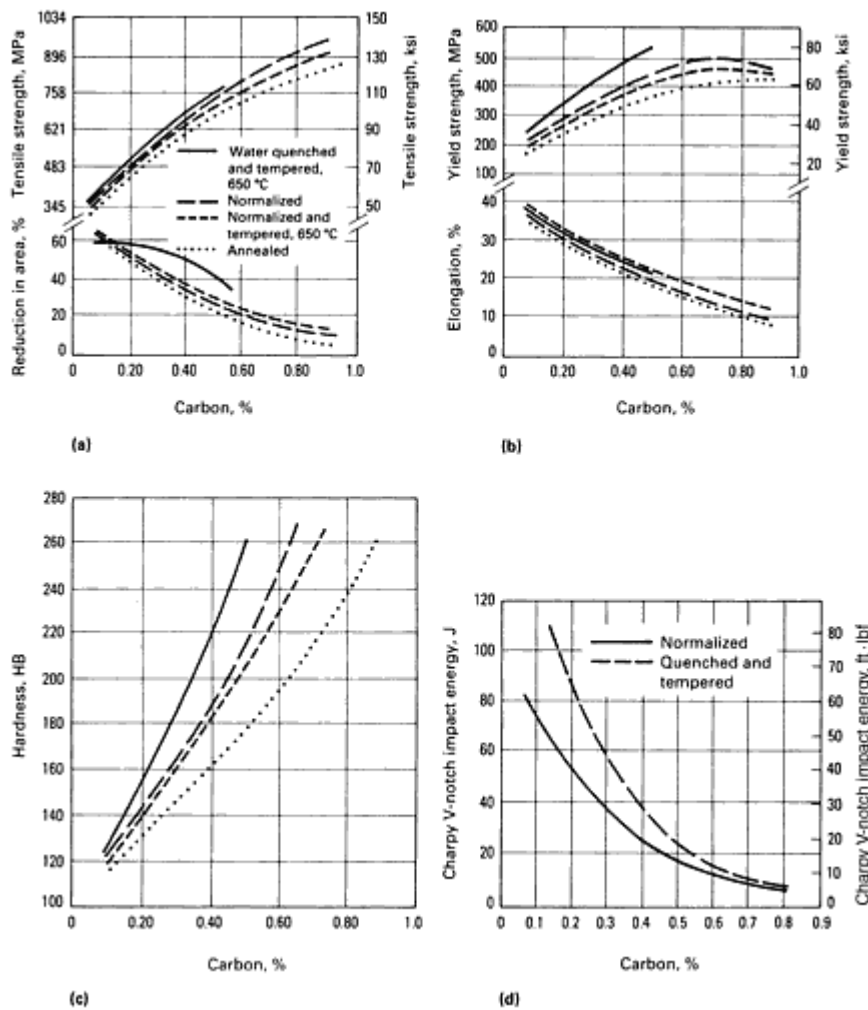

**Fig. 1** End-quench hardenability limits for the hardenability grades of cast steel specified in SAE J435c. The nominal carbon content of these steels is 0.30% C (see Table 1). Manganese and other alloying elements are added as required to produce castings that meet these limits.

Particularly when the purchaser heat treats a part after other processing, a casting will be ordered to compositional limits closely equivalent to the SAE-AISI wrought steel compositions, with somewhat higher silicon permitted. As in other steel castings, it is best not to specify a range of silicon, but to permit the foundry to use the silicon and manganese combination needed to achieve required soundness in the shape being cast. The silicon content is frequently higher in cast steels than for the same nominal composition in wrought steel. A silicon content higher than 0.80% is considered an alloy addition because it contributes significantly to resistance to tempering.

## Mechanical Properties

**General Characteristics.** Figure 2 shows the basic trends of the mechanical properties of cast carbon steels as a function of carbon content for four different heat treatments. For a given heat treatment, a higher carbon content generally results in higher hardness and strength levels with lower ductility and toughness values. Because yield strength is a primary design criterion for structural applications, Fig. 3 plots tensile strength, ductility (as measured by elongation), and toughness (based on Charpy V-notch impact energy) versus yield strength for low-alloy cast steels.

**Fig. 2** Properties of cast carbon steels as a function of carbon content and heat treatment. (a) Tensile strength and reduction of area. (b) Yield strength and elongation. (c) Brinell hardness. (d) Charpy V-notch impact energy

**Fig. 3** Room-temperature properties of cast low-alloy steels. QT, quenched and tempered; NT, normalized and

tempered

**Tensile and Yield Strengths.** If ferritic steels are compared at a given level of hardness and hardenability, the tensile and yield strengths of cast, rolled, forged, and welded metal are virtually identical, regardless of alloy content. Consequently, where tensile and yield properties are controlling criteria, the designer can interchange rolled, forged, welded, and cast steel.

**Ductility.** The ductility of cast steels is nearly the same as that of forged, rolled, or welded steels of the same hardness. The longitudinal properties of rolled or forged steel are somewhat higher than the properties of cast steel or weld metal. However, the transverse properties are lower by an amount that depends on the amount of working. When service conditions involve multidirectional loading, the nondirectional characteristic of cast steels may be advantageous.

**Toughness.** The notched-bar impact test is often used as a measure of the toughness of materials and is particularly useful in determining the transition temperature from ductile to brittle fracture. Nil ductility transition temperature (NDTT) as determined as per method ASTM E 208, lateral expansion values, and the energy absorbed values at specific temperatures are some of the different criteria for evaluating impact properties. The impact properties of wrought steels are usually listed for the longitudinal direction; the values shown are higher than those for cast steels of equivalent composition and thermal treatment. The transverse impact properties of wrought steels are usually 50 to 70% of those in the longitudinal direction above the transition temperature and, in some conditions of composition and degree of working, even lower. Because cast steels are nondirectional, their impact properties usually fall somewhere between the longitudinal and transverse properties of wrought steel of similar composition.

Impact properties are controlled by microstructure and, in general, are not significantly affected by microshrinkage or hydrogen. The effect of microstructure, as controlled by chemical composition and heat treatment, is discussed in the article "Service Characteristics of Carbon and Alloy Steels" in this Section (see the sub-section on "Notch Toughness of Steels"). Curves of impact energy versus temperature for casting steels designed specifically for pressure-containing parts for low-temperature service are presented in Fig. 4. These curves illustrate the significant changes in impact properties that can be effected by changes in steel grade and/or heat treatment.

**Fig. 4** Effect of temperature on Charpy V-notch impact energy of cast steels for low-temperature service. Steel grades conformed to ASTM A 352. Heat treatments were as follows: grade LCB (0.30% C max, 1.00% Mn max steel), water quenched from 890 °C (1650 °F), tempered at 650 °C (1200 °F) and water quenched, aged 40 h at 425 °C (800 °F), and stress relieved 40 h at 595 °C (1100 °F); grade LC2-1 (Ni-Cr-Mo steel), normalized at 955 °C (1750 °F) and air cooled, reheated to 890 °C (1650 °F) and water quenched, either tempered at 595 °C (1100 °F) and aged 40 h at 425 °C (800 °F) or tempered at 650 °C (1200 °F) and aged 64 h at 425 °C (800 °F). All specimens were taken at locations greater than one-fourth the thickness in from the surface of test

blocks 51 by 210 by 229 mm (2 by 8  $\frac{1}{4}$  by 9 in.) having an ASTM grain size of 6 to 8. The curves represent average values for several tests at each test temperature.

Section size also affects the impact properties that are obtained. Figure 5 illustrates this effect for one of the grades of steel castings described in Fig. 4 (grade LCB). When the section size is increased from 25 to 127 mm (1 to 5 in.), the temperature at which the impact energy is reduced to an average of 18 J (13 ft · lbf) is increased by 28 °C (50 °F).

**Fig. 5** Effect of section thickness on Charpy V-notch impact curves of grade LCB steel castings. Steel grade conformed to ASTM A 352. Heat treatment was the same as for Fig. 4. All specimens were taken at locations greater than one-fourth the thickness in from the surface of test blocks of four sizes: 25 by 25 by 279 mm (1 by 1 by 11 in.), 51 by 210 by 229 mm (2 by  $8\frac{1}{4}$  by 9 in.), 76 by 229 by 283 mm (3 by 9 by  $11\frac{1}{8}$  in.), and 127 by 381 by 381 mm (5 by 15 by 15 in.). The ASTM grain size of the blocks was 6 to 8. The curves represent average values for several tests at each test temperature.

**Fatigue Strength.** For cast steels, the fatigue strength, or endurance limits, as determined by tests on smooth bars is generally in the range of 40 to 50% of the tensile strength. Figure 6 compares the fatigue endurance limits of both wrought and cast steels. Although the unnotched fatigue endurance limit of wrought steels is higher, they are much more notch sensitive than are cast steels.

**Fig. 6** Fatigue endurance limit versus tensile strength for notched and unnotched cast and wrought steels with various heat treatments. Data obtained in R.R. Moore rotating-beam fatigue tests; theoretical stress concentration factor = 2.2

**Section Size and Mass Effects.** The size of a cast coupon or casting can have a marked effect on its mechanical properties. This effect reflects the influence of section size on the cooling rates achieved during heat treatment; a larger section has more mass, which slows the cooling rates within the section and thus affects the microstructure and mechanical properties achieved during cooling. The effect of increasing section size on the mechanical properties of a medium-carbon cast steel in the annealed and as-cast condition is shown in Fig. 7. Because of section size effects, the

results of tests on specimens taken from very heavy sections and from large castings are helpful in predicting minimum properties in cast steel parts.

Fig. 7 Effect of section size on tensile strength of medium-carbon steel castings

## Low-Carbon Cast Steels

Low-carbon cast steels are those with a carbon content of less than 0.20%. Most of the tonnage produced in the low-carbon classification contains between 0.16 and 0.19% C, with 0.50 to 0.80% Mn, 0.05% P (max), 0.06% S (max), and 0.35% to 0.70% Si. In order to obtain high magnetic properties in electrical equipment, the manganese content is usually held between 0.10 and 0.20%.

Low-carbon steel castings are made in two important classes. One may be termed railroad castings, and the other miscellaneous jobbing castings. The railroad castings consist mainly of comparatively symmetrical and well-designed castings for which adverse stress conditions have been carefully studied and avoided. Miscellaneous jobbing castings present a wide variation in design and frequently involve the joining of light and heavy sections. Varying sections make it more difficult to avoid high residual stress in the as-cast shape. Because residual stresses of large magnitude cannot be tolerated in many service applications, stress relieving becomes necessary. Therefore, the annealing of those castings is decidedly beneficial even though it may cause little improvement of mechanical properties.

Figure 2 includes the mechanical properties of carbon cast steels with low-carbon contents within the range of about 0.10 to 0.20%. There is very little difference between the properties of the low-carbon

## Medium-Carbon Cast Steels

The medium-carbon grades of cast steel contain 0.20 to 0.50% C and represent the bulk of steel casting production. In addition to carbon, they contain 0.50 to 1.50% Mn, 0.05% P (max), 0.06% S (max), and 0.35 to 0.80% Si. The mechanical properties at room temperature of cast steels containing from 0.20 to 0.50% C are included in Fig. 2. Steels in this carbon range are always heat treated, which relieves casting strains, refines the as-cast structure, and improves the ductility of the steel. A very large proportion of steel castings of this grade are given a normalizing treatment, followed by a tempering treatment.

## High-Carbon Cast Steels

Cast steels containing more than 0.50% C are classified as high-carbon steels. This grade also contains 0.50 to 1.50% Mn, 0.05% P (max), 0.05% S (max), and 0.35 to 0.70% Si. The mechanical properties of high-carbon steels at room temperature are shown in Fig. 2. High-carbon cast steels are often fully annealed. Occasionally, a normalizing and tempering treatment is given, and for certain applications an oil quenching and tempering treatment may be used.

The microstructure of high-carbon steel is controlled by the heat treatment. Carbon also has a marked influence, for example, giving 100% pearlitic structure at eutectoid composition ( $\sim 0.83\%$  carbon). Higher proportions of carbon than eutectoid composition will increase the proeutectoid cementite, which is detrimental to the casting if it forms a network at the grain boundaries because of improper heat treatment (for example, slow cooling from above the  $A_{cm}$  temperature). Faster cooling will prevent the formation of this network and, hence, improve the properties.

## Low-Alloy Cast Steels

Low-alloy cast steels contain a total alloy content of less than 8%. These steels have been developed and used extensively for meeting special requirements that cannot be met by ordinary plain carbon steels with low hardenability. The addition of alloys to plain carbon steel castings may be made for any of several reasons, such as to provide higher hardenability, increased wear resistance, higher impact resistance at increased strength, good machinability even at higher hardness, higher strength at elevated and low temperatures, and better resistance to corrosion and oxidation than the plain carbon steel castings. These materials are produced to meet tensile strength requirements of 485 to 1380 MPa (70 to 200 ksi), together with some of the above special requirements. Figure 3 shows typical room-temperature mechanical properties of low-alloy steels plotted against yield strength. These properties are, of course, a function of alloy content, heat treatment, and section size.

# Bearing Steels

---

## Introduction

ROLLING-ELEMENT BEARINGS, whether ball bearings or roller bearings with spherical, straight, or tapered rollers, are fabricated from a wide variety of steels. In a broad sense, bearing steels can be divided into two classes: standard bearing steels are intended for normal service conditions (see the discussion which follows); whereas special-purpose bearing steels are used for either extended fatigue life or excessive operating conditions of temperature and corrosion.

Bearings for normal service conditions, a category that includes more than 95% of all rolling-element bearings, are applicable when:

- Maximum temperatures are of the order of 120 to 150 °C (250 to 300 °F), although brief excursions to 175 °C (350 °F) may be tolerated.
- Minimum ambient temperatures are about -50 °C (-60 °F).
- The contact surfaces are lubricated with such materials as oil, grease, or mist.
- The maximum Hertzian contact stresses are of the order of 2.1 to 3.1 GPa (300 to 450 ksi).

Bearings used under normal service conditions also experience the effects of vibration, shock, misalignment, debris, and handling. Therefore, the fabrication material must provide toughness, a degree of temper resistance, and microstructural stability under temperature extremes. The material must also exhibit the obvious requirement of surface hardness for wear and fatigue resistance, particularly rolling-contact fatigue resistance.

## Bearing Steel Production and Quality

Apart from a satisfactory microstructure, which is obtained through the proper combination of steel grade and heat treatment, the single most important factor in achieving levels of rolling-contact fatigue life in bearings is the cleanliness, or freedom from harmful nonmetallic inclusions, of the steel. Bearing steels can be produced by one of these techniques:

- Clean-steel air-melt practices
- Electroslag remelting
- Air melting followed by vacuum arc remelting
- Vacuum induction melting followed by vacuum arc remelting (VIM/VAR)

Cleanliness, cost, and reliability can increase depending on which practice is chosen.

Bearing steel cleanliness is most commonly rated by using microscopic techniques, such as those defined in ASTM A 295 for high-carbon steels and A 534 for carburizing steels. The worst fields found in metallographically prepared sections of the steel can be compared with rating charts (J-K charts) according to the type of inclusion: sulfides, stringer-type oxides, silicates, and globular-type oxides.

Bearing steel cleanliness can also be rated by oxygen analysis, the magnetic particle method (AMS 2301, AMS 2300), and ultrasonic methods. Quantified ultrasonic results are supplemented with inclusion imaging and length verification using acoustic microscopy. These tools, along with energy-dispersive or wavelength-dispersive chemical analyses using scanning electron microscopy, have confirmed the aluminum oxide stringers relate directly with bearing fatigue life under operating conditions that promote material fatigue. The size distribution and the total quantity of inclusion stringers in a given group of bearings has been shown to relate to performance (fatigue life) through a summation of the inclusion stringer lengths per unit volume of steel.

The total length of inclusion stringers per unit volume is the abscissa on Fig. 1. The steel cleanliness range starts with an earlier vacuum carbon deoxidation steel process method to the precipitation-shrouded version of today's air-melt steels and to today's vacuum-arc remelted steel. As shown in Fig. 1, the over-all fatigue life range is more than an order of magnitude. VIM/VAR steel lives exceed even the VAR steel lives so that even though the present-day air-melt steels do give better lives, the vacuum-processed steels are meeting the fatigue life requirements for the extended-life applications.

Fig. 1 Effect of total length of inclusion stringers on the rolling contact fatigue life of a 220 mm (8.7 in.) bore tapered roller bearing inner race as a function of steel cleanliness

## Standard Bearing Steels

The steel used in rolling bearings for normal requirements such as industrial or automotive applications is an alloy steel with alloy content, in addition to carbon, that runs from  $\sim 1.5$  to 6%, depending on the bearing ring cross section and hardenability requirements. Typical standard bearing steel compositions for high-carbon or through-hardened steels are given in Table 1, and standard bearing steel compositions for low-carbon or carburizing bearing steels are given in Table 2. Both steels are used depending on specific service condition needs. High-carbon steels provide the following advantages:

- Ability to carry somewhat higher contact stresses, such as those encountered in point contact loading in ball bearings
- A simpler quench and temper heat treatment when compared to carburizing
- Potentially greater dimensional stability under temperature extremes because of their characteristically lower content of retained austenite

Table 1 Nominal compositions of high-carbon bearing steels

Grade	Composition, %

<b>20MnCr5</b>	<b>0.20</b>	<b>1.25</b>	<b>0.27</b>	<b>1.15</b>	...	...

Carburizing steels, on the other hand, offer the following advantages:

- Greater surface ductility (due to their retained austenite content) to better resist the stress-raising effects of asperities, misalignment, and debris particles
- A higher level of core toughness to resist through-section fracture under severe service conditions
- A compressive residual surface stress condition to resist bending loads imposed on the ribs of roller bearings, and to reduce the rate of fatigue crack propagation through the cross section.
- Easier machining of the base material in manufacturing

Surface hardness on the order of 58 to 64 HRC is present for either high-carbon or carburizing bearing steels; however, there are some differences in the core hardnesses of these two types of materials. The data in Table 3 show that the strength and toughness of the core are greater in the quenched and tempered low-carbon steels than in the unhardened portion of an induction-hardened high-carbon steel bearing part.

**Table 3 Core properties of carburized versus induction-hardened components**

Material	Hardness, HB	Yield strength		Ultimate tensile strength		Impact energy		Machining <sup>(a)</sup> , %
		MPa	ksi	MPa	ksi	J	ft · lbf

(a) Where 1212 carbon steel represents 100%.

(b) Quenched and tempered.

(c) Annealed

From a surface fatigue standpoint, it is necessary to maintain sufficient hardness on and below the surface to resist abrasive/adhesive wear and to minimize contact fatigue in the whole region of the surface and below so that the material strength at each point is higher than the surface or subsurface shear stresses that occur from a loaded Hertzian surface stress. Figure 2 shows an estimated relationship between the hardness and shear yield strength that is applicable to either steel type. The success of a given steel in a bearing application is not as much a function of the steel type as how it is treated. Fatigue resistance generally increases with hardness; the maximum depends on the steel type. Figure 3 compares the bending fatigue lives of through-carbon and carburized steels as a function of surface hardness. In bending fatigue, the combination of compressive residual surface stresses with a higher composite section toughness gives the advantage to the carburized steel.

Fig. 2 Plot of shear yield strength versus hardness for typical bearing steel

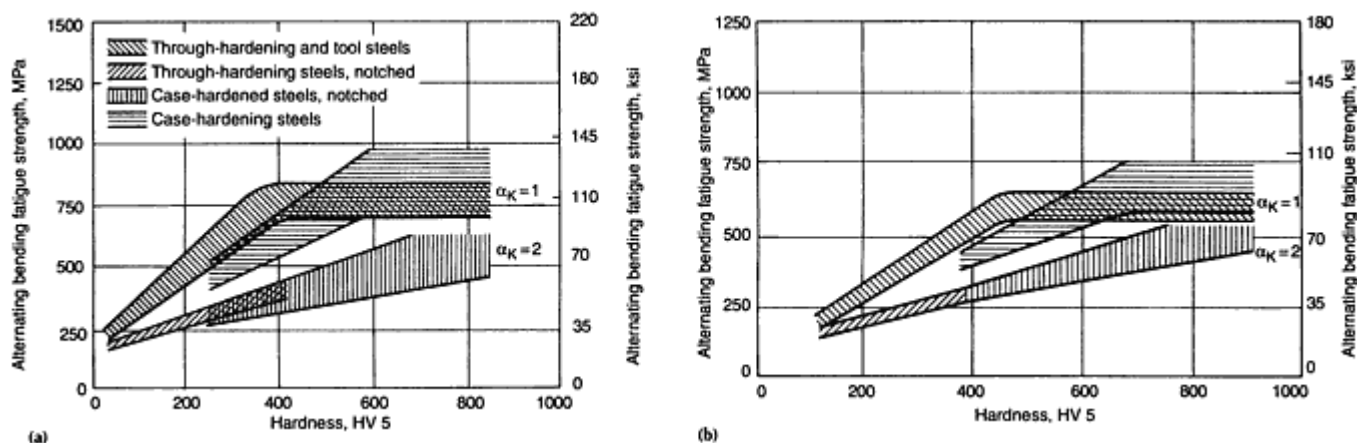

Fig. 3 Rotating-beam fatigue strength of cast-hardening and through-hardening steels as a function of surface hardness. (a) Testpiece diameter of 6mm (0.25 in.), and triangular torque. (b) Testpiece diameter of 12 mm (0.5 in.), constant torque.  $\alpha_K$  is the stress-concentration factor.

**Characteristics of High-Carbon Bearing Steels.** The matrix of hardened-and-tempered bearing steels is high-carbon martensite, containing primary carbides and 5 to 10% retained austenite. The hardness throughout the section is typically 60 to 64 HRC. Table 1 lists the compositions of selected high-carbon bearing steels currently in use. The first grades are listed in order of increasing hardenability; they are applied to bearing sections of increasing thickness to ensure freedom from nonmartensitic transformations in hardening. Grade TBS-9 is a lower-chromium bearing steel, which, because of its residual alloy content, has a hardenability similar to that of SAE-AISI 52100. The remaining steels are representative of overseas steels applied to bearing components.

**Characteristics of Carburizing Bearing Steels.** The case microstructure of carburized bearing steels consists of high-carbon martensite with retained austenite in the range of 15 to 40% (higher amounts of retained austenite increase rolling-contact fatigue life). Case hardness is typically 58 to 64 HRC. In the core of carburized bearings, the microstructure consists of low-carbon martensite; it also often contains variable amounts of bainite and ferrite. The core hardness may vary from 25 to 48 HRC.

Table 2 lists compositions of typical carburizing bearing steels. The SAE-AISI grades are listed in approximate order of increasing hardenability or section size applicability. SCM420 and 20MnCr5 are Japanese and German grades, respectively, found in carburized bearing components. In addition to standard SAE-AISI grades, bearing steels can also be designed so that their hardenability matches the requirements of specific section thicknesses. Alloy conservation and a more consistent heat-treating response are benefits of using specially designed bearing steels.

The selection of a carburizing steel for a specific bearing section is based on the heat-treating practice of the producer, either direct quenching from carburizing or reheating for quenching, and on the characteristics of the quenching equipment. The importance of a proper case microstructure to the ability of a bearing to resist pitting fatigue is illustrated in Fig. 4. In particular, the presence of pearlite, resulting from a mismatch of quenching conditions and case hardenability, is shown to have a detrimental effect.

Fig. 4 Effect of surface microstructure on the shape of *S-N* curve for surface fatigue (pitting)

## Special-Purpose Bearing Steels

When bearing service temperatures exceed about 150 °C (300 °F), common low-alloy steels cannot maintain the necessary surface hardness to provide satisfactory fatigue life. The low corrosion resistance of these steels makes them susceptible to attack by environmental moisture, as well as aggressive gaseous or liquid contaminants. Therefore, specialized steels are often applied when these service conditions exist.

**High-Temperature Service Bearing Steels.** Table 4 lists the compositions of certain bearing steels suited for high-temperature service. These steels are typically alloyed with carbide-stabilizing elements such as chromium, molybdenum, vanadium, and silicon to improve their hot hardness and temper resistance. The listed maximum operating temperatures are those at which the hardness at temperature falls below a minimum of 58 HRC. Figure 5 compares the hot hardness behavior of various tool and bearing steels.

**Table 4 Nominal compositions of high-temperature bearing steels**

Steel	Composition, %								Maximum operating temperature <sup>(a)</sup>	
	C	Mn	Si	Cr	Ni	Mo	V	Other	°C	°F

(a) Maximum service temperature, based on a minimum hot hardness of 58 HRC

**Fig. 5 Hot hardness of homogeneous high-carbon steels for service above 150 °C (300 °F). The dashed line at 58 HRC indicates the maximum service temperature at which a basic dynamic load capacity of about 2100 MPa (300 ksi) can be supported in bearings and gears**

An important application of the high-temperature bearing steels is aircraft and stationary turbine engines. Bearings made from M50 steel have been used in engine applications for many years. Jet engine speeds are being continually increased

in order to improve performance and efficiency; therefore, the bearing materials used in these engines must have increased section toughness to withstand the stresses that result from higher centrifugal forces. For this reason, the carburizing high-temperature bearing steels, such as M50-NiL and CBS-1000M, are receiving much attention. The core toughness of these steels is more than twice that of the through-hardening steels.

In general, high-temperature bearing steels require more care in the carburizing process than conventional low-alloy carburizing steels. Because of the high content of chromium and silicon in the high-temperature steels, some precarburizing treatment, such as preoxidation, is always necessary to promote satisfactory carburizing.

**Corrosion-Resistant Bearing Steels.** Bearings that require the highest corrosion resistance necessitate the use of stainless grades with greater than 12% Cr. At this time, no satisfactory carburizing technique has been developed for these grades. Thus, all corrosion-resistant bearing steels are of the through-hardening type (Table 5). Steels such as the 440C modification, CRB-7, and BG42 also offer good high-temperature hardness.

**Table 5 Nominal compositions of corrosion-resistant bearing steels**

# High-Strength Structural and High-Strength Low-Alloy Steels

## Introduction

THE STEELS discussed in this article are characterized by higher yield strengths than those of plain carbon structural steels. There are three categories: (a) carbon steel grades having minimum yield strengths of 275 to 550 MPa (40 to 80 ksi); (b) microalloyed high-strength low-alloy (HSLA) steels, with improved properties that result from a combination of alloy additions and controlled hot rolling (mechanical properties of HSLA steels are intermediate between those of plain carbon structural steels and heat-treated high-strength carbon and low-alloy constructional steels); and (c) quenched-and-tempered low-alloy steel grades having minimum yield strengths of 550 to 1030 MPa (80 to 150 ksi) that meet the requirements of specifications such as ASTM A 514. Steels with even higher yield strength levels (greater than 1380 MPa, or 200 ksi) are described in the article "Ultrahigh-Strength Steels" which immediately follows in this Section.

High-strength and HSLA grades are generally available in all standard wrought forms: sheet, strip, plate, structural shapes, bars, bar-size shapes, and special sections. These steels are also furnished as cold rolled sheet or strip in gages up to about 1.6 mm (  $\frac{1}{16}$  in.) for greater control of thickness in structures such as trailer bodies or for improved surface finish in instances where parts are to be plated.

The heat treated grades are available as plate, bar and, occasionally, sheet and structural shapes. When intended for applications involving hot forming, they are generally purchased in the non-heat-treated condition. Also, semifinished mill products are available for forging. After forming or forging, such products may be heat treated to develop high strength.

High-strength steels are produced to specified mechanical properties, which may differ slightly for different thickness ranges. Maximum limits of chemical composition are generally published because the carbon and alloy contents are varied as necessary to maintain mechanical properties in products of various thicknesses.

## High-Strength Structural Carbon Steels

High-strength structural carbon steels are basically carbon-manganese or carbon-manganese-silicon steels, with some grades containing small alloying additions of other elements. Such steels are used in either the as-hot-rolled or heat-treated (normalized or quenched and tempered) condition. As listed in Table 1, the yield strength of quenched and tempered carbon-manganese steel plate varies from 315 to 550 MPa (46 to 80 ksi), depending on section thickness. Minimum Charpy V-notch impact toughness may be as high as 27 to 34 J (20 to 25 ft · lbf) at temperatures as low as -68 °C (-90 °F) for quenched and tempered carbon steel having yield strengths of 345 MPa (50 ksi). However, for quenched and tempered carbon steel with 690 MPa (100 ksi) yield strengths (Table 1), the impact values are lower, normally about 20 J (15 ft · lbf) at -60 °C (-75 °F). All grades can be grain refined with aluminum to improve toughness.

**Table 1 Typical compositions, tensile properties, and product sizes of high-strength structural carbon steels**

(a) Product thicknesses are a maximum unless a range is given.

(b) Compositions are a maximum unless a range is given or if otherwise specified in footnotes. Residual amounts of sulfur and phosphorus are limited in all grades and have specified maximums of 0.035 to 0.04% P (max) and 0.04 to 0.05% S (max), depending on the specification.

(c) Minimum amount of copper if specified.

(d) Over 65 mm (2.5 in.), ASTM A 738 grade A requires quenching and tempering and 1.62% Mn (max) to achieve the specified strength levels.

(e) Elongation in 50 mm (2 in.)

In addition to high-strength plate applications, quenched and tempered carbon-manganese steels are used for shafts and couplings. Steels with 0.40 to 0.60% C are used for railway wheels, tires, and axles, while those with higher carbon contents can be used as high-strength wire laminated spring materials, often with silicon-manganese or chromium-vanadium additions. The higher-carbon steels are also used for rails (0.7% C) and, over a range of carbon contents (typically, 0.20-0.50% C, for reinforcing bar.

## High-Strength Low-Alloy Steels

HSLA steels, or microalloyed steels, are designed to provide better mechanical properties and/or greater resistance to atmospheric corrosion than conventional carbon steels. They are not considered to be alloy steels in the normal sense because they are designed to meet specific mechanical properties rather than a chemical composition. (HSLA steels have yield strengths greater than 275 MPa, or 40 ksi.) The chemical composition of a specific HSLA steel may vary for different product thicknesses to meet mechanical property requirements. The HSLA steels have low carbon content (0.05 to  $\sim$ 0.25% C) in order to produce adequate formability and weldability, and they have manganese content up to 2.0%. Small quantities of chromium, nickel, molybdenum, copper, nitrogen, vanadium, niobium, titanium, and zirconium are used in various combinations.

High-strength low-alloy steels are primarily hot-rolled into the usual wrought product forms (sheet, strip, bar, plate, and structural sections) and are commonly furnished in the as-rolled condition. However, the production of hot-rolled HSLA products may also involve special hot-mill processing that further improves the mechanical properties of some HSLA steels and product forms. These processing methods include:

- *The controlled rolling* of precipitation-strengthened HSLA steels to obtain fine austenite grains and/or highly deformed (pancaked) austenite grains. During cooling, these austenite grains transform into fine ferrite grains that greatly enhance toughness while improving yield strength.
- *The accelerated cooling* of, preferably, controlled-rolled HSLA steels to produce fine ferrite grains during the transformation of austenite. These cooling rates cannot be rapid enough to form acicular ferrite, nor can they be slow enough that high coiling temperatures result thereby causing the overaging of precipitates.
- *The quenching or accelerated air or water cooling* of low-carbon steels ( $\leq$ 0.08% C) that possess adequate hardenability to transform into low-carbon bainite (acicular ferrite). This microstructure offers an excellent combination of high yield strengths (275 to 690 MPa, or 60 to 100 ksi), excellent weldability and formability, and high toughness. (Controlled rolling is necessary for low ductile-brittle transition temperatures.)
- *The normalizing* of vanadium-containing HSLA steels. This process refines grain size, thereby improving toughness and yield strength.
- *The intercritical annealing* of HSLA steels to obtain a dual-phase microstructure (martensite islands dispersed in a ferrite matrix). This microstructure exhibits a lower yield strength but, because of rapid work-hardening capability, provides a better combination of ductility and tensile strength than conventional HSLA steels and also improved formability.

The use of these processing methods for controlling/enhancing the properties of HSLA steels is described in the article "Steelmaking Practices and Their Influence on Properties" in this Handbook.

**Table 2 Summary of characteristics and intended uses of HSLA steels described in ASTM specifications**

ASTM specification <sup>(a)</sup>	Title	Alloying elements <sup>(b)</sup>	Available mill forms	Special characteristics	Intended uses
A 242	High-strength low-alloy structural steel	Cr, Cu, N, Ni, Si, Ti, V, Zr	Plate, bar, and shapes $\leq 100$ mm (4 in.) in thickness	Atmospheric-corrosion resistance four times that of carbon steel	<b>Structural members in welded, bolted, or riveted construction</b>
A 572	High-strength low-alloy niobium-vanadium steels of structural quality	Nb, V, N	Plate, bar, shapes, and sheet piling $\leq 150$ mm (6 in.) in thickness	Yield strengths of 290 to 450 MPa (42 to 65 ksi) in six grades	<b>Welded, bolted, or riveted structures, but mainly bolted or riveted bridges and buildings</b>
A 588	High-strength low-alloy structural steel with 345 MPa (50 ksi) minimum yield point $\leq 100$ mm (4 in.) in thickness	Nb, V, Cr, Ni, Mo, Cu, Si, Ti, Zr	Plate, bar, and shapes $\leq 200$ mm (8 in.) in thickness	Atmospheric-corrosion resistance four times that of carbon steel; nine grades of similar strength	<b>Welded, bolted, or riveted structures, but primarily welded bridges and buildings in which weight savings or added durability is important</b>
A 606	Steel sheet and strip, hot-rolled and cold-rolled, high-strength low-alloy with improved corrosion resistance	Not specified	Hot-rolled and cold-rolled sheet and strip	Atmospheric-corrosion resistance twice that of carbon steel (type 2) or four times that of carbon steel (type 4)	<b>Structural and miscellaneous purposes for which weight savings or added durability is important</b>
A 607	Steel sheet and strip, hot-rolled and cold-rolled, high strength low-alloy niobium and/or vanadium	Nb, V, N, Cu	Hot-rolled and cold-rolled sheet and strip	Atmospheric-corrosion resistance twice that of carbon steel, but only when copper content is specified; yield strengths of 310 to 485 MPa (45 to 70 ksi) in six grades	<b>Structural and miscellaneous purposes for which greater strength or weight savings is important</b>
A 618	Hot-formed welded and seamless high-strength low-alloy structural tubing	Nb, V, Si, Cu	Square, rectangular, round, and special-shape structural welded or seamless tubing	Three grades of similar yield strength; may be purchased with atmospheric-corrosion resistance twice that of carbon steel	<b>General structural purposes, included welded, bolted, or riveted bridges and buildings</b>
A 633	Normalized high-strength low-alloy structural steel	Nb, V, Cr, Ni, Mo, Cu, N, Si	Plate, bar, and shapes $\leq 150$ mm (6 in.) in thickness	Enhanced notch toughness; yield strengths of 290 to 415 MPa (42 to 60 ksi) in five grades	<b>Welded, bolted, or riveted structures for service at temperatures at or above -45 °C (-50 °F)</b>
A 656	High-strength, low-alloy, hot-rolled structural vanadium-aluminum-nitrogen and	V, Al, N, Ti, Si	Plate, normally $\leq 16 \frac{5}{8}$ mm ( $\frac{5}{8}$ in.) in	Yield strength of 552 MPa (80 ksi)	<b>Truck frames, brackets, crane booms, rail cars, and other applications</b>

	titanium-aluminum steels		thickness		for which weight savings is important
A 690	High-strength low-alloy steel H-piles and sheet piling	Ni, Cu, Si	Structural-quality H-piles and sheet piling	Corrosion resistance two to three times greater than that of carbon steel in the splash zone of marine structures	<b>Dock walls, sea walls, bulkheads, excavations, and similar structures exposed to seawater</b>
A 709, grade 50 and 50W	Structural steel	V, Nb, N, Cr, Ni, Mo	All structural-shape groups and plate $\leq$ 100 mm (4 in.) in thickness	Minimum yield strength of 345 MPa (50 ksi). Grade 50W is a weathering steel	<b>Bridges</b>
A 714	High-strength low-alloy welded and seamless steel pipe	V, Ni, Cr, Mo, Cu, Nb	Pipe with nominal pipe size diameters of 13 to 660 mm ( $\frac{1}{2}$ to 26 in.)	Minimum yield strengths $\leq$ 345 MPa (50 ksi) and corrosion resistance two to four times that of carbon steel	<b>Piping</b>
A 715	Steel sheet and strip, hot-rolled, high-strength low-alloy with improved formability	Nb, V, Cr, Mo, N, Si, Ti, Zr, B	Hot-rolled sheet and strip	Improved formability <sup>(c)</sup> compared to A 606 and A 607; yield strengths of 345 to 550 MPa (50 to 80 ksi) in four grades	<b>Structural and miscellaneous applications for which high strength, weight savings, improved formability, and good weldability are important</b>
A 808	High-strength low-alloy steel with improved notch toughness	V, Nb	Hot-rolled steel plate $\leq$ 65 mm ( $2\frac{1}{2}$ in.) in thickness	Charpy V-notch impact energies of 40 to 60 J (30 to 45 ft · lbf) at -45 °C (-50 °F)	<b>Railway tank cars</b>
A 812	High-strength low-alloy steels	V, Nb	Steel sheet in coil form	Yields strengths of 450 to 550 MPa (65 to 85 ksi)	<b>Welded layered pressure vessels</b>
A 841	Plate produced by thermomechanical controlled processes	V, Nb, Cr, Mo, Ni	Plates $\leq$ 100 mm (4 in.) in thickness	Yield strengths of 310 to 345 MPa (45 to 50 ksi)	<b>Welded pressure vessels</b>
A 847	Cold-formed welded and seamless high-strength low-alloy structural tubing with improved atmospheric-corrosion resistance	Cu, Cr, Ni, Si, V, Ti, Zr, Nb	Welded tubing with maximum periphery of 1625 mm (64 in.) and wall thickness of 16 mm ( $\frac{5}{8}$ in.) or seamless tubing with maximum periphery of 810 mm (32 in.) and wall thickness of 13 mm ( $\frac{1}{2}$ in.)	Minimum yield strengths $\leq$ 345 MPa (50 ksi) with atmospheric-corrosion resistance twice that of carbon	<b>Round, square, or specially shaped structural tubing for welded, riveted, or bolted construction of bridges and buildings</b>

A 860	High-strength butt-welding fittings of wrought high-strength low-alloy steel	Cu, Cr, Ni, Mo, V, Nb, Ti	Normalized or quenched-and-tempered wrought fittings	Minimum yield strengths $\leq 485$ MPa (70 ksi)	<b>High-pressure gas and oil transmission lines</b>
A 871	<b>High-strength low-alloy steel with atmospheric corrosion resistance</b>	<b>V, Nb, Ti, Cu, Mo, Cr</b>	<b>As-rolled plate <math>\leq 35</math> mm (1 <math>\frac{3}{8}</math> in.) in thickness</b>	<b>Atmospheric-corrosion resistance four times that of carbon structural steel</b>	<b>Tubular structures and poles</b>

- (a) For grades and mechanical properties, see Table 4.
- (b) In addition to carbon, manganese, phosphorus, and sulfur. A given grade may contain one or more of the listed elements, but not necessarily all of them; for specified compositional limits, see Table 3.
- (c) Obtained by producing killed steel, made to fine grain practice, and with microalloying elements such as niobium, vanadium, titanium, and zirconium in the composition

In addition to hot-rolled products, HSLA steels are also furnished as cold-rolled sheet and forgings. The main advantage of HSLA forgings (as that of as-hot-rolled HSLA products) is that yield strengths in the range of 275 to 485 MPa (40 to 70 ksi) or perhaps higher can be achieved without heat treatment. Base compositions of these microalloyed ferrite-pearlite forgings are typically 0.3 to 0.5% C and 1.4 to 1.6% Mn. Low-carbon bainitic HSLA steel forgings have also been developed.

**HSLA Steel Categories.** High-strength low-alloy steels include many standard and proprietary grades designed to provide specific desirable combinations of properties such as strength, toughness, formability, weldability, and atmospheric-corrosion resistance. These steels are not considered alloy steels, even though their desired properties are achieved by the use of small alloy additions. Instead, HSLA steels are classified as a separate steel category, which is similar to as-rolled mild-carbon steel with enhanced mechanical properties obtained by the addition of small amounts of alloys and, perhaps, special processing techniques such as controlled rolling. This separate product recognition of HSLA steels is reflected by the fact that HSLA steels are generally priced from the base price for carbon steels, not from the base price for alloy steels. Moreover, HSLA steels are often sold on the basis of minimum mechanical properties, with the specific alloy content left to the discretion of the steel producer.

HSLA steels can be divided into six categories:

- *Weathering steels*, which contain small amounts of alloying elements such as copper and phosphorus for improved atmospheric corrosion resistance and solid-solution strengthening (see the section "Atmospheric Corrosion" in the article "Corrosion Characteristics of Carbon and Alloy Steels" in this Handbook)
- *Microalloyed ferrite-pearlite steels*, which contain very small (generally less than 0.10%) additions of strong carbide or carbonitride-forming elements such as niobium, vanadium, and/or titanium for precipitation strengthening, grain refinement, and possibly transformation temperature control
- *As-rolled pearlitic steels*, which may include carbon-manganese steels but which may also have small additions of other alloying elements to enhance strength, toughness, formability, and weldability
- *Acicular ferrite (low-carbon bainite) steels*, which are low-carbon (less than 0.08% C) steels with an excellent combination of high yield strengths, weldability, formability, and good toughness
- *Dual-phase steels*, which have a microstructure of martensite dispersed in a ferritic matrix and provide a good combination of ductility and high tensile strength
- *Inclusion-shape-controlled steels*, which provide improved ductility and through-thickness toughness by the small additions of calcium, zirconium, or titanium, or perhaps rare earth elements so

that the shape of the sulfide inclusions is changed from elongated stringers to small, dispersed, almost spherical globules

These categories are not necessarily distinct groupings, as an HSLA steel may have characteristics from more than one grouping. For example, all the above types of steels can be inclusion shape controlled. Table 2 describes some typical HSLA steels, their available mill forms, and their intended applications. Tables 3 and 4 list chemical compositions and properties of HSLA steels covered in various ASTM specifications.

**Table 3 Compositional limits for HSLA steel grades described in ASTM specifications**

(a) For characteristics and intended uses, see Table 2; for mechanical properties, see Table 4.

- (b) If a single value is shown, it is a maximum unless otherwise stated.
- (c) Values may vary, or minimum value may exist, depending on product size and mill form.
- (d) Optional or when specified.
- (e) May be purchased as type 1 (0.005-0.05 Nb), type 2 (0.01-0.15 V), type 3 (0.05 Nb, max, plus 0.02-0.15 V), or type 4 (0.015 N, max, plus V  $\geq 4$  N).
- (f) If chromium and silicon are each 0.50% min, the copper minimum does not apply.
- (g) May be substituted for all or part of V.
- (h) Niobium plus vanadium, 0.02 to 0.15%.
- (i) Nitrogen with vanadium content of 0.015% (max) with a minimum vanadium-to-nitrogen ratio of 4:1.
- (j) When silicon-killed steel is specified.
- (k) For plate under 40 mm (1.5 in.), manganese contents are 0.70 to 1.35% or up to 1.60% if carbon equivalents do not exceed 0.47%. For plate thicker than 40 mm (1 to 5 in.), ASTM A 841 specifies manganese contents of 1.00 to 1.60%.

**Table 4 Tensile properties of HSLA steel grades specified in ASTM standards**

- (d) Optional supplementary requirement given in ASTM A 6

## Heat Treated Structural Low-Alloy Grades

Heat treated structural low-alloy grades have better hardenability than carbon grades and thus can provide both high strength and good toughness in thicker sections. Their alloy content provides improved heat and corrosion resistance. However, these grades are somewhat more difficult to weld and generally are more expensive than carbon or HSLA grades. Quenched-and-tempered low-alloy grades may be ordered to fulfill the requirements of ASTM A 514 or A 517. The properties required of these steels are produced by heating to at least 900 °C (1650 °F), quenching in water or oil, and tempering at not less than 600 °C (1100 °F) to provide microstructures of tempered martensite or tempered martensite plus bainite, depending on section thickness.

Steels in this category typically contain less than 0.25% C and less than 5% alloy content. Yield strength values range from approximately 345 to 895 MPa (50 to 130 ksi), and tensile strength values range from 485 to 1035 MPa (70 to 150 ksi), depending on chemical composition, thickness, and heat treatment. Table 5 lists minimum tensile requirements for low-carbon quenched-and-tempered steels. These steels are furnished primarily as plate, although some are produced as either forgings or castings.

**Table 5 Minimum tensile properties and maximum plate thickness for quenched and tempered low-alloy steels**

Specification or common designation	Grade, type, or class	Plate thickness <sup>(a)</sup>		Minimum yield strength		Tensile strength		Minimum elongation in 50 mm (2 in.), %

Compositions for these steels are provided in the article "Classifications and Designations for Carbon and Alloy Steels" in this Section

(a) Maximum plate thickness for the specified mechanical properties when a single value is shown.

- (b) Maximum plate thickness is not defined in ASTM A 543; plates in ASTM A 543 are intended for applications requiring plate thicknesses of 50 mm (2 in.) or more.

# Ultrahigh-Strength Steels

---

## Introduction

ULTRAHIGH-STRENGTH STEELS are designed to be used in structural applications where very high loads are applied and often where high strength-to-weight ratios are required. In addition, they must also possess good ductility and toughness. The latter properties have been historically measured by tensile ductility, namely, percent elongation and reduction of area, and by impact resistance or energy absorbed in a notched impact test. However, in recent years the property of fracture toughness has become a significant factor in the acceptance of steels for critical high-performance structural applications.

The designation ultrahigh-strength is arbitrary because no universally accepted strength level for the term has been established. Also, as structural steels with greater and greater strength have been developed, the strength range for which the term is applied has gradually increased. This article describes those commercial structural steels capable of a minimum yield strength of 1380 MPa (200 ksi).

In addition to the steels discussed in this article, many other proprietary and standard steels are used for essentially the same types of applications, but at strength levels slightly below the arbitrary, lower limit of 1380 MPa (200 ksi) established above for the ultrahigh-strength class of constructional steels. Medium-alloy steels such as 4330V and 4335V (vanadium-modified versions of the corresponding SAE-AISI standard steels) are among the more widely used steels for yield strengths of 1240 to 1380 MPa (180 to 200 ksi). Certain proprietary steels such as Hy Tuf (a silicon-modified steel similar to 300M) exhibit excellent toughness at strengths up to or slightly above 1380 MPa. The toughness of Hy Tuf is about the same as a maraging steel in this strength range. For properties and other information on steels and strength ranges not discussed here, the reader is referred to sources such as *Aerospace Structural Metals Handbook*, published by the Mechanical Properties Data Center, Battelle Laboratories (Columbus, OH), and to producer data sheets.

The ultrahigh-strength class of constructional steels is quite broad and includes a number of distinctly different families of steels. However, in order to simplify the approach to understanding these alloys, this article divides them into four categories:

- Medium-carbon low-alloy steels
- Medium-alloy air-hardening steels
- High fracture toughness steels
- Maraging steels

Additional information on these steels, specifically, recommended heat treatments, can be found in the Section "Heat Treating" in this Handbook.

## Medium-Carbon Low-Alloy Steels

The medium-carbon low-alloy family of ultrahigh-strength steels includes SAE-AISI 4130, the higher-strength 4140, and the deeper hardening, higher-strength 4340. Several modifications of the basic 4340 steel have been developed. In one modification (300M), silicon content is increased to prevent embrittlement when the steel is tempered at the low temperatures required for very high strength. In AMS 6434, vanadium is added as a grain refiner to increase toughness, and the carbon is slightly reduced to promote weldability. Ladish D-6a contains the grain refiner vanadium; slightly higher carbon, chromium, and molybdenum than 4340; and slightly lower nickel. Other less widely used steels that may be included in this family are 6150 and 8640. Chemical compositions are given in Table 1. Property data on 4340, 300M, and D-6a are given below. Property data on the other SAE-AISI grades listed in Table 1 can be found in the article "Mechanical Properties of Carbon and Alloy Steels" in this Section.

High fracture toughness steels								
AF1410 <sup>(c)</sup>	0.13-0.17	0.10 max	0.10 max	1.80-2.20	9.50-10.50	0.90-1.10	...	<b>13.50-14.50</b>
HP-9-4-30 <sup>(d)</sup>	0.29-0.34	0.10-0.35	0.20 max	0.90-1.10	7.0-8.0	0.90-1.10	0.06-0.12	<b>4.25-4.75</b>

(a) The compositions of the ultrahigh-strength maraging steels described in this article are listed in Table 9.

(b) P and S contents may vary with steelmaking practice. Usually, these steels contain no more than

0.035 P and 0.040 S.

- (c) AF1410 is specified to have 0.008 P and 0.005 S composition. Ranges utilized by some producers are narrower.
- (d) HP-9-4-30 is specified to have 0.10 max P and 0.10 max S. Ranges utilized by some producers are narrower.

No new or distinctly different commercial steels have been added to this class of steels in recent years. Rather, developmental efforts have been primarily aimed at increasing ductility and toughness by improving melting and processing techniques and by using stricter process control and inspection. Steels with fewer and smaller nonmetallic inclusions and mill products with fewer internal and surface imperfections are produced by the use of selected raw materials as the melting charge and the employment of advanced melting techniques such as vacuum carbon deoxidation, vacuum degassing, electroslag remelting (ESR), vacuum arc remelting (VAR), and double vacuum melting (vacuum induction melting followed by vacuum arc remelting, or VIM/VAR). These techniques yield less variation in properties from heat to heat and lot to lot; greater ductility and toughness, especially in the transverse direction; and greater in-service reliability.

### ***4340 Steel***

SAE-AISI 4340 steel is considered the standard by which other ultrahigh-strength steels are compared. It combines deep hardenability with high ductility, toughness, and strength. It has high fatigue and creep resistance. It is often used where severe service conditions exist and where high strength in heavy sections is required. In thin sections, this steel is air hardening; in practice, it is usually oil quenched. It is especially immune to temper embrittlement. It does not soften readily at elevated temperatures; that is, it exhibits good retention of strength. Hydrogen embrittlement is a problem for 4340 heat treated to tensile strengths greater than about 1400 MPa (200 ksi). Parts exposed to hydrogen, such as during pickling and plating, should be baked subsequently. This steel exhibits extremely poor resistance to stress-corrosion cracking when tempered to tensile strengths of 1500 to 1950 MPa (220 to 280 ksi). It can be readily nitrided, which often improves fatigue life.

**Processing.** The 4340 steel is usually forged at 1065 to 1230 °C (1950 to 2250 °F); after forging, parts may be air cooled in a dry place or, preferably, furnace cooled. The machinability rating of 4340 is 55% for cold-drawn material, and 45% for annealed material (cold-rolled B1112, 100%). A partly spheroidized structure obtained by normalizing and then tempering at 650 °C (1200 °F) is best for optimum machinability. The 4340 steel has good welding characteristics. It can be readily gas or arc welded, but welding rods of the same composition should be used. Because 4340 is air hardening, welded parts should be either annealed or normalized and tempered shortly after welding.

**Product Forms and Applications.** The steel 4340 is widely and readily available as billet, bar, rod, forgings, sheet, tubing, and welding wire. It is also produced as light plate and castings. Typical applications include bolts, screws, and other fasteners; gears, pinions, shafts, and similar machinery components; crankshafts and piston rods for engines; and landing gear and other critical structural members for aircraft.

**Properties.** Through-hardening of 4340 steel can be done by oil quenching, for round sections up to 75 mm (3 in.) in diameter, and by water quenching, for larger sections (up to the limit of hardenability). Typical mechanical properties of oil-quenched 4340 are given in Table 2.

**Table 2 Typical mechanical properties of 4340 steel**

### 300M Steel

Alloy 300M is basically a silicon-modified (1.6% Si) 4340 steel, but it has slightly higher carbon and molybdenum contents and also contains vanadium. This steel exhibits deep hardenability and has ductility and toughness at tensile strengths of 1860 to 2070 MPa (270 to 300 ksi). Many of the properties of this steel are similar to those of 4340 steel, except that the increased silicon content provides deeper hardenability, increased solid-solution strengthening, and better resistance to softening at elevated temperatures. Compared to 4340 of similar strength, 300M can be tempered at a higher temperature, which provides greater relief of quenching stresses. The so-called 260 °C (500 °F) embrittlement is displaced to higher temperatures. Because of the high silicon and molybdenum contents, 300M is particularly prone to decarburization. During thermal processing, care should be exercised to avoid decarburization, or the decarburized layer should be removed after processing. When heat treated to strength levels higher than 1380 MPa (200 ksi) 300M is susceptible to hydrogen embrittlement. If the steel is properly baked after plating, the resulting improvement in properties is better than that for 4340 or D-6ac steel of equal strength.

**Processing.** The steel 300M is forged at 1065 to 1095 °C (1950 to 2000 °F). Forging should not be continued below 925 °C (1700 °F). After forging, it is preferred that parts be slowly cooled in a furnace, but they may be allowed to cool in air in a dry place. Although 300M can be readily gas or arc welded, welding is generally not recommended; welding rod of the same composition should be used. Because 300M is an air-hardening steel, parts should be either annealed or normalized and tempered after welding. The machinability rating of annealed 300M is about 45% (B1112, 100%). A partially spheroidized structure, obtained by normalizing and then tempering at 650 to 675 °C (1200 to 1250 °F), gives optimum machinability.

**Product Forms and Applications.** Typical applications of 300M, which is available as bar, sheet, plate, wire, tubing, forgings, and castings, are aircraft landing gear, airframe parts, fasteners, and pressure vessels.

**Properties.** Variations in hardness and mechanical properties of 300M with tempering temperature are presented in Table 3.

**Table 3 Typical mechanical properties of 300M steel**

Tempering temperature		Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Reduction in area, %	Charpy V-notch impact energy		Hardness, HRC

### ***D-6a and D-6ac Steel***

Ladish D-6a is a low-alloy ultrahigh-strength steel developed for aircraft and missile structural applications. It is designed primarily for use at room-temperature tensile strengths of 1800 to 2000 MPa (260 to 290 ksi). The steel D-6a maintains a very high ratio of yield strength to tensile strength up to a tensile strength of 1930 MPa (280 ksi), combined with good ductility. It, has good notch toughness, which results in high resistance to impact loading. It is deeper hardening than 4340 and does not exhibit temper embrittlement. It retains high strength at elevated temperature. Susceptibility of D-6a to stress-corrosion cracking and corrosion fatigue in moist and aqueous environments is comparable to that of 300M steel at the same strength level. The alloy is called D-6a when produced by air melting in an electric furnace and D-6ac when produced by air melting followed by vacuum arc remelting. The mechanical properties of D-6a and D-6ac differ somewhat as a result of the differences in melting practices. Other characteristics of the two steels, including processing behavior, are identical.

**Processing.** To forge D-6a, it should be heated to a maximum temperature of 1230 °C (2250 °F); forging should be finished above 980 °C (1800 °F). Finished forgings should be cooled slowly, either in a furnace or embedded in a suitable insulating medium such as ashes or lime. For maximum machinability, the parts should be charged into a 650 °C (1200 °F) furnace immediately after forging and held for 12 h; temperature should be increased to 900 °C (1650 °F) and held for a time period that depends on section size; parts should be cooled to 650 °C (1200 °F), held 10 h, and finally air cooled to room temperature.

The material D-6a, even in heavy sections, can be welded provided that the techniques and controls normally employed for welding medium-carbon, high hardenability alloy steels are used. Welding rod of the same composition should be used.

Annealed D-6a has a machinability rating of 50 to 55% (B1112, 100%). When the steel is to be severely cold formed, it is usually normalized and then spheroidized before working.

**Product Forms and Applications.** D-6a and D-6ac are available as bar, rod, billet, and forgings and can be made as flat-rolled products (sheet and plate) as well. These forms are used in landing gear and critical structural components for aircraft, motor cases for solid-fuel rockets, shafts, gears, springs, dies, dummy blocks, and backer blocks.

**Properties.** Typical mechanical properties of heat treated D-6a bar are given in Table 4.

**Table 4 Typical mechanical properties of D-6a steel bar**

## Medium-Alloy Air-Hardening Steels

The ultrahigh-strength steels H11 modified (H11 mod) and H13, which are popularly known as 5% Cr hot-work die steels, are discussed in this section. Besides being extensively used in dies, these steels are widely used for structural applications, but not as widely as they once were, primarily because of the development of several other steels at essentially the same cost but with substantially greater fracture toughness at equivalent strength. Nonetheless, H11 mod and H13 possess some attractive features. Both can be hardened through in large sections by air cooling. The chemical compositions of these steels are given in Table 1.

### *H11 Modified*

This steel is a modification of the martensitic hot-work die steel AISI H11, the significant difference being a slightly higher carbon content. The H11 mod steel can be heat treated to strengths exceeding 2070 MPa (300 ksi). It is air hardened, which results in minimal residual stress after hardening. Because H11 mod is a secondary hardening steel, it develops optimum properties when tempered at temperatures above 510 °C (950 °F). The high tempering temperatures used for this steel provide substantial stress relief and stabilization of properties so that the material can be used to advantage at elevated temperatures.

**Processing.** The material H11 mod is readily forged from 1120 to 1150 °C (2050 to 2100 °F). Preferably, stock should be preheated at 790 to 815 °C (1450 to 1500 °F) and then heated uniformly to the forging temperature. Forging should not be continued below 925 °C (1700 °F). Stock may be reheated as often as necessary. Because H11 mod is air hardening, it must be cooled slowly after forging to prevent stress cracks. After forging, the part should be charged into a furnace at about 790 °C (1450 °F); soaked until the temperature is uniform; and then slowly cooled, either while retained in the furnace or buried in an insulating medium such as lime, mica, or a siliceous filler material such as silocel. When the forging has cooled, it should be annealed.

The steel H11 mod, even in heavy sections, is readily welded. Fusion welding generally is accomplished with an inert-gas process or with coated electrodes. Filler metal should be of the same general composition. The machinability rating for H11 mod is about 60% of the rating for 1% C steel, or about 45% of that for B 1112.

**Product Forms and Applications.** The H11 mod steel is available as bar, billet, rod, wire, plate, sheet, strip, forgings, and extrusions. It is used for parts requiring high strength combined with either strength retention at elevated temperatures or moderate corrosion resistance. Typical applications include aircraft landing gear components, airframe components, internal parts for steam and gas turbines, fasteners, springs, and hot-work dies.

**Properties.** Typical longitudinal mechanical properties of H11 Mod after heat treatment are presented in Table 5.

**Table 5 Typical longitudinal mechanical properties of H11 mod steel**

### H13 Steel

AISI H13 is a 5% Cr ultrahigh-strength steel similar to H11 mod in composition, heat treatment, and many properties. The main difference in composition is the higher vanadium content of H13 (see Table 1); this leads to a greater dispersion of hard vanadium carbides, which results in higher wear resistance.

Like H11 mod, H13 is a secondary-hardening steel. It has good temper resistance and maintains high hardness and strength at elevated temperatures. It is deep hardening, which allows large sections to be hardened by air cooling. H13 steel can be heat treated to strengths exceeding 2070 MPa (300 ksi); like H11 mod, it has good ductility and impact strength. Processing procedures for H13 are almost identical to those outlined above for H11 mod.

### High Fracture Toughness Steels

High-strength, high fracture toughness steels as described in this article are commercial structural steels capable of a yield strength of 1380 MPa (200 ksi) and a  $K_{Ic}$  of 100 MPa√m (91 ksi√in.). These steels also exhibit stress corrosion cracking resistance.

Three steels are considered here; HP-9-4-30, AF1410, and AerMet100. These alloys are of the Ni-Co-Fe type. They have a number of similar characteristics. They are all weldable. They all require a minimum of vacuum arc melting and control of residual elements to low levels to obtain maximum toughness.

#### HP-9-4-30 Steel

During the 1960s, Republic Steel Corporation introduced a family of four weldable steels, all of which had high fracture toughness when heat treated to medium/high strength levels. Only HP-9-4-30 has been produced in significant quantities and is comparable to the high-strength, high fracture toughness steels of this article. The chemical composition is given in Table 1. The HP-9-4-30 steel is usually electric arc melted and then vacuum arc remelted. Forging temperatures should not exceed 1120 °C (2050 °F). The HP-9-4-30 steel is capable of developing a tensile strength of 1520 to 1650 MPa (220 to 240 ksi) with a plain-strain fracture toughness of 100 MPa $\sqrt{m}$  (91 ksi $\sqrt{in.}$ ). This steel has deep hardenability and can be fully hardened to martensite in sections up to 150 mm (6 in.) thick. The HP-9-4-30 steel in the heat-treated condition can be formed by bending, rolling, or shear spinning. Heat-treated parts can readily be welded. Tungsten arc welding under inert-gas shielding is the preferred welding process. Neither postheating nor postweld heat treating is required. After welding, parts may be stress relieved at about 540 °C (1000 °F) for 24 h. This is a stress-relieving treatment and has no adverse effect on the strength or toughness of either the weld metal or the base metal. The HP-9-4-30 steel is available as billet, bar, rod, plate, sheet, and strip. It has been used for aircraft structural components, pressure vessels, rotor shafts for metal forming equipment, drop hammer rods, and high-strength shock-absorbing automotive parts.

**Properties.** Table 6 presents room-temperature mechanical properties of HP-9-4-30 double tempered at three different temperatures.

**Table 6 Room-temperature mechanical properties of HP-9-4-30 steel**

Property	Typical value for hardness of		
	49-53 HRC <sup>(a)</sup>	44-48 HRC <sup>(b)</sup>	Minimum value <sup>(c)</sup>
Tensile strength, MPa (ksi)	1650-1790 (240-260)	1520-1650 (220-240)	<b>1520 (220)</b>
Yield strength, MPa (ksi)	1380-1450 (200-210)	1310-1380 (190-200)	<b>1310 (190)</b>
Elongation in 4D gage length, %	8-12	12-16	<b>10</b>
Reduction in area, %	25-35	35-50	<b>35</b>
Charpy V-notch impact energy, J (ft · lbf)	20-27 (15-20)	24-34 (18-25)	<b>24 (18)</b>

(a) Oil quenched from 845 °C (1550 °F), refrigerated to -73 °C (-100 °F) and double tempered at 205 °C (400 °F).

(b) Same heat treatment as (a) except double tempered at 550 °C (1025 °F).

(c) For sections forged to 75 mm (3 in.) or less in thickness (or to less than 0.016 m<sup>2</sup>, or 25 in.<sup>2</sup>, in total cross-sectional area), quenched to martensite and double tempered at 540 °C (1000 °F)

## AF1410 Steel

The steel AF1410 was an outgrowth of the U.S. Air Force sponsorship of the advanced submarine hull steels, the result of which was the development of the low-carbon Fe-Ni-Co type alloys. These alloys had significant stress corrosion cracking resistance. By raising the cobalt and carbon content, the ultimate tensile strength was increased to a typical 1615

MPa (235 ksi). This increase in strength was obtained while maintaining a  $K_{Ic}$  value of 154 MPa  $\sqrt{m}$  (140 ksi  $\sqrt{in.}$ ). This combination of strength and toughness exceeds that of other commercially available steels, and the alloy has been considered as a replacement for titanium in certain aircraft parts. The AF1410 material (see Table 1 for composition) is air hardenable in sections up to 75 mm (3 in.) thick. The preferred melting practice is presently vacuum induction melting followed by vacuum arc remelting (VIM/VAR). However, initially VIM and VIM/ESR practices were used. Melting practice requires that impurity elements be kept at very low levels, to ensure high fracture toughness. Although forgeable to 1120 °C (2050 °F), at least a 40% reduction must be obtained below 900 °C (1650 °F) to attain maximum properties. Weldability is good using a continuous wave (CW)-gas tungsten arc welding (GTAW) process, provided that high-purity wire is used and oxygen contamination is avoided. Obtainable as bar, billet, rod, plate, sheet, and strip; AF1410 has been used for aircraft structural components.

**Properties.** The effects of various quenching media on the tensile properties, impact strength, and fracture toughness of AF1410 are shown in Table 7.

**Table 7 Mechanical properties of a AF1410 steel quenched in various media**

Quench medium	Ultimate strength		Yield strength		Elongation, %	Reduction in area, %	Charpy V-notch		Plane-strain fracture toughness ( $K_{Ic}$ )	
	MPa	ksi	MPa	ksi			J	ft · lbf	MPa $\sqrt{m}$	ksi $\sqrt{in.}$
Air	1680	244	1475	214	16	69	69	51	174	<b>158</b>

Test specimens were 50 mm (2 in.) plate from VIM/VAR melt with the heat treatment: 675 °C (1250 °F) for 8 h with air cooling, 900 °C (1650 °F) for 1 h, quenching, 830 °C (1525 °F) for 1 h, quenching, refrigeration at -73 °C (-100 °F) for 1 h, 510 °C (950 °F) for 5

### ***AerMet 100 Steel***

AerMet 100 steel is the most recently developed (patented in 1991) high-strength nickel-cobalt steel developed for the aircraft and aerospace industries. It is supplied only in the VIM/VAR melted condition. Table 1 lists the composition of AerMet 100, which can be heat treated to 1930 to 2070 MPa (280 to 300 ksi) tensile strength, while exhibiting fracture toughness exceeding 110 MPa  $\sqrt{m}$  at 1930 MPa (100 ksi  $\sqrt{in.}$  at 280 ksi). In addition, it offers exceptional resistance to stress-corrosion cracking and fatigue compared with other steels. Like other medium-carbon ultrahigh-strength steels, AerMet 100 is subject to decarburization, and heat treatment should be conducted in a neutral atmosphere furnace, salt bath, or in vacuum. AerMet 100 is available as solid bar, hollow bar, wire, strip, billet, sheet, and plate. These product forms can be used in landing-gear components, arresting hooks, catapult hooks, fasteners, structural members, armor, actuators, ordnance, ballistic-tolerant components, jet engine shafts, drive shafts, helicopter masts, and containment rings.

**Properties.** Typical mechanical properties of AerMet 100 are listed in Table 8.

**Table 8 Typical mechanical properties of AerMet 100 steel**

Yield strength		Ultimate tensile strength		Elongation, %	Reduction of area, %	Charpy V-notch impact energy		Fracture toughness ( $K_{Ic}$ )	
MPa	ksi	MPa	ksi			J	ft · lbf	MPa $\sqrt{m}$	ksi $\sqrt{in.}$
Longitudinal orientation									
1724	250	1965	285	14	65	41	30	126	115
Transverse orientation									
1724	250	1965	285	13	55	34	25	110	100

Solution heat treated at 885 °C (1625 °F) for 1 h, air cooled, refrigerated at -73 °C (-100 °F) for 1 h, and aged at 480 °C (900 °F) for 5

## Maraging Steels

Maraging steels comprise a special class of ultrahigh-strength steels that differ from conventional steels in that they are hardened by a metallurgical reaction that does not involve carbon. Instead, these steels are strengthened by the precipitation of intermetallic compounds at temperatures of about 480 °C (900 °F). The term maraging is derived from martensite age hardening and denotes the age hardening of a low-carbon, iron-nickel lath martensite matrix.

Commercial maraging steels are designed to provide specific levels of yield strength from 1030 to 2420 MPa (150 to 350 ksi). Some experimental maraging steel have yield strengths as high as 3450 MPa (500 ksi). These steels typically have very high nickel, cobalt, and molybdenum contents and very low carbon contents. Carbon, in fact, is an impurity in these steels and is kept as low as commercially feasible in order to minimize the formation of titanium carbide (TiC), which can adversely affect strength, ductility, and toughness.

## Physical Metallurgy

Maraging steels can be considered highly alloyed low-carbon, iron-nickel lath martensites. The phase transformations in these steels can be explained with the help of the two phase diagrams shown in Fig. 1, which depict the iron-rich end of the Fe-Ni binary system. Figure 1(a) is the metastable diagram plotting the austenite-to-martensite transformation upon cooling and the martensite-to-austenite reversion upon heating. Figure 1(b) is the equilibrium diagram showing that at higher nickel contents the equilibrium phases at low temperatures are austenite and ferrite.

Fig. 1 Phase relationships in the iron-nickel system. (a) Metastable. (b) Equilibrium

The age hardening of maraging steels is produced by heat treating for 3 to 9 h at temperatures of the order of 455 to 510 °C (850 to 950 °F). The metallurgical reactions that take place during such treatment can be explained by using the equilibrium diagram (Fig. 1b).

### Commercial Alloys

Table 9 lists the chemical compositions of the more common grades of maraging steel. The nomenclature that has become established for these steels is nominal yield strength (ksi units) in parentheses. Thus, for example, 18Ni(200) steel is normally age hardened to a yield strength of 1380 MPa (200 ksi). The first three steels in Table 9--18Ni(200), 18Ni(250), and 18Ni(300)--are the most widely used and most commonly available grades. The 18Ni(350) grade is an ultrahigh-strength variety made in limited quantities for special applications. Two 18Ni(350) compositions have been produced (see the footnote in Table 9). The 18Ni(Cast) grade was developed specifically as a cast composition.

Table 9 Nominal compositions of commercial maraging steels

Grade	Composition <sup>(a)</sup> , %					
	Ni	Mo	Co	Ti	Al	Nb
Standard grades						
18Ni(200)	18	3.3	8.5	0.2	0.1	...
18Ni(250)	18	5.0	8.5	0.4	0.1	...
18Ni(300)	18	5.0	9.0	0.7	0.1	...
18Ni(350)	18	4.2 <sup>(b)</sup>	12.5	1.6	0.1	...
18Ni(Cast)	17	4.6	10.0	0.3	0.1	...

12-5-3(180) <sup>(c)</sup>	12	3	...	0.2	0.3	...
Cobalt-free and low-cobalt bearing grades						
Cobalt-free 18Ni(200)	18.5	3.0	...	0.7	0.1	...
Cobalt-free 18Ni(250)	18.5	3.0	...	1.4	0.1	...
Low-cobalt 18Ni(250)	18.5	2.6	2.0	1.2	0.1	<b>0.1</b>
<b>Cobalt-free 18Ni(300)</b>	<b>18.5</b>	<b>4.0</b>	<b>...</b>	<b>1.85</b>	<b>0.1</b>	<b>...</b>

(a) All grades contain no more than 0.03% C.

(b) Some producers use a combination of 4.8% Mo and 1.4% Ti, nominal.

(c) Contains 5% Cr

A number of cobalt-free maraging steels and a low-cobalt bearing maraging steel have recently been developed. The driving force for the development of these particular alloys was the cobalt shortage and resultant price escalation of cobalt during the late 1970s and early 1980s. The nominal compositions for these alloys are also listed in Table 9.

## ***Processing***

**Melting.** Most grades of maraging steel are either air melted, then vacuum arc remelted, or vacuum induction melted, then vacuum arc remelted. Premium grades of maraging steels used in critical aircraft and aerospace applications, for which minimum residual element (carbon, manganese, sulfur, and phosphorus) and gas (O<sub>2</sub>, N<sub>2</sub>, and H<sub>2</sub>) contents are required, are triple melted using the air, vacuum induction, and vacuum arc remelting processes.

**Hot Working.** Maraging steels can be hot worked by conventional steel mill techniques, even though allowances must be made for several unique characteristics. Steels with high titanium contents have greater hot strength than conventional steels and require higher hot-working loads or higher working temperatures. Working above about 1260 °C (2300 °F) should be avoided.

**Cold Working.** Maraging steels can be cold worked by any conventional technique when in the solution-annealed (unaged or as-transformed) condition. They have very low work-hardening rates and can be subjected to very heavy reductions (>50%) with only slight accompanying gains in hardness.

**Machining.** Maraging steels can be machined by any conventional technique when in the solution-annealed or age-hardened condition. Machinability is generally as good as or better than that of conventional steels of the same hardness.

**Welding.** All conventional welding processes have been used for joining maraging steels. Most fabrication has, however, employed inert-gas welding processes. Filler metals of matching composition should be employed.

## ***Mechanical Properties***

Typical tensile properties and fracture toughness values of the conventional grades of maraging steel are listed in Table 10. One of the distinguishing features of maraging steels is superior toughness compared to conventional steels. Figure 2

compares  $K_{Ic}$  values for several maraging steels with those of quenched and tempered alloy steels as a function of tensile strength. The toughness of maraging steels is sensitive to purity level, and carbon and sulfur levels in particular should be kept low to obtain optimum fracture toughness.

**Table 10 Heat treatments and typical mechanical properties of standard 18Ni maraging steels**

Grade	Heat treatment <sup>(a)</sup>	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Reduction in area, %	Fracture toughness	
		MPa	ksi	MPa	ksi			MPa $\sqrt{m}$	ksi $\sqrt{in}$

(a) Treatment A: solution treat 1 h at 820 °C (1500 °F), then age 3 h at 480 °C (900 °F); treatment B: solution treat 1 h at 820 °C (1500 °F), then age 12 h at 480 °C (900 °F); treatment C: anneal 1 h at 1150 °C (2100 °F), age 1 h at 595 °C (1100 °F), solution treat 1 h at 820 °C (1500 °F), and age 3 h at 480 °C (900 °F)

**Fig. 2 Plane-strain fracture toughness of maraging steels compared with fracture toughness of several ultrahigh-strength steels as a function of tensile strength**

### Comparative Data for Ultrahigh-Strength Steels

The choice of an ultrahigh-strength steel for a particular application is dependent on many factors. They constitute not only strength and toughness, but also those requirements dictated by environment, such as temperature and corrosion or resistance to stress-corrosion cracking. In addition to these, commercial factors of availability and cost are significant in the final selection of a steel.

To assist the designer in selecting the optimum grade of ultrahigh-strength steels, data have been generated which compare the four classes of steels described in this article. Examples of these comparative data are shown in Fig. 3 and 4. Standard or producer recommended heat treatments were utilized. As these data indicate, the older, more established medium-carbon low-alloy steels and the medium-alloy air-hardening steels have comparable yield strength values when compared with the high fracture toughness steels and maraging steels. However, the toughness, fatigue strength (not shown in Fig. 3 and 4), and resistance to stress-corrosion cracking are much greater for the nickel-cobalt steels and maraging steels. These more highly alloyed steels are, however, much more expensive and their availability is sometimes limited.

# Wear-Resistant Austenitic Manganese Steels

## Introduction

THE ORIGINAL AUSTENITIC MANGANESE STEEL, containing about 1.2% C and 12% Mn, was invented by Sir Robert Hadfield in 1882. Hadfield's steel was unique in that it combined high toughness and ductility with high work-hardening capacity and, usually, good resistance to wear. Consequently, it rapidly gained acceptance as a very useful engineering material.

Hadfield's austenitic manganese steel is still used extensively, with minor modifications in composition and heat treatment, primarily in the fields of earthmoving, mining, quarrying, oil well drilling, steelmaking, railroading, dredging, lumbering, cement manufacture, and clay production. Austenitic manganese steel is used in equipment for handling and processing earthen materials (such as rock crushers, grinding mills, dredge buckets, power shovel buckets and teeth, and pumps for handling gravel and rocks). Other applications include fragmentizer hammers and grates for automobile recycling and tank track pads for military applications. Another important use is in railway trackwork at frogs, switches, and crossings, where wheel impacts at intersections are especially severe. Because austenitic manganese steel resists metal-to-metal wear, it is used in sprockets, pinions, gears, wheels, conveyor chains, wear plates, and shoes.

Austenitic manganese steel has certain properties that tend to restrict its use. It is difficult to machine and usually has a yield strength of only 345 to 415 MPa (50 to 60 ksi). Consequently, it is not well suited for parts that require close-tolerance machining or that must resist plastic deformation when highly stressed in service. However, hammering, pressing, cold rolling, or explosion shocking of the surface raises the yield strength to provide a hard surface on a tough core structure.

## Composition

Many variations of the original austenitic manganese steel have been proposed, often in unexploited patents, but only a few have been adopted as significant improvements. These usually involve variations of carbon and manganese, with or without additional alloys such as chromium, nickel, molybdenum, vanadium, titanium, and bismuth. The most common of these compositions, as listed in ASTM A 128, are given in Table 1.

Table 1 Standard composition ranges for austenitic manganese steel castings

ASTM A 128 grade	Composition, %						
	C	Mn	Cr	Mo	Ni	Si (max)	P (max)
A	1.05-1.35	11.0 min	...	...	...	1.00	0.007
B-1	0.9-1.05	11.5-14.0	...	...	...	1.00	0.07

B-3	1.12-1.28	11.5-14.0	...	...	...	1.00	<b>0.07</b>
B-4	1.2-1.35	11.5-14.0	...	...	...	1.00	<b>0.07</b>
C	1.05-1.35	11.5-14.0	1.5-2.5	...	...	1.00	<b>0.07</b>
D	0.07-1.3	11.5-14.0	...	...	3.0-4.0	1.00	<b>0.07</b>
E-1	0.7-1.3	11.5-14.0	...	0.9-1.2	...	1.00	<b>0.07</b>
E-2	1.05-1.45	11.5-14.0	...	1.8-2.1	...	1.00	<b>0.07</b>
<b>F</b>	<b>1.05-1.35</b>	<b>6.0-8.0</b>	...	<b>0.9-1.2</b>	...	<b>1.00</b>	<b>0.07</b>

The available assortment of wrought grades is smaller and usually approximates ASTM composition B-3. Some wrought grades contain about 0.8% C and either 3% Ni or 1% Mo. Large heat orders are usually required for the production of wrought grades, while small lots more easily yield cast grades and their modifications. A manganese steel foundry may have several dozen modified grades on its production list. Modified grades are usually produced to meet the requirements of application, section size, casting size, cost, and weldability considerations. Higher manganese content steels (15 to 30% Mn) have also been developed for low magnetic permeability and cryogenic applications.

## As-Cast Properties

Although austenitic manganese steels in the as-cast condition are generally considered too brittle for normal use, Table 2 demonstrates that there are exceptions to this rule. Mechanical properties are listed for five grades of as-cast austenitic manganese steels of various thicknesses. These data indicate that lowering carbon content to less than 1.1% and/or adding about 1.0% Mo or about 3.5% Ni results in commercially acceptable as-cast ductilities in light and moderate section thicknesses. These data also apply to weld deposits that are normally left in the as-deposited condition and therefore are essentially equivalent to material in the as-cast condition.

**Table 2 Composition and mechanical properties of typical as-cast austenitic manganese steels**

For grade E-2 manganese steel (see Table 1), a modified heat treatment is often specified or recommended. This treatment consists of heating castings to about 595 °C (1100 °F) and soaking them 8 to 12 h at temperature, which causes substantial amounts of pearlite to form in the structure. The castings are then further heated to about 980 °C (1800 °F) to reaustenitize the structure. This step converts the pearlitic areas to fine-grain austenite containing a dispersion of small carbide particles, which remain undissolved as long as the austenitizing temperature does not exceed about 1010 °C (1850 °F). Quenching then results in a dispersion-hardened austenite that is characterized by higher yield strength, higher hardness, and lower ductility than that obtained if the same steel were given a full solution treatment at a higher austenitizing temperature. This dispersion-hardening heat treatment permits a relatively high carbon content, which in turn can improve abrasion resistance.

**Precautions.** Speed of quenching is important, but it is difficult to increase beyond the rate of heat transfer from a hot surface to agitated water or beyond the rate fixed by the thermal conductivity of the metal. As a result, heavy-section castings have lower mechanical properties at the center than do thinner castings. Figure 2 shows the cooling rates that can be expected when metal plates of four different thicknesses are quenched in water. Table 3 lists average properties observed in castings of 1.11C-12.7Mn-0.5Si-0.043P steel water quenched from about 980 °C (1800 °F), which cooled the castings at the rates shown in Fig. 2.

(a) In 25 mm (1 in.)

**Fig. 2** Cooling curves for austenitic manganese steel of various thicknesses. Cooling curves are approximately equivalent to those for plate of the thicknesses indicated.

Residual stresses from quenching, coupled with the lower properties of heavy sections, establish the usual maximum thickness of commercial castings at about 127 to 152 mm (5 to 6 in.), although castings with sections up to 406 mm (16 in.) thick have been produced.

## Mechanical Properties After Heat Treatment

As the section size of manganese steel increases, tensile strength and ductility decrease substantially in specimens cut from heat-treated castings. This occurs because, except under specialty controlled conditions, heavy sections do not solidify in the mold fast enough to prevent coarse grain size, a condition that is not altered by heat treatment. As shown in Table 3, fine-grain specimens may exhibit tensile strength and elongation as much as 30% greater than those of coarse-grain specimens.

Grain size also is the chief reason for the differences between cast and wrought manganese steels (the latter are usually of fine grain size). For cast grade B-2, the standard deviations for tensile strength and elongation are about 69 MPa (10 ksi) and 9%, respectively. The midrange values of 825 MPa (120 ksi) and 40% apply to sound, medium-grain cast specimens that have been properly heat treated. The scatter bands for this grade extend from 620 to 1035 MPa (90 to 150 ksi) for tensile strength and from 13 to 67% for elongation.

Mechanical properties vary with section size. Tensile strength, tensile elongation, reduction in area, and impact strength are substantially lower in 102 mm (4 in.) thick sections than in 25 mm (1 in.) thick sections. Because section thicknesses of production castings are often from 102 to 152 mm (4 to 6 in.), this factor is an important consideration for proper grade specification.

Notched-bar impact test values can be exceptionally high. Charpy test specimens are sometimes bent and dragged through the machine rather than being fractured. Occasionally, observed values are biased because of the incorrect preparation of specimens. Notches should be cut by precision grinding to minimize work hardening at the apex of the notch.

Austenitic manganese steel remains tough at subzero temperatures above the  $M_s$  temperature. The steel is apparently immune to hydrogen embrittlement, although embrittlement has been produced in steels with low carbon content ( $< \sim 0.02\%$ ) and high manganese content. There is a gradual decrease in impact strength with decreasing temperature. The transition temperature is not well defined because there is no sharp inflection in the impact strength-temperature curve down to temperatures as low as  $-85^\circ\text{C}$  ( $-120^\circ\text{F}$ ). At a given temperature and section size, nickel and manganese additions usually are beneficial for enhancing impact strength, while higher carbon and chromium levels are not.

Resistance to crack propagation is high and associated with very sluggish progressive failures. Because of this, any fatigue cracks that develop might be detected, and the affected part or parts removed from service before complete failure occurs, a capability that is a distinct advantage in railway track work. The fatigue limit of austenitic manganese steel has been reported as 270 MPa (39 ksi).

Yield strength and hardness vary only slightly with section size. The hardness of most grades is about 200 HB after solution annealing and quenching, but this value has little significance for estimating machinability or wear resistance.

Hardness increases so rapidly because of work hardening during machining or while in service that austenitic manganese steels must be evaluated on some basis other than hardness.

The true tensile characteristics of manganese steel are better revealed by the stress-strain curves in Fig. 3, which compare manganese steel with gray iron and with a heat-treated high-strength low-alloy steel of about the same nominal tensile strength. The low yield strength is significant and may prevent the selection of this alloy where slight or moderate deformation is undesirable, unless the usefulness of the parts in question can be restored by grinding. However, if deformation is immaterial, the low yield values may be considered temporary, that is, deformation will produce a new, higher yield strength corresponding to the amount of strain that is absorbed locally.

Alloy	Composition, %

## Work Hardening

Manganese steels are unequalled in their ability to work harden, exceeding even the metastable austenitic stainless steels in this feature. For example, a standard grade of manganese steel containing 1.0 to 1.4% C and 10 to 14% Mn can work harden from an initial level of 220 HV to a maximum of more than 900 HV. After extended service, the hardness at the wearing surfaces of railway frogs typically ranges from 495 to 535 HB. Maximum attainable hardness depends on many factors, including specified composition, service limitations, method of work hardening, and preservice hardening procedures. It appears that rubbing under heavy pressure can produce higher values of maximum attainable hardness than those produced by simple impact.

**Work-Hardening Methods.** Work hardening is usually induced by impact, as from hammer blows. Light blows, even if they are of high velocity, cause shallow deformation with only superficial hardening even though the resulting surface hardness is ordinarily high. Heavy impact produces deeper hardening, usually with lower values of surface hardness. The

course of flow under impact and the associated increase in hardness are shown in Fig. 4, which compares a standard 12% Mn steel with an air-hardening chromium-nickel-molybdenum alloy steel. Less well known is the fact that abrasion itself can produce work hardening.

**Fig. 4** Plastic flow (top) and work hardening (bottom) of a manganese steel and an air-hardening steel under repeat impact. Specimens 25 mm (1 in.) in both diameter and length were struck repeatedly on one end by blows with an impact energy of 680 J (500 ft·lbf). Composition and heat treatment of the manganese steels were 1.17C-12.8Mn-0.46Si, water quenched from 1010 °C (1850 °F). Composition and heat treatment of the air-hardening steel were: 0.74C-0.88Mn-0.30Si-0.75Ni-1.40Cr-0.38Mo; air cooled from 900 °C (1650 °F), reheated to 705 °C (1300 °F), and air cooled

Explosion hardening was developed as a substitute for hammer or press hardening to achieve hardening with less deformation. Pentaerythritol tetranitrate in the form of plastic explosive sheet 2.11 mm (0.083 in.) thick or mixtures of ammonium nitrate and trinitrotoluene (TNT) are cemented to the surface of the steel and detonated. Usually, three explosions are required to attain the desired hardness in railway track work.

## Reheating

Before manganese steel parts are reheated in the field, the effects of such reheating must be seriously considered. Unlike ordinary structural steels, which become softer and more ductile when reheated, manganese steels suffer reduced ductility when reheated enough to induce carbide precipitation or transformation of the austenite. As a general rule, manganese steels should never be heated above 260 °C (500 °F) either intentionally or accidentally, unless such heating can be followed by standard solution annealing and quenching.

## Wear Resistance

Compared to most other abrasion-resistant ferrous alloys, manganese steels are superior in toughness and moderate in cost, and it is primarily for these reasons that they are selected for a wide variety of abrasive applications. They are usually less resistant to abrasion than are martensitic white irons or martensitic high-carbon steels, but are often more resistant than pearlitic white irons or pearlitic steels.

The type of wear that is sustained has a major influence on the performance of manganese steels. They have excellent resistance to metal-to-metal wear, as in sheave wheels, crane wheels, and car wheels; good resistance to gouging abrasion, as in equipment for handling or crushing rock; intermediate resistance to high-stress (grinding) abrasion, as in ball-mill

and rod-mill liners; and relatively low resistance to low-stress abrasion, as in equipment for handling loose sand or sand slurries.

**Metal-to-Metal Contact.** In applications involving metal-to-metal contact, the work hardening of manganese steel is a distinct advantage because it decreases the coefficient of friction and confers resistance to galling if temperatures are not excessive. Compressive loads, rather than impact loads, provide the deformation required, producing a smooth, hard surface that has good resistance to wear but does not abrade the contacting part. Sheaves, wear plates, and castings for railway track work are common applications of this type. Manganese steel also has been used in some water-lubricated bearings.

**Abrasion.** In applications that involve heavy blows or high compressive and structural stresses, the very hard and abrasion-resistant martensitic cast irons may wear more slowly than manganese steel. However, these irons usually fail by early fracture with a considerable portion of the original cross section unworn, whereas manganese steel may become almost paper thin before fracturing.

Pearlitic white cast iron, which has a hardness of about 400 to 450 HB, is equally brittle but less resistant to wear. Comparative tests on log washer lugs indicated that manganese steel was about 25% worn out with no breakage, whereas in the same period white iron lugs wore to the point of uselessness with 14% breakage. In clay crusher rolls, manganese steel lasted two to three times as long as white or chilled iron. In grinding barrel liners, cast irons lasted two to three years compared to ten years for manganese steel. Part of the superiority of manganese steel over white cast iron is attributed to greater freedom from breakage and spalling, but some is probably due to better intrinsic wear resistance.

Manganese steel chain, with endless links cast in interlocking molds, also provides resistance to wear, lasting three to nine times as long as heat-treated steel chain in certain applications. Manganese steel is valuable in conveyors as well as in dragline chain subjected to abrasion and used for carrying heavy loads.

Manganese steel is not satisfactorily resistant to wear by a stream of airborne abrasive particles (impingement erosion), such as in sandblasting or gritblasting equipment, and consequently should not be selected for such service.

The abrasion resistance of austenitic 12 to 14% Mn steels with various carbon contents has been compared with the resistance of other steels and white irons in a jaw crusher abrasion test (see Fig. 5). The wear rate for a quenched and tempered low-carbon low-alloy steel (ASTM 517, type B, at 269 HB), which was used as a comparative standard in each test, is also shown. When the relative wear rate (wear ratio) of each test material is plotted against increasing carbon content on a log-log scale, results for austenitic steels and irons tend to fall on a descending straight line, and results for martensitic steels and irons fall on a parallel line below the line for the austenitic alloys. A decrease in wear ratio represents a proportionate increase in abrasion resistance. Thus, Fig. 5 strongly supports the conclusion that the abrasion resistance of both austenitic and martensitic steels improves with increasing carbon content, and that, for a given carbon content, martensitic steels have better abrasion resistance than do austenitic steels. However, martensitic steels and white irons have limited resistance to gouging abrasion because of their lack of toughness. The wear ratios of pearlitic steels, if plotted on Fig. 5, would lie above those of the austenitic steels. There is considerable scatter in the rates for pearlitic steels due to their wide variation in hardness for any given carbon content.

Fig. 5 Relative wear ratios of ferrous alloys in jaw crusher tests

## Corrosion

Manganese steel is not corrosion resistant; it rusts readily. Furthermore, where corrosion and abrasion are combined, as they frequently are in mining and manufacturing environments, the metal may deteriorate or be dissolved at a rate only slightly lower than that of carbon steel. If the toughness or nonmagnetic nature of manganese steel is essential for a marine application, protection by galvanizing is usually satisfactory.

# Hardenability of Carbon and Alloy Steels

## Introduction

HARDENABILITY OF STEEL is the property that determines the depth and distribution of hardness induced by quenching. Steels that exhibit deep hardness penetration are considered to have high hardenability, while those that exhibit shallow hardness penetration are of low hardenability. Because the primary objective in quenching is to obtain satisfactory hardening to some desired depth, it follows that hardenability is usually the most important single factor in the selection of steel for heat treated parts.

Hardenability should not be confused with hardness as such or with maximum hardness. The maximum attainable hardness of any steel depends solely on carbon content. Also, the maximum hardness values that can be obtained with small test specimens under the fastest cooling rates of water quenching are nearly always higher than those developed under production heat treating conditions, because hardenability limitations in quenching larger sizes may result in less than 100% martensite formation. Effects of carbon and martensite content on hardness are shown in Fig. 1.

**Fig. 1** Effect of carbon on hardness of martensite structures

The hardenability of steel is governed almost entirely by the chemical composition (carbon and alloy content) at the austenitizing temperature and the austenite grain size at the moment of quenching. In some instances, the chemical composition of the austenite may not be the same as that determined by chemical analysis, because some carbide may be undissolved at the austenitizing temperature. Such carbides would be reflected in the chemical analysis, but, being undissolved in the austenite, neither their carbon nor alloy content can contribute to hardenability. Also, by nucleating transformation products, undissolved carbides can actively decrease hardenability. This is especially important in high-carbon (0.50 to 1.10%) and alloy carburizing steels, which may contain excess carbides at the austenitizing temperature. Consequently, such factors as austenitizing temperature, time at temperature, and prior microstructure are sometimes very important variables when determining the basic hardenability of a specific steel composition.

## Hardenability Testing

Hardenability of a steel is best assessed by studying the hardening response of the steel to cooling in a standardized configuration in which a variety of cooling rates can be easily and consistently reproduced from one test to another.

**The end-quench, or Jominy, test** fulfills the cooling rate requirements of hardenability testing most conveniently. The test specimen, a 1 in. (25.4 mm) diam bar 4 in. (102 mm) in length, is water quenched on one end face. The bar from which the specimen is made must be normalized before the test specimen is machined. The test involves heating the test specimen to the proper austenitizing temperature and then transferring it to a quenching fixture designed so that the

specimen is held vertically 12.7 mm ( $\frac{1}{2}$  in.) above an opening through which a column of water may be directed against the bottom face of the specimen. While the bottom end is being quenched by the column of water, the opposite end is cooling slowly in air, and intermediate positions along the specimen are cooling at intermediate rates. After the specimen has been quenched, parallel flats 180° apart are ground 0.015 in. (0.38 mm) deep on the cylindrical surface, Rockwell C

hardness is measured at intervals of  $\frac{1}{16}$  in. (1.59 mm) for alloy steels and  $\frac{1}{32}$  in. (0.79 mm) for carbon steels, starting from the water-quenched end. A plot of these hardness values and their positions on the test bar, as shown in Fig. 2, indicates the relation between hardness and cooling rate, which, in effect, is the hardenability of the steel. Figure 2 also shows the cooling rate for the designated test positions. Details of the standard test method are contained in ASTM A 255 and SAE J406.

**SAC Hardenability Test.** This test is applicable to all plain carbon and low-alloy steels other than carbon tool steels and is suitable only for shallow-hardening steels that will not through harden in sizes larger than 25 mm (1 in.) in diameter. The surface-area-center (SAC) test is sometimes found to be more discriminating than the end-quench test for determining hardenability of shallow-hardening steels because of the sharp gradient on the end-quench curve.

The SAC test surveys hardnesses on an austenitized and quenched cross section. The specimen is 140 mm ( $5\frac{1}{2}$  in.) long by 25.4 mm. (1 in.) in diameter. After normalizing at the specified temperature for 1 h and cooling in air, it is austenitized by holding at temperature for 30 min and quenching in water at  $24 \pm 5.5$  °C ( $75 \pm 10$  °F), where it is allowed to remain until the temperature is uniform throughout the specimen.

After quenching, a cylinder 25.4 mm (1 in.) in length is cut from the middle of the hardened specimen. The cut faces of the cylinder are carefully ground parallel to remove any burning or tempering that might result from cutting and to assure that a flat face will be presented to the anvil or fixture of the hardness-testing machine. Rockwell C hardness is measured on the cylindrical surface of the specimen at a minimum of four points at 90° angles to each other. The average of these reading becomes the surface reading. Next, a series of Rockwell C readings is taken on the cross section in steps of 1.59 mm ( $\frac{1}{16}$  in.) from the surface to center. From these, a quantitative value can be computed and designated by a code known as the SAC number. The code consists of a set of three two-digit numbers, e.g., SAC No. 63-52-42. This indicates a surface hardness of 63 HRC, a Rockwell-inch area of 52, and a center hardness, of 42 HRC. The computation of area is shown in Fig. 4.

Fig. 4 SAC estimation of area

## Effect of Carbon Content

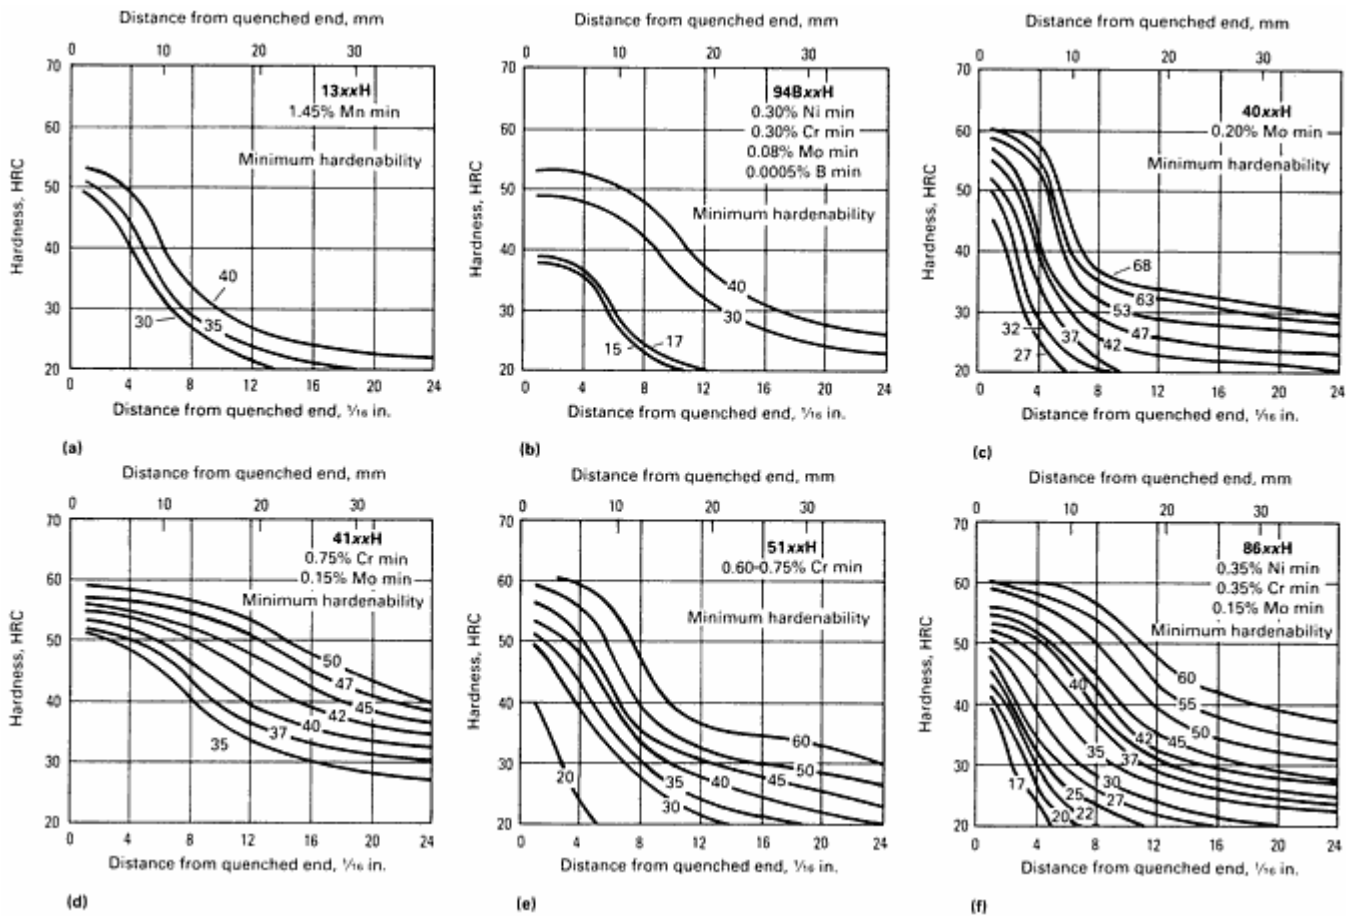

Carbon has a dual effect in hardenable alloy steels. It controls maximum attainable hardness and contributes substantially to hardenability. The latter effect is substantially enhanced by the quantity and type of alloying elements present, because hardenability is the product of the carbon factor and the total of the alloy multiplying factors. It might be concluded, therefore, that increasing carbon content is the least expensive approach to improving hardenability. This is true to a degree, but several factors rule against the use of large amounts of carbon:

- High carbon content generally decreases toughness at room and subzero temperatures.
- It produces harder and more abrasive microstructures in the annealed conditions, which makes cold shearing, sawing, machining, and other forms of cold processing more difficult.
- It makes the steel more susceptible to hot shortness in hot working.
- It makes the steel more prone to cracking and distortion in heat treatment. Because of these disadvantages, more than 0.60% carbon is seldom used in steels for machine parts, except for springs and bearings, and steels with 0.50 to 0.60% carbon are used less frequently than those containing less

than 0.5%.

Figure 5 shows the differences between minimum hardenability curves for six series of steels. In each series, alloy content is essentially constant, and the effect of carbon content on hardenability can be observed over a range from 0.15 to 0.60%. The hardness effect is shown by the vertical distance between the curves at any position on the end-quench specimen--that is, for any cooling rate. This effect varies significantly, depending on the kind and amount of alloying elements. For instance, referring to Fig. 5(d), 5(e), and 5(f), an increase in carbon content from 0.35 to 0.50% in each of the three series of steels causes hardness increases (in Rockwell C points) at four different end-quench positions as follows:

Series	Distance from quenched surface, in.			
	$\frac{1}{16}$	$\frac{4}{16}$	$\frac{8}{16}$	$\frac{12}{16}$
41xxH	8	10	17	<b>20</b>
51xxH	8	13	9	<b>8</b>
<b>86xxH</b>	<b>8</b>	<b>12</b>	<b>18</b>	<b>12</b>

**Fig. 5** Effect of carbon content on the minimum end-quench hardenability of six series of alloy H-steels. The number adjacent to each curve indicates the carbon content of the steel, to be inserted in place of xx in alloy designation.

The hardenability effect of carbon content is read on the horizontal axis. For example, in comparing the effect of carbon content on hardenability in 8650 versus 8630 at 45 HRC, the effect can be expressed as  $\frac{6}{16}$  ( $\frac{10}{16}$  minus  $\frac{4}{16}$ ).

Similarly, at 45 HRC and with nominal carbon contents of 0.35 and 0.50%, the hardenability effect of carbon content is found to be much less in 51xx series steels and much greater in 41xx steels.

Considering the hardenability effect in terms of quenching speed, the cooling rate (or quenching speed) required to produce 45 HRC is affected more by 0.15% carbon with certain combinations of alloying elements than it is by other combinations. For instance, in a steel containing 0.75 Cr and 0.15 Mo (a 41xxH series steel, for example), increasing the carbon content by 0.15% lowers the required or critical cooling rate to obtain 45 HRC from 25 to 4.6 °C (45 to 8.3 °F) per second, while in a steel containing 0.75% Cr and no molybdenum (51xxH series), the same increase in carbon content lowers the cooling rate from 47 to 26 °C (85 to 37 °F) per second.

The practical significance of the effect of carbon and alloy contents on cooling rate is considerable. In a 51 mm (2 in.) diameter bar of 4150 steel, a hardness of 45 HRC can be obtained at half-radius using an oil quench without agitation. In a 4135 steel bar of the same diameter, to obtain the same hardness at half-radius would require a strongly agitated water quench. Comparing 32 mm ( $1\frac{1}{4}$  in.) diameter bars of 5135 and 5150 steel, an agitated water quench will produce a hardness of 45 HRC at half-radius in the 5135 bar; the identical condition can be obtained in the 5150 bar using an oil quench with moderate agitation. To summarize, an increase or decrease in carbon content or an alloying addition, such as 0.15% molybdenum, affects the results obtained both in terms of the quenching severity required and the section size in which the desired results can be obtained.

The above method of rating differs from rating in terms of ideal critical diameter, which is based on hardening not to a given hardness but to 50% martensite at the center of a section, the hardness of which varies according to carbon content. Therefore, a part that must be hardened to a minimum hardness regardless of carbon content requires a steel rated in terms of that hardness and not in terms of 50% martensite, which varies in hardness. Figure 6 shows how steels are rated on the basis of ideal critical diameter by expressing the effect of carbon and alloy content on the section size that will harden to 50% martensite at the center, assuming an ideal quench. An ideal quench is defined as one that removes heat from the surface of the steel as fast as it is delivered to the surface.

**Fig. 6** Effect of carbon content on ideal critical diameter, calculated for the minimum chemical composition of each grade

## Alloying Elements

The most important function of the alloying elements in heat treatable steel is to increase hardenability, which makes possible the hardening of larger sections and the use of an oil rather than a water quench to minimize distortion and avoid quench cracking.

When the standard alloy steels are considered, it is found that, for practical purposes, all compositions develop the same tensile properties when quenched to martensite and tempered to the same hardness below 50 HRC. However, it should not be inferred that all tempered martensites of the same hardness are alike in all respects. For instance, plain carbon martensites have lower reduction-in-area values than do alloy martensites. A further difference, sometimes important, is that fully quenched alloy steels require, for the same hardness levels, higher tempering temperatures than do carbon steels. This difference in tempering temperature may serve to reduce the residual stress level in finished parts. The stress reduction could be an advantage or a disadvantage, depending on whether a controlled compressive stress is desired in the part. Although tensile properties may not differ significantly from one alloy steel to another, considerable differences may exist in fracture toughness and low-temperature impact properties. In general, steels with a higher nickel content, such as 4320, 3310, and 4340, offer much greater toughness at a given hardness or hardenability level. In some applications, the toughness factor rather than hardenability may dictate steel selection, but hardenability is still important because steels that can be fully quenched to 100% martensite are much tougher than those that cannot.

Usually, the least expensive means of increasing hardenability at a given carbon content is by increasing the manganese content. Chromium and molybdenum, already referred to as increasing hardenability, are also among the most economical elements per unit of increased hardenability. Nickel is the most expensive per unit, but is warranted when toughness is a prime consideration.

Another potent and economical alloying element is boron, which markedly increased hardenability when added to a fully deoxidized steel. The effects of boron on hardenability are unique in several respects: (a) a very small amount of boron (about 0.001%) has a powerful effect on hardenability; (b) the effect of boron on hardenability is much less in high-carbon than in low-carbon steels; (c) nitrogen and deoxidizers influence the effectiveness of boron; (d) high-temperature treatment reduces the hardenability effect of boron. (Recommended austenitizing temperatures for boron H-steels are given with the H-bands.)

## Effect of Grain Size

The hardenability of a carbon steel may increase as much as 50% with an increase in austenite grain size from ASTM 8 (6 to 10) to ASTM 3 (1 to 4). The effect becomes more pronounced if the carbon content is increased at the same time. When the danger of quench cracking is remote (no abrupt changes in section thickness) and engineering considerations permit, it can sometimes appear to be more practical to use coarser-grained steel than a fine-grained or more expensive alloy steel to obtain hardenability. However, this is not recommended, because the use of coarser-grained steels usually involves a serious sacrifice in notch toughness and may lead to other difficulties.

## Variations Within Heats

Segregation of carbon, manganese, and other elements always occurs during ingot pouring and solidification. As a result, hardenability of the steel in these segregated portions will differ from that in the remainder of the ingot. In general, specimens taken from the top of the ingot have higher hardenability than steel from the middle, and specimens from the bottom of the ingot will have lower hardenability than steel from the middle.

The same effect is observed in alloy steels. End-quench hardenability test results for one heat of 4028 steel (Fig. 7) show higher hardenability for a cast bar taken from the top of the last ingot of the heat than for a specimen from the melting floor labeled "cast end-quench specimen." The latter was taken from about the middle of the heat.

Fig. 7 Variation of hardenability within a heat of 4028 steel

---

## Determining Hardenability Requirements

The basic information needed before a steel with adequate hardenability can be specified includes: (a) the as-quenched hardness required prior to tempering to final hardness that will produce the best stress-resisting microstructure; (b) the depth below the surface to which this hardness must extend; and (c) the quenching medium that should be used in hardening.

**As-Quenched Hardness.** A common and economical practice is to select the steel with the lowest carbon content that will produce the indicated as-quenched hardness using the quenching medium available (or one that can be made available). Following this procedure, the structures possessing the indicated hardnesses would be fully hardened. That is, they would contain more than 90% martensite, which is a common and practical definition of full hardening.

**Depth of Hardening.** The depth and percentage martensite to which parts are hardened can affect their serviceability, but it always affects the hardenability required and, therefore, the cost. In parts less highly stressed in bending, hardening to 80% martensite at three-quarter-radius of the part as finished may be sufficient; in other parts, even less depth may be required. The latter include principally those parts designed for low deflection under load, in which even the exterior regions are only moderately stressed. In contrast, some parts loaded principally in tension and others operating at high hardness levels, such as springs of all types, are usually hardened more nearly through the section. In automobile leaf springs, the leaves are designed with a low section modulus in the direction of loading. The allowable deflection is large, and most of the cross section is highly stressed.

In general, hardening need be no deeper than is required to provide the strength to sustain the load at any given depth below the surface. When these requirements are not wholly justified, the results are overspecification of steel at higher cost, and greater likelihood of distortion and quench cracking.

**Quenching Media.** The cooling potential of quenching media is a critical factor in heat treating processes because of its contribution to attaining the minimum hardenability requirement of the part or section being heat treated. The cooling potential, a measure of quenching severity, can be varied over a rather wide range by (a) selection of a particular quenching medium, (b) control of agitation, and (c) additives that improve the cooling capability of the quenchant.

In general, the more severe the quenchant and the less symmetrical the part being quenched, the greater are the size and shape changes that result from quenching and the greater is the risk of quench cracking. Consequently, although water quenching is less costly than oil quenching and water-quenching steels are less expensive than those requiring oil quenching, it is important that parts to be hardened be carefully reviewed to determine whether the amount of distortion and the possibility of cracking as a result of water quenching will permit taking advantage of the lower cost of water quenching. Oil, salt, and synthetic water-polymer quenchants are alternatives, but their use often requires steels of higher alloy content to satisfy hardenability requirements.

A rule regarding selection of a steel and quenching medium for a given part is that the steel should have a minimum hardenability not exceeding that required by the quenching severity of the medium selected. The steel should also contain the lowest carbon content compatible with required hardness and strength properties. This rule is based on the fact that the quench cracking susceptibility of steels increases with a decrease in  $M_s$  temperature, and/or an increase in carbon content.

Table 1 lists typical quenching severities, or "H" values, for the common quenching media and conditions. These data are for media containing no additives. Considerable improvement in the cooling capability can be obtained by such additions as polyalkylene glycol (polymer) to water, proprietary additives to oil, and water to hot salt.

**Table 1 Quenching severities, H, for various media and quenching conditions**

Quenchant agitation	Typical flow rates		Typical H values			
	m/min	sfm	Air	Mineral oil	Water	Brine
None	0	0	0.02	0.20-0.30	0.9-1.0	<b>2.0</b>
Mild	15	50	...	0.20-0.35	1.0-1.1	<b>2.1</b>
Moderate	30	100	...	0.35-0.40	1.2-1.3	...
Good	61	200	0.05	0.40-0.60	1.4-2.0	...

**Hardenability versus Size and Shape.** When end-quench data such as those shown in Fig. 2 are available, either of two methods can be used to estimate the hardenability that a steel part of given size and configuration must have in order for it to achieve desired hardness, strength, and microstructure at critical locations when benched in various production media. These methods comprise:

1. The correlation of end-quench hardness ( $J_{eh}$ ) with equivalent hardness locations in variously quenched shapes
2. The correlation of end-quench cooling-rate data ( $J_{ec}$ ) with equivalent cooling-rate locations in

variously quenched production shapes

Method 1, which is described in Fig. 8, is the more accurate and preferred method, because in practice it has been found that, when cooling at the same rates, large sections produce somewhat lower hardnesses than smaller sections.

Jominy equivalent cooling ( $J_{eh}$ ) rates are determined by comparing hardness of cross sections of parts receiving the established production heat treatment to hardnesses obtained on end-quenched bars of the same steel. A typical procedure is:

1. Select hardening and quenching conditions that your production hardening equipment can fulfill easily.
2. Select a low hardenability steel, such as 8620, 4023, or 1040, and manufacture a quantity of finished components: gears, bearings, shafts.
3. Quench a number of these components (in the uncarburized condition) in the production facility.
4. Measure hardnesses obtained at all critical locations from the surface to the core.
5. Compare the measured hardness values at these locations with equivalent hardness values produced at some end quench ( $J_{eh}$ ) location on a Jominy bar made from the same heat and end quenched from the same thermal conditions.
6. The  $J_{eh}$  values obtained in this fashion define the equal hardness cooling conditions for each location in the production quenched component.

Fig. 8 Determination of Jominy equivalent cooling ( $J_{eh}$ ) rates

## Service Characteristics of Carbon and Alloy Steels

### Wear Resistance of Steels

WEAR of metals occurs by the plastic displacement of surface and near-surface material and by the detachment of particles that form wear debris. In metals, this process may occur by contact with other metals, nonmetallic solids, flowing liquids, or solid particles or liquid droplets entrained in flowing gases.

Wear involves damage to a solid surface due to relative motion between that surface and one or more contacting substances and generally consists of a progressive loss of material from the wearing surface. It may include oxidation, corrosion, creep, fatigue, frictional effects, battering from impact, pseudomachining due to rough surfaces, and the cutting and deformation action of abrasive particles. This complex is difficult to handle rigorously; consequently, investigations are usually limited to only certain facets of wear. Mechanical effects are those usually considered, whereby local deformation or metal removal results from stresses applied either directly or indirectly to a surface.

Wear can result in alteration of critical dimensions, increased vibration, fatigue damage, clogging of critical passages and contacts by debris, generation of abrasive particles, leaking fluid from enclosures, inefficient operation, and system failure.

### Classification of Wear

One of the simplest classifications of wear is based on the presence or absence of effective lubricants--namely, lubricated and nonlubricated wear. (The various types of lubrication are described later in this article.) Wear may also be classified by mechanisms. For example, the following wear mode classification was used in *Friction, Lubrication, and Wear Technology*, Volume 18 of *ASM Handbook*:

#### **Wear by particles or fluids**

- Abrasive wear
- Polishing wear
- Solid particle erosion
- Cavitation erosion
- Liquid impingement erosion
- Slurry erosion

#### **Wear by rolling, sliding, or impact**

- Sliding and adhesive wear
- Fretting wear
- Rolling contact wear
- Impact wear

#### **Chemically assisted wear**

- Corrosive wear
- Oxidational wear

Classifications based on wear mechanisms have generally emphasized one or more of the following factors: removal of individual atoms, plastic deformation, ductile or brittle fracture, and cutting, fatigue, adhesion, and chemical-electrochemical effects.

An inherent problem exists in any classification scheme that relies mainly on labels implying mechanisms. Overuse of such labels (that is, use without adequate experimental evidence) could lead to the misconception that knowledge of a particular wear situation is well understood. This, in turn, may discourage innovative efforts in wear control.

A third approach to wear classification emphasizes the nature of the contacting materials and the experimental conditions, using descriptive terms that are widely understood and accepted. The following is an example of this type of classification:

#### **Metal against nonmetallic abrasive**

- High-stress gouging or grinding:
  - Wet, as in ball and rod mills
  - Dry, as in jaw-type or roll-type ore crushers
- Low-stress scratching or sliding:
  - Wet, such as conveyor screws for wet sand
  - Dry, as against plows or earthmoving devices operating in dry soil

<ul style="list-style-type: none"> <li>• Impact of loose abrasive (erosion): <ul style="list-style-type: none"> <li>○ Wet, as against impellers in slurry pumps</li> <li>○ Dry, as in sandblasting</li> </ul> </li> <li>•</li> </ul>
<p><b>Metal against metal</b></p> <ul style="list-style-type: none"> <li>• Sliding: <ul style="list-style-type: none"> <li>○ Lubricated, such as engine crosshead or shaft in a bearing</li> <li>○ Nonlubricated, such as fasteners, nuts, and bolts</li> </ul> </li> <li>• Rolling: <ul style="list-style-type: none"> <li>○ Lubricated, such as roller bearings and gears</li> <li>○ Nonlubricated, such as wheels on tracks</li> </ul> </li> <li>•</li> </ul>
<p><b>Liquid or vapor impingement on metals</b></p> <ul style="list-style-type: none"> <li>• Wet steam, such as turbines</li> <li>• Combustion gases, such as gas turbines</li> <li>• Water, such as pump impellers</li> <li>• Cavitations, as in turbulent, high-velocity flowing liquids</li> </ul>

Frequently, these conditions are combined in service so an application that was originally metal against metal may evolve into metal against nonmetal wear, such as the generation of oxide wear debris and the introduction of nonmetallic particles through imperfect seals. Other combinations include rolling with sliding and lubricated-nonlubricated situations.

## Wear Testing and Evaluation

It is often difficult to compare published wear data obtained by different investigators, either because some of the experimental conditions are not reported or because significantly different wear tests have been used. Wear testing has not yet been adequately standardized. Hundreds of different wear test devices and procedures have been described in the technical literature. Many of these are based on simple configurations, such as pin-on-disk, block-on-ring, ring-on-ring, or cylinder-on-cylinder. Many other devices have been designed to simulate as closely as possible actual operating conditions for actual components. This is frequently a desirable approach, particularly if the designer has difficulty adapting published wear data to his own situation, although it contributes to the proliferation of wear tests.

Despite the great variety of wear tests, the main variables in sliding mechanical wear may be identified by asking three simple questions:

- Is the system lubricated or unlubricated?
- Is most of the wear debris removed?
- Is the wearing surface in steady contact with another surface?

Types of wear tests are discussed in greater detail in the Section "Mechanical, Wear, and Corrosion Testing" in this Handbook.

**Reporting wear data** is not well standardized; however, some of the more common reporting methods are discussed below. The simplest and most widely used way to summarize wear data is to note changes in length, volume, or mass (or these same measures per unit time) for specified conditions. Wear resistance is sometimes given as the inverse of one of these quantities. Of course, when expressed in this manner, the results are not materials constants, because they are based on experimental conditions.

Several models of sliding wear lead to the prediction for volume change:

$$\Delta V = kLS/3H$$

where  $L$  is load,  $S$  is sliding distance,  $H$  is Vickers hardness, and  $k$  is a coefficient. Therefore, wear rate is commonly reported as  $\Delta V/L$ . For mild wear,  $k$  would be approximately  $10^{-8}$  to  $10^{-7}$ ; for severe wear, it would be about  $10^{-4}$  to  $10^{-3}$ . Sometimes a wear factor defined as  $\Delta V/SL$  or  $k/3H$  is used.

Wear is sometimes reported as "specific wear," or  $d/PS$ , where  $d$  is depth of wear,  $P$  is bearing pressure, and  $S$  is sliding distance. Wear data may also be expressed as lifetime-in-service when wear is the main determinant of lifetime. Wear rates are commonly reported as values that are relative to the wear of a standard material subjected to the same conditions as the test specimen. The use of a good reference material is almost imperative. It is the only reasonable way of ranking materials for comparison to other wear situations, because values of metal loss generally do not agree even when different investigators make every effort to subject specimens to identical test conditions. In fact, the amount of metal loss from different specimens of a standard reference material tested under standard conditions in a single test apparatus can vary by as much as 25% over an extended period, with no apparent trend implying that test conditions are changing systematically.

**Wear Rate Transitions.** Wear testing of many materials results in a linear variation of wear with load. It is therefore tempting to extrapolate such data to higher load situations, especially because simple wear models generally predict a linear load dependence. However, this is not a reliable practice because one or more wear rate transitions associated with changes in microstructure, temperature, or other test conditions can occur.

Several examples of such transitions are summarized in Table 1 for the wear of gray iron pins in a series of pin-on-disk tests. At low loads, the wear debris was mainly oxide, but at higher loads, the debris particles were metal flakes approximately five times larger than the oxide debris particles. Lowest wear rates in both regimes were found for ASTM type A flake graphite of size 3 to 4, randomly distributed in a pearlite matrix. Similar transitions with load are observed for many ferrous materials.

**Table 1 Wear of gray iron pins in pin-on-disk tests**

Iron structure		Free ferrite, %	Transition load, kg	Weight loss <sup>(a)</sup> , g		
Graphite form	Graphite size			Running-in wear <sup>(b)</sup>	Wear in mild regions <sup>(c)</sup>	Wear in severe regions <sup>(c)</sup>
ASTM type A	3-4	5	1.70	1.90	0.0	<b>5.0</b>
	4	10	2.10	2.90	0.016	<b>5.0</b>
ASTM type D, some type A	5-6	15	3.55	1.45	0.083	<b>13.2</b>

ASTM type E	6-7	25	3.20	0.40	0.049	22.0
-------------	-----	----	------	------	-------	------

- (a) Per kilogram of load.
- (b) At the end of 6700 m of sliding.
- (c) At the end of 10,000 m of sliding

**White-Etching Layers.** In the wear literature, reference is frequently made to a "white layer" or "white-etching layer." This white layer is usually much harder than the adjacent material, but seldom are any other characteristics of the layer clearly defined. Some confusion arises because there are many distinct types of "white layer." For example, the white layer may be a region of martensite developed during frictional heating and rapid cooling. In other wear situations, it may be a nitride layer formed by special surface treatment or it may be a highly deformed region with a fine cell microstructure.

**Wear debris** consists of pieces of material (varied in size and shape) that become loose during wear. The structure and properties of the debris can provide clues to the type of wear involved and the prevailing conditions during its formation.

Wear debris is a sensitive indicator of wear mechanisms and operating conditions. When the debris from two different test devices is similar, comparable wear situations can be expected. This principle can be extended to comparisons of published wear data (when wear debris information is given) and even to actual operating equipment. In the latter case, wear debris analysis facilitates monitoring of wear conditions, thus providing advance warning of wear failure.

## Abrasive Wear

Abrasive wear involves the plowing of localized surface contacts through a softer mating material. The wear is most frequently caused by nonmetallic materials, but metallic particles can also cause abrasion. Generally, a substance is seriously abraded or scratched only by materials that are harder than itself. Most protection against abrasion is based on this generalization, but there are exceptions.

When abrasion takes place under high surface loads, such as in ball or rod mills or in ore-crushing devices, the action is more complex. The abrasive is continually broken into smaller and smaller fragments. As a result, action that starts as gouging and surface deformation under the forces that drive large particles against the surface becomes transformed into cutting and scratching as the particles become finer and more angular.

**Types of Abrasive Wear.** Abrasive wear can take the form of gouging abrasion, high-stress grinding abrasion, or erosion and low-stress scratching abrasion:

- *Gouging abrasion* involves removal of relatively coarse particles from the steel wearing surface and is similar to the removal of metal by machining or grinding with a coarse-grit grinding wheel. In service, this occurs on parts such as dipper teeth handling large sharp rocks, impact pulverizer hammers, and some chute liners. Gouging abrasion is at least partially responsible for wear in crusher liners.
- *High-stress grinding abrasion* involves removal of relatively fine (microscopic) particles from the wearing surface. The pinching action of two metal surfaces causes the abrasive to fragment. Unit compressive or shear stresses are very high. Consequently, the harder abrasives, such as quartz, are capable of indenting or scratching steel with a hardness of 65 to 70 HRC. Metal may be removed from the wearing surface by microscopic gouging or by a combination of local plastic flow and microcracking. Ball milling is a good example of grinding abrasion. In machinery, such abrasion occurs where parts rub against each other in a gritty environment.
- *Erosion and low-stress scratching abrasion* occur by very light rubbing contact from sharp abrasive particles. The stresses are due mainly to velocity and are normally insufficient to cause much

fragmentation of the abrasive. Examples of this exist on screens, chute liners handling sand, parts handling sand slurries, and parts exposed to airborne abrasives. Erosion also can occur when a flowing liquid containing suspended abrasive particles flows over a surface. Liquids themselves can cause erosion when a stream of liquid impinges directly on a surface, when fluid flow conditions induce cavitation in the liquid adjacent to a surface, and when droplets carried by a flowing gas impact against a surface. Corrosion may be involved in the erosion process, especially in liquids or when the temperature is above room ambient.

**Abrasion Testing.** When abrasion testing of materials under actual service conditions is not practical, a laboratory abrasion test that closely simulates service conditions should be selected. However, in laboratory testing, the following factors must be considered:

- The position of the abrasive--whether fixed, as in abrasive paper (two-body abrasion), or free to rotate, as in loose sand (three-body abrasion)
- The size, shape, and hardness values of the dominant abrasive (usually the hardest component in a mixture)
- The direction and speed of relative motion during abrasion
- The contact pressures or loads in the system

To simulate low-stress or scratching abrasion with loose abrasive, a rubber wheel test has been found useful. Figure 1 shows test results for a wide range of materials. The least wear-resistant material in Fig. 1 wears 1500 times faster than the most wear-resistant material.

**Fig. 1** Rubber wheel abrasion test results in terms of volume loss, normalized to 55 Durometer hardness of the rubber wheel. Note the logarithmic scale for wear loss.

**Correlations between Dissimilar Abrasion Tests.** In some applications, data from one type of abrasion test can be used to predict relative wear rates under quite different conditions. For instance, several steels and cast irons were tested in a rubber wheel device and also by movement through an abrasive slurry. Despite the obvious differences in test conditions, correlation between results from both types of tests is quite good (see Fig. 2). In both cases, the abrasive was loose and the stresses low. If test conditions were more dissimilar, the simple correlation could not be expected to continue.

**Fig. 2** Correlation between results of the rubber wheel abrasion test and Sumitomo Metal Industries abrasion-testing machine

**Abrasive Particle Size.** Airborne dirt is a chronic cause of excessive ring wear in an internal combustion engine. Proper maintenance and design of filter equipment are essential controls, Prevention of air leaks between filters and the engine is also imperative. Lubricating oil contaminated with dirt is a less frequent problem, but design and maintenance of oil filters and seals are necessary considerations to control occurrence. When particles of dirt in an engine reach a certain size, wear subsides and the dirt particles often allay rather than increase friction. Test data in Fig. 3 for piston ring wear indicate that abrasion is most severe at a particle size of about 20  $\mu$ m. Apparently, the lubricating effectiveness of the oil over a wide range of viscosities has little influence on the wear peak established by particle size.

**Fig. 3** Effect of dust particle size on the wear of engine piston rings lubricated by oils of three different viscosities

**Hardness of the abrasive** significantly influences abrasion. As the hardness of the abrasive increases, variations in wear rates for different steels diminish. Conversely, as the abrasive hardness decreases, differences in the hardness and microstructure of steels become more important.

**Hardness of Metal.** Wear problems are solved, wholly or in part, by the proper selection of metals (see Table 2). Metal hardness is one of the most important characteristics to consider when selecting for maximum wear. If other factors remain relatively constant, comparisons of hardness values provide an approximate guide to relative wear behavior among different metals, especially in metal-to-metal sliding and abrasive applications. However, hardness alone cannot be

expected to determine the optimal material choice for a given application. Later sections of this article describe other factors to be considered when selecting material for wear resistance, one of the most important of which is microstructure.

**Table 2 Relative hardness and abrasion resistance of several steels against hard and soft abrasives**

Material	Carbon, %	Hardness, HV	Wear resistance <sup>(a)</sup>		Flint abrasive <sup>(b)</sup>			Glass abrasive <sup>(c)</sup>		
			SiC 180 grit	Al <sub>2</sub> O <sub>3</sub> 180 grit	Relative hardness <sup>(d)</sup>	Wear resistance <sup>(a)</sup>		Relative hardness <sup>(d)</sup>	Wear resistance <sup>(a)</sup>	
						180 grit	36 grit		180- 200 grit	30 grit

------------------	-------	-----	------	------	-------	------	------	-------	------	------

- (a) Volumetric wear of reference material divided by volumetric wear of test material; reference material, Armco ingot iron.
- (b) 1060 HV.
- (c) 590 HV.
- (d)  $HV_{\mu}/HV_a$ , where  $HV_{\mu}$  is maximum Vickers hardness on abraded face and  $HV_a$  is Vickers hardness of abrasive.

In the example that follows, hardness appears to be a dominant factor governing the wear resistance of various materials in each specific application.

### Example 1: Wear of Grinding Balls.

Performances of low-alloy martensitic steel grinding balls containing 0.80% C, 0.70% Mn, 0.30% Si, 0.20% Cr, 0.15% Mo, and 0.002% B (water quenched to 60 HRC) and pearlitic steel containing 0.80% C, 0.70% Mn, and 0.30% Si (oil quenched to give a fine pearlitic structure at 40 HRC) are compared in Fig. 4(a) and 4(b). Adding balls to a ball mill requires no shutdown time; therefore, selection is based on cost per pound compared with wear rate, as well as availability. The low-alloy martensitic balls cost more per pound, but their high wear resistance justifies the increased cost of these and numerous other grinding applications.

**Fig. 4** Effect of steel composition, hardness, and type of material being ground on the wear rate of 75 mm (3 in.) diam steel grinding balls

In another series of tests, summarized in Fig. 4(c), three types of balls of fully hardened, low-alloy steel with varying carbon content were compared. Their compositions and hardnesses were as follows:

- *Low-carbon steel:* 0.25% C, 0.90% Mn, 0.30% Si, 0.60% Cr, 0.20% Mo, 0.002% B at 40 to 50 HRC
- *Medium-carbon steel:* 0.55% C, 0.90% Mn, 0.25% Si, 0.30% Cr, 0.05% Mo, 0.001% B at 54 to 58 HRC

- *High-carbon steel*: 0.80% C, 0.70% Mn, 0.30% Si, 0.20% Cr, 0.15% Mo, 0.002% B at 60 to 64 HRC

## Lubrication and Lubricated Wear

Use of an effective lubricant can reduce wear in several ways. The lubricant serves to separate the rubbing surfaces, preventing or greatly reducing metal-to-metal contact. Complete separation is more readily achieved if the mating surfaces are smooth (except for microscopic asperities). The lubricant can also serve as a vehicle to remove loose wear debris from the rubbing areas before abrasive damage occurs. The lubricant, especially in a flowing system can control increases in temperature due to frictional heating.

**Hydrodynamic lubrication** occurs when the viscous property of a fluid during a shearing between two surfaces in relative motion produces sufficient fluid pressure to separate the surfaces and support a load. The hydrodynamic effect occurs when the fluid is forced to flow into a converging wedge configuration. In a journal bearing, this occurs when the rotating shaft surface drags a film of oil into a converging wedge formed by the displacement of the shaft center from the bearing center under applied load. Surface separation during hydrodynamic lubrication is sufficient to prevent any contact between asperities. Bearing friction is proportional to fluid viscosity and surface velocity. Minimum film thickness is proportional to viscosity and surface velocity. Hydrodynamic lubrication is also called "thick film" and "fluid film" lubrication.

**Hydrostatic lubrication** refers to a condition in which lubricant is supplied under sufficient pressure to separate the surfaces.

**Elastohydrodynamic lubrication** refers to the fluid film lubrication of high-speed rolling contacts. The contact area between the rolling elements is separated by a thin lubricant film (as small as  $0.25 \mu\text{m}$ ). Fluid dynamic conditions exist in the thin film. Under concentrated contact, such as a ball in contact with a race, a Hertzian pressure distribution is assumed to exist between the contact areas, and elastic deformation is assumed to cause a flattening in the contact zone. The fluid film is separated by approximately parallel surfaces. The entry condition in the hydrodynamic wedge and the elastically deformed region is one in which the fluid is subjected to high pressure and high shear rates. These conditions alter the apparent viscosity of the fluid (viscosity increases with pressure). Elastohydrodynamic lubrication requires very smooth surface finishes to prevent asperity contact.

**Boundary lubrication** denotes a range of contact conditions that occur when the hydrodynamic film collapses under high load or with too low a shear rate. Solid surface contact occurs between adsorbed soft surface films. The surface film can be an array of oriented long-chain fatty-acid molecules that have sufficient penetration resistance to prevent metal-to-metal contact. They also have a low shear resistance parallel to the surface, which allows sliding contact with reasonable friction levels (0.05 to 0.1 friction coefficient) and mild wear. Friction no longer becomes a function of viscosity or surface velocity. Boundary lubrication usually involves some metal-to-metal contact. A boundary film can be physically adsorbed or chemisorbed. The film is formed and replenished from the fluid lubricant environment. The success of boundary lubrication depends greatly on the surface chemistry of the lubricated surfaces and the operating conditions.

**Solid lubrication** describes a condition in which a soft solid is used instead of a fluid lubricant. The solid lubricant adheres to the rubbing surfaces and forms a low shear strength solid film. Natural solid lubricants include graphite and  $\text{MoS}_2$ . Once a solid film of lubricant becomes established, it tends to wear away unless continually replenished. The soft solid is suspended as a pigment in a resin or inorganic binder in solid lubricant coatings. Many of the effective solid lubricants have layer structures; however, this is not a prerequisite for classification as a solid lubricant.

**Dry wear** generally implies wear between surfaces without benefit of lubrication. Under certain conditions of load, speed, surface finish, and temperature, dry wear can occur even when a lubricant is present. Dry friction can lead to temperature increases that are sufficient to change microstructure and mechanical properties. Materials that achieve their hardness and strength by heat treatment are most likely to be affected by frictional heat. The actual surface temperatures achieved during dry wear are virtually impossible to measure, and both the temperatures themselves and the methods used to obtain them are matters of continuous controversy.

## Selection of Steels for Wear Resistance

Wear problems are solved, wholly or in part, by the proper selection of metals. Stress analysis and laboratory investigation usually provide only a partial solution and seldom completely resolve wear problems. Frequently, a metal is selected for trial, shaped into an experimental or service part, incorporated in an operating mechanism, and observed for wear rate. If superior performance is proved in such limited service, the part may be incorporated in production models and run in varying conditions so further observations can be recorded on its life and suitability. Lubrication and design of contacting components also play important roles in wear control.

Mild steel demonstrates poor wear resistance and resistance to surface damage during dry sliding. The use of mild steel in sliding surface contact requires surface treatment, such as hardening or coating, and/or the selection of a "compatible" mating material such as bronze or babbitt. Where hard minerals come in contact with steel, wear is very rapid unless the steel surface is hardened or coated with a very hard material.

Steel is subject to accelerated wear in a corrosive environment. Unprotected steel is also susceptible to fretting damage or formation of oxidized wear debris between two contacting surfaces in low-amplitude oscillating motion. A wide variety of microstructures are possible in the heat treatment of steel or cast iron. Wear properties can be related to specific microstructures.

**Relative Costs.** When selecting steel for wear resistance, the total cost of the steel and its heat treatment must be considered. The following steels, which may have suitable wear-resistance properties in specific applications, are listed in order of increasing total cost:

- *Low-carbon steels*, such as 1020, not heat treated
- *Simple high-carbon steels*, such as 1095, not heat treated
- *Directly hardened carbon or low-alloy steels*, either through hardened or surface hardened by induction or flame
- *Low-carbon or low-alloy steels* that are surface hardened by carburizing, cyaniding, or carbonitriding
- *Medium-carbon chromium or chromium-aluminum steels* that are hardened by nitriding
- *Directly hardened high-alloy steels*, such as D2 high-carbon, high-chromium tool steel (1.50% C, 12% Cr), that contain particles of free carbide
- *Precipitation-hardening stainless steels* (mainly for applications involving heat or corrosion, or both, as well as wear)
- *Specialty steels* produced by powder metallurgy or mechanical alloying techniques
- *Alloy carbides* bonded by steel matrices

Other ferrous materials, such as high-manganese austenitic steels and various classes of cast irons, are also widely used for wear-resistance applications (see the article "Wear-Resistant Austenitic Manganese Steels" in this Section).

**Depth of Hardened Regions.** Skids, grinding rods, chute liners, and similar parts may be considerably reduced in section before being replaced. In such parts, a more expensive deep-hardening steel may be more economical than a shallow-hardening steel. For example, a round bar 64 mm ( $2\frac{1}{2}$  in.) in diameter with a surface hardness of 50 HRC may be made of either a water-quenched 1040 or an oil-quenched 5160 steel. However, by the time the bar has been worn to three-fourths of its original diameter (about 48 mm, or  $1\frac{7}{8}$  in.), the 1040 steel will have a surface hardness of about 25 HRC and thus would wear at a much faster rate than the 5160 steel with its hardness of about 37 HRC at the same location.

**Toughness.** Wear resistance tends to increase with hardness, but it decreases as toughness increases. This is an important relationship in applications that require both wear resistance and impact resistance.

A correlation of wear resistance and toughness for a variety of ferrous alloys is shown in Fig. 5. The scatter arises, at least in part, from microstructural effects. For example, point 22B (Fig. 5) refers to AISI 4340 steel, quenched and tempered at a high temperature of about 650 °C (1200 °F) to produce fine carbides in a ferrite matrix. Point 22A represents the same steel, except it is normalized to produce fine pearlite; point 22C represents a quenched sample tempered at 205 °C (400 °F), a relatively low tempering temperature. Steels in the lower band of Fig. 5 combine toughness with wear resistance;

these are mainly the austenitic manganese steels. Figure 5 indicates that for most ferrous alloys there is a trade-off between wear resistance and toughness. In some alloys, altering carbon content is a simple way to adjust these properties.

**Fig. 5** Relationship between resistance to gouging abrasion and toughness of various materials. Area A, wrought and cast low-alloy steels; area B, austenitic manganese steels; area C, variety of heat-treated steels; area D, high-chromium white cast irons

**Carbon Content.** The wear resistance of ferritic steel is improved by hardening, either throughout the section or superficially. The maximum hardness depends on the carbon content of the steel and the amount of martensite (efficiency of quenching). This relationship is illustrated in the preceding article in this Section, "Hardenability of Carbon and Alloy Steels" (see Fig. 1).

Standard hardness measurements may indicate that a martensitic steel is largely transformed, although it may retain some austenite. Exposure to ultralow temperatures (followed by tempering) can help complete the transformation to martensite and improve wear resistance. Because martensite is a metastable structure, it begins to transform to more stable structures as the temperature is raised. Consequently, martensitic steels are not suitable for wear resistance at elevated temperatures or for applications in which the heat of friction can raise the temperature significantly. They should not be used at temperatures above 200 °C (390 °F). Special alloy steels, such as tool steels or martensitic stainless steels, are appropriate for service at higher temperatures. The thermal instability of martensite should also be considered during finishing operations (such as grinding), when a heat-affected zone could be produced at the surface. The resultant tempering effects could be localized or general; in either case, wear resistance is likely to be reduced.

Carbon content also affects hardness and wear resistance through the formation of various simple and complex carbides. Wear properties depend on the type, amount, shape, size, and distribution of carbides present, as well as the properties of the matrix (hardness, toughness, and stability). Despite this complexity, correlation of relative wear rates with carbon content is possible (see, for example, Fig. 6). Because most carbides are relatively stable compared to martensite, wear resistance achieved with the aid of these hard microconstituents is retained at higher temperatures.

Fig. 6 Relation between gouging wear and carbon content for various types of steel and cast iron

**Hardness and Microstructure.** The frequent use of bulk hardness as a guide to abrasive wear resistance is supported by the data shown in Fig. 7 for annealed unalloyed metals. These data were obtained using abrasive cloth (two-body abrasion) with an abrasive hardness much greater than that of the metal samples. The data points are approximate; the experimental scatter of the measurements is not shown.

Fig. 7 Abrasive wear resistance versus hardness for annealed unalloyed metals and steel

Corresponding correlations with other properties related to hardness (such as elastic modulus) have also been presented. In all cases, if the metals are unalloyed, a simple correlation is obtained for controlled tests of two-body abrasion. Different crystal structures would be expected to yield different correlations, but the data in Fig. 7 do not show such an effect.

Care must be exercised in extending the simple hardness correlation to metals containing impurities or solutes, or to more complicated alloys. Figure 8 shows how wear resistance and hardness correlate for various classes of materials. The linear plot shown for pure metals in Fig. 7 is repeated as the steep line in Fig. 8. Another straight line describes brittle ceramics reasonably well. The differences in bonding type may account for these two distinct lines.

**Fig. 8** Schematic representation of the correlation between wear resistance and hardness of different materials in various microstructural conditions

## Wear and Microstructure

The preceding discussion established the importance of hardness and microstructure as factors in resistance to wear. Metallurgically, hardness and microstructure are commonly interrelated. Increasing the carbon content of a carbon steel, for example, results in microstructural alteration that increases as-quenched hardness and decreases ductility or toughness.

**Wear Resistance at Constant Hardness.** Very few tests of the comparative wear resistance of different steels at a constant hardness have been reported. However, in one series of tests for seizure resistance under heavy loads, a variety of steels were selected to provide a wide range of mechanical properties and microstructures when heat treated to 40 HRC. The steels, which are listed in Table 3, include a plain carbon steel, a tool steel, an alloy steel, a martensitic stainless steel, two precipitation-hardening steels, and a maraging steel. Details of heat treatment and a description of the various microstructures are also given in Table 3.

**Table 3** Steels used in seizure-resistance tests

Type of Steel	Type of heat treatment	Details of heat treatment	Description of structure
1040	Quenched and tempered	830 °C (1525 °F), 20 min, WQ; 415 °C (780 °F), 4 h, AC	<b>Tempered martensite with very fine carbide distribution</b>
W1 (I)	Quenched and tempered	790 °C (1455 °F), 20 min, WQ; 440 °C (825 °F), 4 h, AC	<b>Tempered martensite with very fine carbide distribution</b>
W1 (II)	Quenched and tempered	900 °C (1650 °F), 20 min, OQ; 470 °C (880 °F), 4 h, AC	<b>Primary carbides (4 to 8 μm) in tempered martensite matrix</b>
4340	Quenched and tempered	830 °C (1525 °F), 20 min, OQ; 485 °C (905 °F), 4 h, AC	<b>Tempered martensite with very fine carbide distribution</b>
440C	Quenched and tempered	1065 °C (1950 °F), 20 min, OQ; 580 °C (1075 °F), 2 h, AC	<b>Large primary Cr and Fe carbides (20 μm) in tempered martensitic matrix</b>

15-5 PH	Solution treated and aged	1040 °C (1905 °F), 30 min, OQ; 530 °C (985 °F), 4 h, AC	<b>Martensite</b>
17-4 PH	Solution treated and aged	1040 °C (1905 °F), 30 min, OQ; 530 °C (985 °F), 4 h, AC	<b>δ-ferrite stringers in martensitic matrix</b>
18Ni (250) (I)	Solution treated and underaged	815 °C (1500 °F), 60 min (in vacuum), AC; 320 °C (610 °F), 2 h, AC	<b>Lath martensite</b>
<b>18Ni (250) (II)</b>	<b>Solution treated and overaged</b>	<b>815 °C (1500 °F), 60 min (in vacuum), AC; 630 °C (1165 °F), 2 h, AC</b>	<b>Lath martensite and very fine reverted austenite</b>

**Effect of Carbides on Wear.** The amount, size, and distribution of carbides in a steel microstructure have a distinct influence on wear resistance. For the most part, wear resistance increases as the amount or size of carbide particles at the wear surface increases. This effect is most often attributed to the proportion of the surface area occupied by the carbides and is more pronounced when gouging abrasion is not a factor. The following examples illustrate the effect of carbides in various wear applications.

## **Example 2: Influence of Amount of Carbides on Wear of High-Speed Tool Steels.**

Specimens of several different high-hardness, high-speed tool steels were tested in a crossed-cylinder sliding wear machine. The fixed cylinder was made of tungsten carbide (6% Co), rotating at 40,000 rev/h, with an applied load of 68 kg (15 lb). Sliding distances ranged from  $1 \times 10^{-5}$  to  $5 \times 10^{-5}$  in. Bulk hardness values of all four steels were in the narrow range of 65 to 67.5 HRC. However, wear rates varied considerably, as shown in Fig. 9. The dominant factor seems to have been the content of hard MC-type vanadium carbide (2800 HK), which was highest in the T15 steel and lowest in the T1 and M1 steels.

Type grade or	Composition, %		Total carbide	MC-type carbide	Hardness, HRC
	C	V			
T1,M1	0.75	1	29	2	<b>65</b>
M2,M25	0.85	2	28	3	<b>65</b>
M7,M10, M2,M25	1.10	2	26	4	<b>66</b>
M2,M41	1.1	2	28	4.5	<b>67.5</b>

Fig. 9 Wear rates for high-speed steels

### Hardness Evaluation

With some exceptions, the data in this article have indicated that hardness is the most significant factor in controlling wear of steel. Conventional methods of hardness evaluation such as Rockwell and Brinell tests may not always provide sufficient information or may be insensitive to minor, but significant, aberrations. Small amounts of retained austenite, decarburization or variation in microconstituents, and other factors that are not always evaluated in conventional hardness tests may have a marked influence on wear resistance.

**Microhardness testing** is more effective for detecting local differences. Hardness traverses taken on polished cross sections may reveal conditions not registered by other means.

### Elevated-Temperature Properties of Steels

CARBON AND LOW-ALLOY STEELS are used extensively at elevated temperatures in fossil-fired power-generating plants, aircraft power plants, chemical-processing plants, and petroleum-processing plants. The term "elevated temperature" can be used to mean any temperature above room temperature. As applied to the carbon and low-alloy

chromium-molybdenum (Cr-Mo) steels considered in this article, elevated temperature relates primarily to the temperature range of almost 370 to 650 °C (700 to 1200 °F). The properties of carbon and Cr-Mo steels vary considerably over this temperature range.

Some devices, such as steam power plants and gas turbines, operate with increasing efficiency as the operating temperature is raised. The maximum temperature at which such equipment can operate is limited by the capabilities of materials from which it is made. Resistance of steels to degradation of properties at elevated temperatures usually increases with alloy content; the cost of these steels also increased with alloy content. Thus, selection of steels to be used at elevated temperatures generally involves a compromise between the higher efficiencies obtained at higher operating temperatures and the cost of the equipment, including materials, fabrication, replacement, and down-time costs.

## Carbon Steels

Carbon steels are widely used in pressure vessel fabrication because of their low cost, versatile mechanical properties, and availability in fabricated forms. They are the most common materials used in noncorrosive environments in the temperature range of -29 to 425 °C (-20 to 800 °F) in oil refineries and chemical plants. Although the ASME Boiler and Pressure Vessel Code (BPVC) gives allowable stresses for temperatures greater than 425 °C (800 °F), it also notes that prolonged exposure at these temperatures may result in the carbide phase of the carbon steel being converted to graphite. This phenomenon, known as "graphitization," is a cumulative process dependent on the time the material is at or above 425 °C (800 °F). The result is a weakening of the steel after high-temperature exposure. Carbon steels are also increasingly affected by creep at temperatures above 370 °C (700 °F).

## Heat-Resistant Cr-Mo Steels

The Cr-Mo steels are preferred in the construction of high-temperature components because they possess excellent strength, toughness, and corrosion resistance relative to carbon steels and most low-alloy steels. Components fabricated from Cr-Mo steels serve in the petroleum, petrochemical, fossil power, and pulp and paper industries. The steels are most often used at temperatures of 316 °C (600 °F) and higher, when creep effects, graphitization, or hydrogen attack may be significant in carbon steels.

Like most steels, the Cr-Mo steels respond to heat treatment, and a single composition may be produced in several strength classes. The low-chromium Cr-Mo steels have moderate hardenability. Slow cooling and isothermal annealing during cooling produce ferrite-pearlite microstructures that have long-time stability but relatively low tensile strength and toughness. Rapid air cooling and enhanced cooling produce bainitic steels, which tend to be stronger and tougher. Medium-chromium Cr-Mo steels have moderate hardenability, and air cooling is generally sufficient to produce bainite through-thicknesses of 150 mm (6 in.) and more. The bainitic steels are usually tempered. The high-chromium Cr-Mo steels have excellent hardening ability, and air cooling is sufficient to produce martensite through most thicknesses. Accelerated cooling of the steels is permitted, but care must be taken to avoid cracking. The martensitic steels are always tempered.

**Compositions and Metallurgy.** Nominal compositions for the heat-resistant, Cr-Mo steels are provided in Table 4.

The steels range from  $\frac{1}{2}$  to 12% Cr and  $\frac{1}{2}$  to 1% Mo. Product forms include tubes, pipes, forgings, fittings, plates, and castings. Welded tubing and pipes are included. Depending on the product, the maximum use temperature for pressure-boundary applications ranges from 480 to 650 °C (900 to 1200 °F).

**Table 4 Summary of Cr-Mo steels used in high-temperature service**

Nominal composition	ASTM specification	Product form	UNS numbers	Minimum or range of ultimate strength		Minimum yield strength		Maximum use temperature	
				MPa	ksi	MPa	ksi	°C	°F

The  $\frac{1}{2}$ Cr- $\frac{1}{2}$ Mo steel is produced to three strength levels and is approved in the ASME BPVC for service to 540 °C (1000 °F). The 1Cr- $\frac{1}{2}$ Mo and  $1\frac{1}{4}$ Cr- $\frac{1}{2}$ Mo steels are produced in three strength levels and are approved for service to 650 °C (1200 °F). The  $1\frac{1}{4}$ Cr- $\frac{1}{2}$ Mo steel is the most widely used of the Cr-Mo steels, but the greatest body of information is available for  $2\frac{1}{4}$ Cr-1Mo steel. Wrought  $2\frac{1}{4}$ Cr-1Mo steel is produced to several strength levels. The annealed steel (class 1) has a largely ferrite-pearlite microstructure, although bainite is often present. The class 1 steel is used in the power industry as superheater/reheater tubing, headers, and main steam line piping for service temperatures to 650 °C (1200 °F). The normalized-and-tempered steel (class 2) is used for heavy-wall pressure vessels in the petroleum and petrochemical industries for temperatures to 480 °C (900 °F). In Europe and Asia, the class 2 material is often used for tubing and piping in the power industry for service to 650 °C (1200 °F). Quenched-and-tempered versions of  $2\frac{1}{4}$ Cr-1Mo steels exist. These steels are intended for heavy-wall pressure vessels but are limited to service at temperatures below the creep range because of their susceptibility to hydrogen attack. The 3Cr-1Mo steel is available in two strength levels and has strength properties comparable to those of  $2\frac{1}{4}$ Cr-1Mo steel, but improved resistance to hydrogen attack.

Recently,  $2\frac{1}{4}$ Cr-1Mo and 3Cr-1Mo steels with vanadium additions have been commercially developed for high-temperature pressure vessels and piping. The vanadium-bearing steels have better strength and are more resistant to hydrogen attack than steels without vanadium additions. The use of vanadium-modified  $2\frac{1}{4}$ Cr-1Mo steel and 3Cr-1Mo steel has been for heavy-wall pressure vessels. Further modifications of the 3Cr-1Mo- $\frac{1}{4}$ V steels have been produced by adding titanium, niobium, calcium, and the like. The strength and toughness of the steels are comparable to that of the steels listed in Table 4.

The straight 9Cr-1Mo steel is approved for service in the BPVC to 650 °C (1200 °F), but usage has not been widespread. However, the 9Cr-1Mo-V steel developed in the late 1980s has been installed as tubing, piping, forgings, and castings in a variety of applications for the power, petroleum, and petrochemical industries and has accumulated up to 15 years of exposure at temperatures in the creep regime.

Even more recently, tungsten has been used as a replacement for some of the molybdenum to improve the weldability and toughness of Cr-Mo steels. Three steels included in the grouping include a  $2\frac{1}{4}$ Cr-1.6W steel, a 9Cr-2W steel, and a 12Cr-2W steel. The tungsten-bearing steels contain  $\frac{1}{2}$ % Mo and  $\frac{1}{4}$ % V, and they are intended for superheater/reheater tubing and piping for steam lines.

## Mechanical Properties at Elevated Temperatures

The allowable design stresses for steels at elevated temperatures may be controlled by different mechanical properties, depending on the application and temperature exposure. For applications with temperatures below the creep-temperature range, tensile strength or yield strength at the expected service temperature generally controls allowable stresses. For temperatures in the creep range, allowable stresses are determined from either creep-rupture properties or the degree of deformation from creep. In recent years, the worldwide interest in life extension of high-temperature components has also promoted considerably more interest in elevated-temperature fatigue. This effort has led to tests and methods for evaluating the effects of creep-fatigue interaction on the life of elevated-temperature components.

Ductility and toughness may also be important considerations, although ductility and toughness considerations usually do not enter directly into the setting of allowable stresses. In elevated-temperature applications, ductility and toughness might not remain fixed in magnitude or character and often change with temperature and with time at temperature. The changes, which may be beneficial but often are deleterious, are of interest both at service temperature and, because of shutdowns, at ambient temperatures. Ductility is also an important factor that influences notch sensitivity and creep-fatigue interaction.

The types of tests most commonly used to evaluate the mechanical properties of steels at elevated temperatures include:

- Short-term elevated-temperature tests
- Long-term elevated-temperature tests
- Short-term and long-term tests following long-term exposure to elevated temperatures
- Fatigue tests (including thermal fatigue and thermal shock tests)
- Time-dependent fatigue tests

**Short-term elevated temperature tests** include the elevated-temperature tensile tests (described in ASTM E 21), a test for elastic modulus (ASTM E 231), compression tests, pin bearing load tests, and the hot hardness test. The mechanical properties determined by means of the tensile test include ultimate tensile strength, yield strength, percent elongation, and percent reduction in area. Because elevated-temperature tensile properties are sensitive to strain rate,

these tests are conducted at carefully controlled strain rates. Tensile strength data obtained on specimens of annealed  $2\frac{1}{4}$  Cr-1Mo steel at various temperatures and at strain rates ranging from  $2.7 \times 10^{-6} \text{ s}^{-1}$  to  $144 \text{ s}^{-1}$  are shown in Fig. 10.

**Fig. 10** Effect of test temperature and strain rate on the strength of annealed  $2\frac{1}{4}$  Cr-1 Mo steel. Tensile strength (a) and yield strength (b) of  $2\frac{1}{4}$  Cr-1 Mo steel tested at various temperatures and strain rates

In designing components that are to be produced from low-alloy steels and to be exposed to temperatures up to  $370^\circ\text{C}$  ( $700^\circ\text{F}$ ), the yield and ultimate strengths at the maximum service temperature can be used much as they would be used in the design of components for service at room temperature. Certain codes require that appropriate factors be applied in calculating allowable stresses.

Elevated-temperature values of elastic modulus can be determined during tensile testing or dynamic testing by measuring the natural frequency of a test bar at the designated test temperature. Figure 11 shows values of elastic modulus at temperatures between room temperature and  $650^\circ\text{C}$  ( $1200^\circ\text{F}$ ) for several low-alloy steels, determined during static tensile loading and dynamic loading.

**Fig. 11** Effect of test temperature on elastic modulus for several steels commonly used at elevated temperatures. Dynamic measurements of elastic modulus were made by determining the natural frequencies of test specimens; static measurements were made during tensile testing.

Compression tests and pin bearing load tests (ASTM E 209 and E 238) can be used to evaluate materials for applications in which the components will be subjected to these types of loading at elevated temperatures. Hot hardness tests can be used to evaluate materials for elevated-temperature service and can be applied to the qualification of materials in the same way in which room-temperature hardness tests are applied.

Components for many elevated-temperature applications are joined by welding. Elevated-temperature properties of both the weld metal and the heat-affected zones can be determined by the same methods used to evaluate the properties of the base metal.

**Long-term elevated-temperature tests** are used to evaluate the effects of creep, which is defined as the time-dependent strain that occurs under constant load at elevated temperatures. Creep is observed in steels at temperatures above about 370 °C (700 °F). In general, creep occurs at a temperature slightly above the recrystallization temperature of a metal or alloy; at such a temperature, atoms become sufficiently mobile to allow time-dependent rearrangement of the structure. In time, creep may lead to excessive deformation and even fracture at stresses considerably below those determined in room-temperature and elevated-temperature short-term tension tests.

Typical creep behavior consists of three distinct stages as shown in Fig. 12. Following initial elastic-plastic strain resulting from the immediate effects of the applied load, there is a region of increasing plastic strain at a decreasing strain rate (first-stage, or primary, creep). Following the primary creep region, there is a region where the creep strain increases at a minimum, and almost constant, rate of plastic strain (second-stage, or secondary creep). This nominally constant creep rate is generally known as the minimum creep rate and is widely employed in research and engineering studies. Finally, there is a region of drastically increased strain rate with rapid extension to fracture (third-stage, or tertiary creep). Tertiary creep has no distinct beginning, but does refer to the region with an increasing rate of extension that is followed by fracture.

Fig. 12 Schematic representation of classical creep behavior

Of all the parameters pertaining to the creep curve, the most important for engineering applications are the creep rate and the time to rupture. These parameters are determined from long-term elevated-temperature tests that include creep, creep-rupture, and stress-rupture tests (ASTM E 139) and notched-bar rupture tests (ASTM E 292). In addition, relaxation tests (ASTM E 328) are used to evaluate the effect of creep behavior on the performance of high-temperature bolt steels.

When the rate or degree of deformation is the limiting factor, the design stress is based on the minimum (secondary) creep rate and design life after allowing for initial transient creep. The stress that produces a specified minimum creep rate of an alloy or a specified amount of creep deformation in a given time (for example, 1% total creep in 100,000 h) is referred to as the limiting creep strength or limiting stress. Typical creep strengths of various low-alloy steels are shown in Fig. 13.

Fig. 13 General comparison of creep strengths of various creep-resistant low-alloy steels

When fracture is a limiting factor, stress-rupture values are used in design. Stress-rupture values of various low-alloy chromium-molybdenum steels are shown in Fig. 14.

Fig. 14 Variation of 100,000 h creep-rupture strength as a function of temperature for  $2\frac{1}{4}$ Cr-1Mo steel, standard 9Cr-1Mo, modified 9Cr-1Mo, and 304 stainless steel

For those alloys in which failure occurs before a well-defined start of tertiary creep, it is useful to use notched specimens or specimens with both smooth and notched test sections (with the cross-sectional area of the notch equal to that of the smooth test section). If the material is notch sensitive, the specimen will fail in the notch before failure occurs in the smooth section. It has been well recognized for many years that notch sensitivity is related to creep ductility. It has been suggested that a minimum smooth-bar creep ductility of about 10% in terms of reduction in area may be desirable for avoidance of notch sensitivity. Limited published data on notched stress-rupture properties of low-alloy ferritic steels for elevated temperatures indicate that these steels generally are not notch sensitive. Representative stress-rupture data for notched and unnotched specimens of 17-22 AV steel (Fe-0.27C-0.75Mn-0.65Si-1.25Cr-0.50Mo-0.85V) are presented in Fig. 15.

**Fig. 15 Effect of notch on stress-rupture behavior.** Stress-rupture behavior of smooth ( $K = 1.0$ ) and notched specimens of Fe-0.27C-0.75Mn-0.65Si-1.25Cr-0.50Mo-0.85V steel tested at 595 °C (1100 °F). All specimens were normalized at 980 °C (1800 °F) and tempered at 6 h at 675 °C (1250 °F)

**Long-term exposure to elevated temperature** may affect either short-term or long-term properties. For example, exposure of plain carbon steels to elevated temperatures (such as 650 °C, or 1200 °F) can cause overtempering or spheroidization. Such a change in microstructure can logically be expected to change the mechanical properties of the steel. Other metallurgical instabilities may affect the mechanical properties of steels. For example, long-term exposure of Cr-Mo steel can result in an evolution of the carbide structure resulting in coarsening of the carbides, changes in the matrix composition, and an overall decrease in creep strength.

Long-term exposure to elevated temperature may also affect the properties of steels through alteration of the steel by the environment. Carbon steels are subject to oxidation in air, and the cross-sectional area of a steel part may be reduced by flaking away of surface oxide. Long-term exposure to carbon-bearing or sulfur-bearing atmospheres will result in carbon or sulfur pickup; after such exposure, the steel can be expected to have different properties.

**Thermal shock tests** may be used to determine the effects of rapid changes in temperature on the properties of steel parts. Thermal shock can occur as the result of a single change in temperature (quench cracking, for example), or as the result of cyclic variations in temperature such as those experienced by heat treating fixtures.

**Time-Dependent Fatigue Tests.** Creep and relaxation data are obtained at constant temperatures and either constant-load or constant-strain conditions. However, in many service applications, cyclic variations in either temperature or applied stress, (or strain) can occur. These variations may occur randomly or in regular, uniform cycles. In order to determine the effect of cyclic loading superimposed on a constant load at elevated temperatures, several types of fatigue testing may be employed: constant alternating stress, constant alternating strain, tension-tension loading with the stress ratios greater than zero, and special waveforms that provide specific holding times at maximum load. Results of these tests show what factors are most contributory to deformation and fracture of the specimens for the testing conditions employed. A more detailed account of the complex interactions of creep and fatigue can be found in the *ASM Specialty Handbook: Heat-Resistant Materials*.

## Data Presentation and Analysis

The behavior of steels at elevated temperatures can be affected by many variables, some of which are time, temperature, stress, and strength. Attempting to analyze so many variables is difficult. Presentation of the data is difficult also. A variety of methods for correlating, interpolating, and extrapolating elevated-temperature mechanical-property data have been devised. Appropriate texts, such as *Mechanical Testing*, Vol 8, *ASM Handbook*, should be consulted.

One method for comparing steels of different strengths is to report elevated-temperature strength as a percentage of room-temperature strength; this method is illustrated in Fig. 16. The strength levels of the steels represented in Fig. 16 varied from 480 to 1100 MPa (70 to 160 ksi).

**Fig. 16** Ratios of elevated-temperature strength to room-temperature strength for hardened-and-tempered  $2\frac{1}{4}$ Cr-1Mo steel tempered to room-temperature tensile strengths ranging from 480 to 1100 MPa (70 to 160 ksi). (a) Tensile strength. (b) Yield strength

Four different presentations of the same creep data for  $2\frac{1}{4}$ Cr-1Mo steel are given in Fig. 17. In parts (a), (b), and (c), only the creep strain is plotted. In the isochronous stress-strain diagram (part d), total strain is used. The over-all format of Fig. 17(d) is particularly useful in design problems where total strain is a major consideration; the linear scales make unjustified extrapolation a little more difficult.

## Effects of Composition

The mechanical properties of carbon and low-alloy steels are determined primarily by composition and heat treatment. The effects of alloying elements in annealed, normalized and tempered, and quenched and tempered steels are discussed below.

**Carbon** increases both the strength and hardenability of steel at room temperature but decreases the weldability and impact toughness. In plain carbon and carbon-molybdenum steels intended for elevated-temperature service, carbon content is usually limited to about 0.20%. In some classes of tubing for boilers, however, carbon may be as high as 0.35%. For chromium-containing steels, carbon content is usually limited to 0.15%. Carbon increases short-term tensile strength but does not add appreciably to creep resistance at temperatures above 540 °C (1000 °F), because carbides eventually become spheroidized at such temperatures.

**Manganese**, in addition to its normal function of preventing hot shortness by forming dispersed manganese sulfide inclusions, also appears to enhance the effectiveness of nitrogen in increasing the strength of plain carbon steels at elevated temperatures. Manganese significantly improves hardenability but contributes to temper embrittlement.

**Phosphorus and sulfur** are considered undesirable because they reduce the elevated-temperature ductility of steel. This reduction in ductility is demonstrated by reductions in stress-rupture life and thermal fatigue life. Phosphorus contributes to temper embrittlement.

**Silicon** increases the elevated-temperature strength of steel. It also increases the resistance to scaling of the low-chromium steels in air at elevated temperatures.

**Chromium** in small amounts ( $\sim 0.5\%$ ) is a carbide former and stabilizer. In larger amounts (up to 9% or more), it increases the resistance of steels to corrosion. Chromium also influences hardenability.

The effect of chromium in creep-resistant Cr-Mo steels is complex. By itself, chromium enhances creep strength, although increasing the chromium content in lower-carbon grades does not increase resistance to deformation at elevated temperatures. When added to molybdenum steel, chromium generally leads to some reduction in creep strength, such as that shown in Fig. 18. For the 1Mo steel in Fig. 18, the optimum creep strength occurs with about 2.5% Cr. Chromium is most effective in strengthening molybdenum steels (0.5 to 1% Mo) when it is used in amounts of 1 to 2.5%.

**Fig. 18** Effect of chromium on the creep strength (stress to produce a minimum creep rate of 0.0001% per hour) of several steels containing small amounts of molybdenum, silicon, and aluminum at 540 °C (1000 °F)

**Molybdenum** is an essential alloying element in heat-resistant steels where good creep resistance above 450 °C (840 °F) is required. Even in small amounts (0.1 to 0.5%), molybdenum increases the resistance of these steels to deformation at elevated temperatures. Much greater creep strength can be obtained by increasing the molybdenum level to about 1%, but at the expense of greatly reduced rupture ductility. Additions of chromium can improve rupture ductility.

Molybdenum is a carbide stabilizer and prevents graphitization. For certain ranges of stress and temperature, the dissolving of iron carbide and the concurrent precipitation of molybdenum carbide cause strain hardening in these steels. Molybdenum in amounts of 0.5% or less also minimizes temper embrittlement.

**Niobium and vanadium** are added to improve elevated-strength properties. Vanadium is also added to some of the higher-carbon steels to provide additional resistance to tempering and to retard the growth of carbides at service temperatures. Niobium is sometimes added to these steels to increase their strength through the formation of carbides.

## Fatigue Resistance of Steels

**FATIGUE** is the progressive, localized, and permanent structural change that occurs in a material subjected to repeated or fluctuating strains at nominal stresses that have maximum values less than (and often much less than) the static yield strength of the material. Fatigue may culminate into cracks and cause fracture after a sufficient number of fluctuations. The process of fatigue consists of three stages:

- *Stage I*: initial fatigue damage leading to crack initiation
- *Stage II*: crack propagation to some critical size (a size at which the remaining uncracked cross section of the part becomes too weak to carry the imposed loads)
- *Stage III*: final, sudden fracture of the remaining cross section

Fatigue damage is caused by the simultaneous action of cyclic stress, tensile stress, and plastic strain. If any one of these three is not present, a fatigue crack will not initiate and propagate. The plastic strain resulting from cyclic stress initiates the crack; the tensile stress promotes crack growth (propagation). Careful measurement of strain shows that microscopic plastic strains can be present at low levels of stress where the strain might otherwise appear to be totally elastic. Although compressive stresses will not cause fatigue, compressive loads may result in local tensile stresses.

## Fatigue Resistance

Variations in mechanical properties, composition, microstructure, and macrostructure, along with their subsequent effects on fatigue life, have been studied extensively to aid in the appropriate selection of steel to meet specific end-use requirements. Studies have shown that the fatigue strength of steels is usually proportional to hardness and tensile strength; this generalization is not true, however, for high tensile strength values where toughness and critical flaw size may govern ultimate load-carrying ability. Processing, fabrication, heat treatment, surface treatments, finishing, and service environments significantly influence the ultimate behavior of a metal subjected to cyclic stressing.

Predicting the fatigue life of a metal part is complicated because materials are sensitive to small changes in loading conditions and stress concentrations and to other factors. The resistance of a metal structural member to fatigue is also affected by manufacturing procedures such as cold forming, welding, brazing, and plating, and by surface conditions such as surface roughness and residual stresses. Fatigue tests performed on small specimens are not sufficient for precisely establishing the fatigue life of a part. These tests are useful for rating the relative resistance of a material and the baseline properties of the material to cyclic stressing. The baseline properties must be combined with the load history of the part in a design analysis before a component life prediction can be made.

In addition to material properties and loads, the design analysis must take into consideration the type of applied loading (uniaxial, bending, or torsional), loading pattern (either periodic loading at a constant or variable amplitude or random loading), magnitude of peak stresses, overall size of the part, fabrication method, surface roughness, presence of fretting or corroded surface, operating temperature and environment, and occurrence of service-induced imperfections.

Traditionally, fatigue life has been expressed as the total number of stress cycles required for a fatigue crack to initiate and grow large enough to produce catastrophic failure, that is, separation into two pieces. In this article, fatigue data are expressed in terms of total life. For the small samples that are used in the laboratory to determine fatigue properties, this is generally the case; but, for real components, crack initiation may be as little as a few percent or the majority of the total component life.

Fatigue data can also be expressed in terms of crack growth rate. In the past, it was commonly assumed that total fatigue life consisted mainly of crack initiation (stage 1 of fatigue crack development) and that the time required for a minute fatigue crack to grow and produce failure was a minor portion of the total life. However, as better methods of crack detection became available, it was discovered that cracks often developed early in the fatigue life of the material (after as little as 10% of total lifetime) and grow continuously until catastrophic failure occurs. This discovery has led to the use of crack growth rate, critical crack size, and fracture mechanics for the prediction of total life in some applications. The use of fracture mechanics methods to predict fatigue life is discussed in the Section "Failure Analysis" in this Handbook.

## Prevention of Fatigue Failure

The incidence of fatigue failure can be considerably reduced by careful attention to design details and manufacturing processes. As long as the metal is sound and free from major flaws, a change in material composition is not as effective in achieving satisfactory fatigue life as are care in design, fabrication, and maintenance during service. The most effective and economical method of improving fatigue strength is improvement in design to: (a) eliminate stress raisers by streamlining the part, (b) avoid sharp surface tears resulting from punching, stamping, shearing, etc., (c) prevent the development of surface discontinuities or decarburization during processing or heat treatment, (d) reduce or eliminate tensile residual stresses caused by manufacturing, heat treating, and welding, and (e) improve the details of fabrication

and fastening procedures. Control of or protection against corrosion, erosion, chemical attack, or service-induced nicks and other gouges is an important part of proper maintenance of fatigue strength during active service life.

## Symbols and Definitions

**Applied Stresses.** The mean stress,  $S_m$ , is the algebraic average of the maximum and minimum stresses in one cycle,  $S_m = (S_{\max} + S_{\min})/2$ . In the completely reversed test, the mean stress is zero. The range of stress,  $S_r$ , is the algebraic reference between the maximum and minimum stresses in one cycle,  $S_r = S_{\max} - S_{\min}$ . The stress amplitude,  $S_a$ , is one-half the range of stress,  $S_a = S_r/2 = (S_{\max} - S_{\min})/2$ .

During a fatigue test, the stress cycle is usually maintained constant so that the applied stress conditions can be written as  $S_m \pm S_a$ , where  $S_m$  is the static or mean stress, and  $S_a$  is the alternating stress equal to half the stress range. The positive sign is used to denote a tensile stress and the negative sign, a compressive stress. Some of the possible combinations of  $S_m$  and  $S_a$  are illustrated in Fig. 19. When  $S_m = 0$  (Fig. 19a), the minimum tensile stress is equal to the maximum compressive stress; this is called an alternating stress or a completely reversed stress. When  $S_m = S_a$  (Fig. 19b), the minimum stress of the cycle is zero; this is called a pulsating or repeated tensile (or compressive) stress. Any other combination is known as a fluctuating stress, which may be a fluctuating tensile stress (Fig. 19c), a fluctuating compressive stress, or a stress that fluctuates between a tensile and a compressive value (Fig. 19d).

**Fig. 19** Types of fatigue test stress. (a) Alternating stress in which  $S_m = 0$  and  $R = -1$ . (b) Pulsating tensile stress in which  $S_m = S_a$ , the minimum stress is zero, and  $R = 0$ . (c) Fluctuating tensile strength in which both the minimum and maximum stresses are tensile stresses,  $R = \frac{1}{3}$ . (d) Fluctuating tensile-to-compressive stress in which the minimum stress is a compressive stress and the maximum stress is a tensile stress,  $R = -\frac{1}{3}$ .

**Nominal stresses** can be calculated on the net section of a part ( $S = P/A$ ) without consideration of variations in stress conditions caused by holes, grooves, fillets, etc. Nominal stresses are often used in these calculations, although a closer estimate of actual stresses through the use of a stress-concentration factor might be preferred.

**Stress ratio** is the algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are the ratio,  $A$ , of the alternating stress amplitude to the mean stress ( $A = S_a/S_m$ ) and the ratio,  $R$ , of the minimum stress to the maximum stress ( $R = S_{\min}/S_{\max}$ ). If the stresses are fully reversed, the stress ratio  $R$  becomes  $-1$ ; if the stresses are partially

reversed,  $R$  becomes a negative number less than 1. If the stress is cycled between a maximum stress and no load, the stress ratio  $R$  becomes zero. If the stress is cycled between two tensile stresses, the stress ratio  $R$  becomes a positive number less than 1. A stress ratio  $R$  of 1 indicates no variation in stress, and the test would become a sustained-load creep test rather than a fatigue test.

**S-N Curves.** The results of fatigue tests are usually plotted as a maximum stress or stress amplitude to number of cycles,  $N$ , to fracture using a logarithmic scale for the number of cycles. Stress is plotted on either a linear or a logarithmic scale. The resulting curve of data points is called an  $S$ - $N$  curve. A family of  $S$ - $N$  curves for a material tested at various stress ratios is shown schematically in Fig. 20. For carbon and low-alloy steels,  $S$ - $N$  curves typically have a fairly straight slanting portion at low cycles changing into a straight, horizontal line at higher cycles, with a sharp transition between the two.

**Fig. 20** Schematic  $S$ - $N$  curves for a material at various stress ratios. UTS and YS indicate ultimate tensile strength and yield strength, respectively, in uniaxial tensile testing.

An  $S$ - $N$  curve usually represents the median life for a given stress--the life that half the specimens attain or surpass and half fail to attain. Scatter of fatigue lives can cover a very wide range.

**Fatigue limit** (or endurance limit) is the value of the stress below which a material can presumably endure an infinite number of stress cycles--that is, the stress at which the  $S$ - $N$  diagram becomes and appears to remain horizontal. The existence of a fatigue limit is typical for carbon and low-alloy steels.

**Fatigue strength**, which should not be confused with fatigue limit, is the stress to which the material can be subjected for a specified number of cycles. Fatigue strength is used for materials, such as most nonferrous metals, that do not exhibit well-defined fatigue limits. It is also used to describe the fatigue behavior of carbon and low-alloy steels at stresses higher than the fatigue limit.

**Stress-Concentration Factor.** Concentrated stress in a metal is evidenced by discontinuities such as notches, holes, and scratches, and by changes in microstructure. The stress-concentration factor,  $K_t$ , is the ratio of the greatest stress in the region of the notch (or other stress concentrators) to the corresponding nominal stress. For determination of  $K_t$ , the greatest stress in the region of the notch is calculated from the theory of elasticity, or equivalent values may be derived experimentally. An experimental stress-concentration factor is a ratio of stress in a notched specimen to the stress in a smooth (unnotched) specimen.

**Fatigue notch factor,  $K_f$ .** is the ratio of the fatigue strength of a smooth (unnotched) specimen to the fatigue strength of a notched specimen at the same number of cycles. The fatigue notch factor will vary with the position on the  $S$ - $N$  curve and with the mean shear stress. At high stress levels and short cycles, the factor is usually less than at lower stress levels and longer cycles due to blunting of the notch by plastic deformation.

**Fatigue notch sensitivity,  $q$ ,** is determined by comparing the fatigue notch factor,  $K_f$ , and the stress-concentration factor,  $K_t$ , for a specimen of a given size containing a stress concentrator of a given shape and size. A common definition of fatigue notch sensitivity is  $q = (K_f - 1)/(K_t - 1)$ , in which  $q$  may vary between zero (where  $K_f = 1$ ) and 1 (where  $K_f = K_t$ ). This value may be stated as a percentage. As the fatigue notch factor varies with the position on the  $S$ - $N$  curve, so will the

notch sensitivity. Most metals are fully notch sensitive at low stresses and long cycles. If they are not, it may be that the fatigue strengths for the smooth (unnotched) specimens are lower than they could be because of surface imperfections.

## Stress-Based Approach to Fatigue

The design of a machine element that will be subjected to cyclic loading can be approached by adjusting the configuration of the part so that the calculated stresses fall safely below the required line on an  $S-N$  plot. In a stress-based analysis, the material is assumed to deform in a nominally elastic manner, and local plastic strains are neglected. To the extent that these approximations are valid, the stress-based approach is useful. These assumptions imply that all the stresses will essentially be elastic. The stress-based approach is best applied to components that look like the test samples and are approximately the same size. Much of the technology in application of this approach is based on steels. Other materials may not respond in a similar manner.

Examples of the stress-fatigue life approach are given in Fig. 21 and 22. Figure 21 shows the combinations of cyclic stresses that can be tolerated by the same steel when the specimens are heat treated to different tensile strengths ranging from 860 to 1790 MPa (125 to 260 ksi). The effect of elevated temperature on the fatigue behavior of 4340 steel heat treated to 1035 MPa (150 ksi) is shown in Fig. 22. An increase in temperature reduces the fatigue strength of the steel and is most deleterious for those applications in which the stress ratio,  $R$ , lies between 0.4 and 1.0. A decrease in temperature may increase the fatigue limit of steel; however, parts with preexisting cracks may also show decreased total life as temperature is lowered, because of accompanying reductions in critical crack size and fracture toughness.

Fig. 21 Room temperature  $S-N$  curves for AISI 4340 alloy steel with various ultimate tensile strengths and with  $R = -1.0$

**Fig. 22** *S-N* curves at various temperatures for AISI 4340 alloy steel with an ultimate tensile strength of 1090 MPa (158 ksi). Stress ratio, *R*, equals -1.0

## Strain-Based Approach to Fatigue

A strain-based approach to fatigue, developed for the analysis of low-cycle fatigue data, has proved to be useful for analyzing long-life fatigue data as well. The approach can take into account both elastic and plastic responses to applied loadings. The data are presented on a log-log plot similar in shape to an *S-N* curve; the value plotted on the abscissa is the number of strain reversals (twice the number of cycles) to failure, and the ordinate is the strain amplitude (half the strain range).

During cyclic loading, the stress-strain relationship can usually be described by a loop, such as that shown in Fig. 23. For purely elastic loading, the loop becomes a straight line whose slope is the elastic modulus, *E*, of the material. The occurrence of a hysteresis loop is most common. The definitions of the plastic strain range,  $\Delta\epsilon_p$ , the total strain range,  $\Delta\epsilon$ , and the stress range,  $\Delta\sigma$ , are indicated in Fig. 23. A series of fatigue tests, each having a different total strain range, will generate a series of hysteresis loops. For each set of conditions, a characteristic number of strain reversals is necessary to cause failure.

**Fig. 23** Stress-strain hysteresis loop

As shown in Fig. 24, a plot on logarithmic coordinates of the plastic portion of the strain amplitude (half the plastic strain range) versus the fatigue life often yields a straight line, described by the equation:

$$\frac{\Delta\epsilon_p}{2} = \epsilon_f (2N_f)^c$$

where  $\epsilon_f$  is the fatigue ductility coefficient, *c* is the fatigue ductility exponent, and *N<sub>f</sub>* is the number of cycles to failure.

Fig. 24 Ductility versus fatigue life for annealed AISI-SAE 4340 steel

## Effect of Metallurgical Variables on Fatigue Behavior

The metallurgical variables having the most pronounced effects on the fatigue behavior of carbon and low-alloy steels are strength level, ductility, cleanliness of the steel, surface conditions, and aggressive environments. At least partly because of the characteristic scatter of fatigue testing data, it is difficult to distinguish the direct effects of other variables such as composition on fatigue from their effects on the strength level of steel.

**Strength Level.** For most steels with hardnesses below 400 HB (not including precipitation-hardening steels), the fatigue limit is about half the ultimate tensile strength. Thus, any heat treatment or alloying addition that increases the strength (or hardness) of a steel can be expected to increase its fatigue limit as shown in Fig. 21 for a low-alloy steel (AISI 4340). However, as shown in Fig. 25 for medium-carbon steel, a higher hardness (or strength) may not be associated with improved fatigue behavior in a low-cycle regime ( $<10^3$  cycles) because ductility may be a more important factor.

**Fig. 25** Effect of hardness level on plot of total strain versus fatigue life. These are predicted plots for typical medium-carbon steel at the indicated hardness levels.

**Ductility** is generally important to fatigue life only under low-cycle fatigue conditions. Exceptions to this include spectrum loading where there is an occasional overload with millions of smaller cycles, or extremely brittle materials where crack propagation dominates.

**Cleanliness** of a steel refers to relative freedom from nonmetallic inclusions. These inclusions generally have a deleterious effect on the fatigue behavior of steels (Fig. 26), particularly for long-life applications. The type, number, size, and distribution of nonmetallic inclusions can have a greater effect on the fatigue life of carbon and alloy steel than will differences in composition, microstructure, or stress gradients. Nonmetallic inclusions, however, are rarely the prime cause of the fatigue failure of production parts; if the design fatigue properties were determined using specimens containing inclusions representative of those in the parts, any effects of these inclusions would already be incorporated in the test results.

**Fig. 26** Effect of nonmetallic inclusion size on fatigue. Steels were two lots of AISI-SAE 4340H: one lot (lower curve) contained abnormally large inclusions; the other lot (upper curve) contained small inclusions.

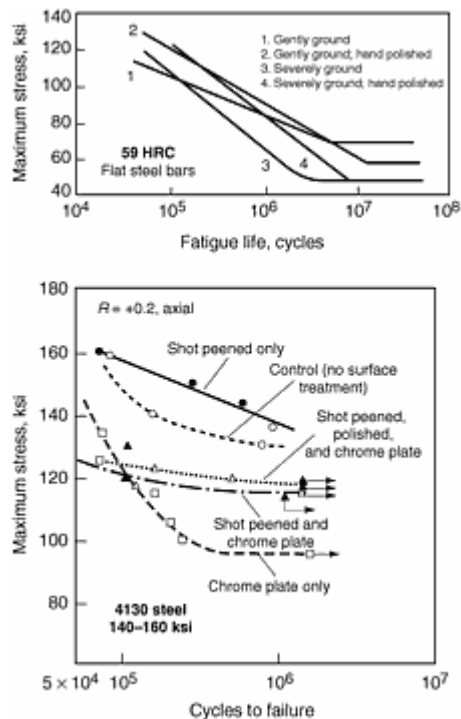

Large nonmetallic inclusions can often be detected by nondestructive inspection; steels can be selected on the basis of such inspection. Vacuum melting, which reduces the number and size of nonmetallic inclusions, increases the fatigue limit of 4340 steel, as can be seen in Table 5. Improvement in fatigue limit is especially evident in the transverse direction.

**Table 5** Influence of steelmaking practices on fatigue limit of SAE 4340 steel

	Electric furnace-melted	Vacuum-melted
Longitudinal fatigue limit, MPa (ksi)	800 (116)	960 (139)
Transverse fatigue limit, MPa (ksi)	545 (79)	825 (120)
Ratio transverse to longitudinal	0.68	0.86
Hardness, HRC	27	29

Determined in repeated-bending fatigue test ( $R = 0$ ).

**Surface conditions** of a metal part can significantly affect the resistance to fatigue. Surface imperfections and roughness reduce the fatigue limit of the part; this effect is most apparent for high-strength steels. Residual stresses also play a key role. Tensile residual stresses at the surface, such as those produced by rough grinding, reduce fatigue life (top of Fig. 27). Compressive residual stresses at the surface, such as those produced by shot peening, can improve fatigue resistance (bottom portion of Fig. 27).

**Fig. 27** Influence of surface roughness and finish on fatigue resistance of smooth specimens. Roughness and finish effects include some residual stress effects, as noted in test. Some surface treatments, such as hard chrome plating, can produce surface cracks, which result in a lower life.

Decarburization is the removal of carbon from the surface of a steel part; as indicated in Fig. 28, it significantly reduces the fatigue limit of steel. Decarburization of from 0.08 to 0.75 mm (0.003 to 0.030 in.) on AISI-SAE 4340 notched specimens heat treated to a strength level of 1860 MPa (270 ksi) reduces the fatigue limit almost as much as a notch with  $K_t = 3$ .

**Fig. 28 Effect of decarburization on the fatigue behavior of a steel**

When subjected to the same heat treatment as the core of the part, the decarburized surface layer is weaker and therefore less resistant to fatigue than the core. Hardening a part with a decarburized surface can also introduce residual tensile stresses, which reduce the fatigue limit of the material. Results of research studies have indicated that fatigue properties lost through decarburization can be at least partially regained by recarburization (carbon restoration in the surfaces) or by shot peening.

## **Embrittlement of Steels**

STEELS are susceptible to a number of embrittlement (loss of ductility) phenomena. Some of these affect a wide range of compositions, while others are specific to a rather narrow range of compositions. These problems promote brittle service failures that can be catastrophic or can reduce the service life of a component. This article reviews the embrittlement problems encountered during thermal treatment or elevated-temperature service. The forms of embrittlement associated with carbon and low-alloy steels that will be discussed include:

- Strain-age embrittlement (low-carbon steels)
- Blue brittleness (carbon steels)
- Quench-age embrittlement (low-carbon steels)
- Temper embrittlement (alloy steels)
- Tempered martensite embrittlement (ultrahigh-strength alloy steels)
- Graphitization (carbon steels and chromium-molybdenum alloy steels)
- Overheating (carbon and alloy steels)
- Quench cracking (medium-carbon alloy steels)

More highly alloyed steels are also susceptible to embrittlement phenomena. The types of embrittlement affecting stainless steels and maraging steels include:

- Sensitization (austenitic and duplex stainless steels)
- 475 °C, or 885 °F, embrittlement (ferritic stainless steels)
- Sigma-phase embrittlement (austenitic, ferritic, and duplex stainless steels)
- Thermal embrittlement (maraging steels)

Only the thermal embrittlement of maraging steels will be discussed in this article. Embrittlement mechanisms associated with stainless steels are described in the Section "Stainless Steels" in this Handbook.

In addition, steels (and other metals and alloys) can be embrittled by environmental conditions. The forms of environmental embrittlement include:

- Neutron embrittlement
- Hydrogen embrittlement
- Stress-corrosion cracking
- Liquid-metal and solid-metal embrittlement

These forms of embrittlement are described elsewhere in this Handbook (see, for example, the Section "Failure Analysis").

## **Strain-Age Embrittlement**

Strain aging occurs in low-carbon steels that are deformed certain amounts and then aged, which produces an increase in strength and hardness but a loss in ductility. The degree of deformation, or cold work, is important. Generally, about a 15% reduction in thickness provides the maximum effect. The resulting brittleness varies with the aging temperature and time. Aging at room temperature is very slow, requiring several months to obtain maximum embrittlement. As the aging temperature is increased, the time for maximum embrittlement decreases, with embrittlement occurring in a matter of minutes at about 200 °C (400 °F).

Strain aging may also lead to Lüders bands (stretcher-strain marks) on cold-formed low-carbon sheet components. These marks are cosmetic defects rather than cracks, but their presence on formed parts is unacceptable. During tensile loading, sheet steel that is susceptible to this defect exhibits nonuniform yielding followed by uniform elongation. The elongation at maximum load and the total elongation are reduced, decreasing cold formability. In a non-aluminum-killed sheet steel, a small amount of deformation, typically 1% reduction, suppresses the yield point for several months. This process is referred to as roller leveling or temper rolling. This process is more effective in eliminating the sharp yield point and preventing strain aging than stretching the steel through the Lüders strain, which requires about 4 to 6% reduction. However, if the material is not formed within the safe period, discontinuous yielding eventually returns and impairs formability.

Certain coating treatments, such as hot-dip galvanizing, can produce a high degree of embrittlement in areas that were cold worked the critical amount; this can lead to brittle fractures. To prevent this problem, the part can be annealed before it is galvanized.

## **Blue Brittleness**

Carbon steels generally exhibit an increase in strength and a reduction of ductility and toughness at temperatures around 300 °C (570 °F). Because such temperatures produce a bluish temper color on the surface of the specimen, this problem has been called blue brittleness. It is generally believed that blue brittleness is an accelerated form of strain-age embrittlement. Deformation in the blue-heat range, followed by testing at room temperature, produces an increase in strength that is greater than when the deformation is performed at ambient temperature. Blue brittleness can be eliminated if elements that tie up nitrogen, such as aluminum or titanium, are added to the steel (studies have shown that higher nitrogen contents lead to both blue brittleness and strain-age embrittlement).

## **Quench-Age Embrittlement**

If low-carbon steels are rapidly cooled from temperatures slightly below the lower critical temperature ( $A_{c1}$ ) of the steel, the hardness of the steel increases, with a resultant loss of ductility upon aging at room temperature. As with strain-aging, quench-age embrittlement is a function of time at the aging temperature until the maximum degree of embrittlement is reached. An aging period of several weeks at room temperature is required for maximum embrittlement.

A decrease in the quenching temperature decreases the extent of the embrittlement. Quenching from temperatures of 560 °C (1040 °F) and below does not produce quench-age embrittlement. Steels with carbon contents of 0.04 to 0.12% appear most susceptible to quench-age embrittlement; increasing the carbon content above 0.12% reduces the effect. Quench-age embrittlement results from (a) precipitation of solute carbon at existing dislocations and (b) precipitation hardening because of differences in the solid solubility of carbon in ferrite at different temperatures.

## **Temper Embrittlement**

Temper embrittlement (also known as temper brittleness, two-step temper embrittlement, or reversible temper embrittlement) is associated with tempered alloy steels that are heated within, or slowly cooled through, a critical temperature range, generally 300 to 600 °C (570 to 1110 °F) for low-alloy steels. This treatment causes a decrease in toughness as determined with Charpy V-notch impact specimens. It is a particular problem for heavy-section components, such as pressure vessels and turbine rotors, that are slowly cooled through the embrittling range after tempering and also experience service at temperatures within the critical range.

Temper embrittled steels exhibit an increase in their ductile-to-brittle transition temperature (DBTT) and a change in fracture mode in the brittle test temperature range from cleavage to intergranular. The DBTT can be assessed in several ways. The most common is the temperature for 50% ductile and 50% brittle fracture (50% fracture appearance transition temperature, or FATT), or the lowest temperature at which the fracture is 100% ductile (100% fibrous criterion). Transition temperatures based on absorbed energy values are not normally employed. Temper embrittlement is reversible;

that is, the toughness of embrittled steels can be restored by tempering them above the critical region, followed by rapid cooling (e.g., water quenching). This decreases the DBTT and changes the low-temperature (that is, below the 50% FATT) intergranular brittle appearance back to the cleavage mode.

Temper embrittlement occurs only in alloy steels, not in plain carbon steels, and the degree of embrittlement varies with alloy steel composition. Therefore, the alloying elements present, and their combinations and levels, are important. Both bulk composition and impurity levels are important, although without the latter, temper will not occur. The most potent impurity elements are antimony, phosphorus, tin, and arsenic (in order of decreasing potency). Manganese and silicon also promote embrittlement. Alloys containing nickel and chromium in combination are more susceptible than those that contain nickel or chromium separately. Molybdenum additions are effective in retarding or eliminating temper embrittlement when impurities are present. However, to be effective, the molybdenum must be dissolved in the ferritic matrix, not tied up as carbides.

## **Tempered Martensite Embrittlement**

Tempered martensite embrittlement (TME, also known as one-step temper embrittlement and as 350 °C, or 500 °F, embrittlement) of high-strength alloy steels occurs upon tempering in the range of 205 to 370 °C (400 to 700 °F). It differs from temper embrittlement in the strength of the material and the temperature exposure range. In temper embrittlement, the steel is usually tempered at a relatively high temperature, producing lower strength and hardness, and embrittlement occurs upon slow cooling after tempering and during service at temperatures within the embrittlement range. In TME, the steel is tempered within the embrittlement range, and service exposure is usually at room temperature. This is why temper embrittlement is often called two-step temper embrittlement, while TME is often called one-step temper embrittlement.

It is well established that lower bainite is also embrittled when tempered in the range of 205 to 370 °C (400 to 700 °F). Other structures, such as upper bainite and pearlite/ferrite, are not embrittled by tempering in this region.

While temper embrittlement is evaluated by the change in the DBTT, most studies of TME have evaluated only the change in room-temperature impact energy. In general, when an as-quenched alloy steel is tempered, the toughness at room temperature increases with tempering temperature, up to about 200 °C (390 °F). With further increases in tempering temperature, the toughness decreases. Then, with increasing tempering temperatures above about 400 °C (750 °F), the toughness increases again. This change in toughness with tempering temperature is not apparent when examining hardness or tensile strength data, which generally decrease with increasing tempering temperatures.

The cause of TME is not as well defined as the cause of temper embrittlement. 500 °F embrittlement is believed to be caused by ferrite networks resulting from precipitation of cementite platelets along prior austenite grain boundaries. However, some investigators believe that the precipitation of grain-boundary cementite platelets as such is responsible for TME.

Steels containing substantial amounts of chromium or manganese are highly susceptible to TME. Aluminum contents above 0.04% reduce embrittlement, and additions of 0.1% aluminum usually eliminate the problem. Some degree of embrittlement has been observed when phosphorus, antimony, arsenic, tin, silicon, manganese, or nitrogen additions were made to high-purity steels. Additions of nitrogen produced intergranular fractures, but the other embrittling agents did not. (Commercial grades of steel that are subjected to TME treatments fracture intergranularly.)

Embrittlement in low-alloy steels heat treated to high strength levels can be minimized by:

- Developing special steels with retarded martensite-tempering characteristics
- Developing steels with faster rates of martensite tempering
- Using steels capable of transformation to 100% upper bainite at the desired strength level and section size
- Avoiding tempering in the region of susceptibility
- Using the lowest possible carbon content consistent with the desired strength level

## **Graphitization**

Graphitization of carbon and carbon-molybdenum steel piping during service at elevated temperatures above 425 °C (800 °F) has caused numerous failures in steam power plants and refineries. Graphite formation generally occurs in a narrow region in the heat-affected zone of a weld where the metal has been briefly heated above the lower critical temperature. The graphitization tendency of carbon and carbon-molybdenum steels is increased when the aluminum content exceeds about 0.025%. Steels deoxidized with silicon may also be susceptible to graphitization. Deoxidation with titanium usually will produce good resistance to graphitization. Carbon-molybdenum steels exhibit greater resistance to graphitization than do carbon steels.

The degree of embrittlement depends on the distribution, size, and shape of the graphite. The severity of graphitization is frequently evaluated by bend testing. If graphitization is detected in its early stages, the material often can be rehabilitated by normalizing and tempering just below the lower critical temperature. Steel that has undergone more severe graphitization cannot be salvaged in this manner; the defective region must be cut out and rewelded, or the section must be replaced. Carbon and carbon-molybdenum steels can be rendered less susceptible to graphitization by tempering just below the lower critical temperature.

## Overheating

The overheating of steels occurs when they are heated to excessively high temperatures prior to hot working. Heating at even higher temperatures causes incipient grain-boundary melting, a problem known as burning. Thus, overheating occurs in the temperature range between the safe range normally used prior to hot working and the higher range where liquation begins. Hot working after burning generally results in the tearing or rupture of the steel due to the liquid in the grain boundaries. Hot working after overheating generally does not result in cracking; if sufficient hot reduction occurs, the influence of overheating may be minor or negligible. If the degree of hot reduction is small, mechanical properties, chiefly toughness and ductility, will be affected.

Fracture surfaces of overheated steels that are given limited hot reduction often exhibit a coarse-grain faceted appearance. Such features are most evident after quenching and tempering to develop optimum toughness.

Although the mechanical properties of burnt steels are always very poor, the mechanical properties of overheated steels show considerable scatter. For tensile tests, the elongation and reduction of area are most affected by overheating and decrease with increasing heating temperature. Fracture faceting and substantial decreases in tensile ductility normally are observed after severe overheating.

Impact properties are usually more sensitive to overheating than tensile ductility. In examining impact test results, several interrelated features should be examined: change in upper-shelf energy, impact strength transition temperature, and the presence of facets.

## Quench Cracking

The production of fully martensitic microstructures in steels requires a heat treatment cycle that involves quenching after austenitization. The composition of the steel, its size, and the desired depth of hardening dictate the required quench medium. Certain steels are known to be susceptible to cracking during or slightly after quenching. This is a relatively common problem for tool steels, particularly those that require liquid quenching.

Numerous factors can contribute to cracking susceptibility:

- Carbon content
- Hardenability
- $M_s$  temperature (the temperature at which martensite starts to form)
- Part design
- Surface quality
- Furnace atmosphere
- Heat treatment practice

As the carbon content is raised, the  $M_s$  and the  $M_f$  (the temperature at which martensite formation ends) decrease, and the volumetric expansion and transformation stresses accompanying martensite formation increase. In general, steels with

less than 0.35% C are free of quench cracking problems. Such low-carbon steels have higher  $M_s$  and  $M_f$  temperatures that allow some stress relief to occur during the quench. Also, transformation stresses are lower, and the lower strength of the martensite formed (low-carbon lath martensite) can accommodate the strains more readily than a higher-carbon steel.

Alloy steels with ideal critical diameters of 4 or greater are more susceptible to quench cracking than lower-hardenability steels. Quench crack sensitivity also increases as the severity of the quench rate increases. Control of the austenitizing temperature is also important, particularly for high-carbon tool steels. Excessive retained austenite and coarse-grain structures promote quench cracking. Quench uniformity is important, particularly when liquid quenchant is employed. When high-carbon steels are quenched to form martensite, they are in a highly stressed condition. Therefore, tempering must be done immediately after quenching to relieve these stresses and minimize the risk of cracking. Surface quality is also very important because seams, laps, tool marks, stamp marks, and so on act as stress concentrators to locate and enhance quench cracking susceptibility.

## Thermal Embrittlement of Maraging Steels

Maraging steels fracture intergranularly at low impact energies if improperly processed after hot working. This problem, known as thermal embrittlement, occurs when maraging steels that have been heated above 1095 °C (2000 °F) are slowly cooled through, or held within, the temperature range of 980 to 815 °C (1800 to 1500 °F). The embrittlement is caused by the precipitation of TiC and/or Ti(C,N) on the austenite grain boundaries during cooling through, or holding within, the critical temperature range. The degree of embrittlement increases with time within the critical range. Increased levels of carbon and nitrogen render maraging steels more susceptible to thermal embrittlement. Auger analysis has shown that embrittlement begins with the diffusion of titanium, carbon, and nitrogen to the grain boundaries, and the appearance of TiC or Ti(C,N) precipitates represent an advanced stage of embrittlement.

## Notch Toughness of Steels

TOUGHNESS is an indication of the capacity of a steel to absorb energy and is dependent on strength as well as ductility. Notch toughness is an indication of the capacity of a steel to absorb energy when a stress concentrator or notch is present. All carbon and low-alloy steels undergo a ductile-to-brittle transition as the temperature is lowered. Depending on chemical composition, product processing, and service environment, this transition can occur at temperatures from several hundred degrees above to several hundred degrees below room temperature. A number of notch impact tests have been developed to screen and rate steel product toughness on a relative basis and to determine the ductile-to-brittle transition for a specific steel product. Examples of various notch toughness tests are:

Test	ASTM specification
Charpy V-notch	<b>E 23</b>
Izod cantilever-beam	<b>E 23</b>
Drop-weight nil-ductility	<b>E 208</b>
Drop-weight tear	<b>E 436</b>
Dynamic tear	<b>E 604</b>

Of all the notched tests, the most widely applied is the Charpy V-notch test.

An illustration of a Charpy testing machine is shown in Fig. 29. The Charpy specimen shown in Fig. 30 is generally oriented so that the root of the notch lies perpendicular to the surface of the component being tested. The orientation (longitudinal or transverse) of the specimen is selected according to the appropriate product specification. The specimen is held for 10 min at the test temperature and then broken in the Charpy-type impact tester by a single blow of a freely swinging pendulum. Upon the breaking of the Charpy specimen, three criteria are commonly measured. The loss of energy in the pendulum swing provides the energy in terms of joules (foot-pounds of force) absorbed in breaking the specimen. The fracture appearance of the broken specimen can be rated in terms of ductile and brittle fracture modes. Also, the lateral expansion at the base of the fracture opposite the notch can be measured. Any of these three criteria can be plotted versus temperature to obtain a ductile-to-brittle transition curve. The most commonly used measurement is energy absorbed. For steel product specifications, a specific Charpy V-notch requirement can be negotiated between the customer and supplier (for example, a minimum energy absorbed at a specified test temperature).

**Fig. 29** Typical Charpy testing machine. The coupon is chilled to the desired temperature, then quickly placed into the anvil to be broken.

**Fig. 30** Charpy V-notch specimen used for the evaluation of notch toughness (ASTM E 23). Dimensions given in millimeters

## Ductile-to-Brittle Transition

In body-centered cubic metals such as plain carbon and low-alloy steels, a unique characteristic is found during impact testing over a temperature range of approximately 120 to -130 °C (250 to -200 °F). This characteristic is a ductile-to-brittle transition in toughness. At the higher end of the temperature range, the fracture behavior is ductile with an accompanying large degree of plastic deformation. The ductile mode of fracture is most commonly associated with microvoid coalescence. At the lower end of the range the fracture is brittle, and the mode of fracture is cleavage with little or no plastic deformation. Figure 31 is a Charpy curve showing a typical ductile-to-brittle transition in steel. The plot shows absorbed energy versus test temperature. The stable region at the higher temperatures is called the upper shelf, and

the stable region at the lower temperatures is called the lower shelf. The region between the upper and lower shelves that displays a mixture of ductile and cleavage fracture is called the transition region.

**Fig. 31** Charpy curve of impact energy versus test temperature for a Ni-Cr-Mo steel

Figure 32(a) shows an example of the fracture surface of a broken Charpy specimen from a low-alloy steel tested at the upper-shelf region. The absorbed energy was 117 J (86 ft · lbf). The fracture appears as a ductile, dimplelike surface with many shear lips. Inclusions, in this case titanium nitrides (square particles) and manganese sulfides (round particles), are usually located at the center of each large dimple. These inclusions initiated the formation of a void, which created the dimple. Figure 32(b) shows the typical cleavage fracture surface at the lower-shelf region for the same steel. The absorbed energy was 6.1 J (4.5 ft · lbf). In fractograph, no regions of ductile tearing or shear lips are present.

**Fig. 32** SEM micrographs showing the fracture surfaces of broken Charpy V-notch specimens (Ni-Cr-Mo steel) tested in the (a) upper-shelf region and (b) lower-shelf region of the Charpy curve shown in Fig. 31. Both 670×

From the Charpy curve shown in Fig. 31, a transition temperature can be determined. There are a number of criteria for transition temperature, one being the median temperature of this transition range. In Fig. 31 this would be 25 °C (75 °F). The transition temperature could also be the temperature at a specified absorbed energy (20 J or 15 ft · lbf, for example). Thus, in Fig. 31, the 20 J (15 ft · lbf) transition temperature would be -30 °C (-25 °F).

In addition to absorbed energy, other important measurements can be obtained from the Charpy test. For example, the lateral expansion can be measured on the broken Charpy specimen at the edge of the specimen opposite to the notch. Lateral expansion is used as a measure of notch toughness similar to absorbed energy. Another important measurement is fracture appearance transition temperature (FATT). To obtain this value, the percentage of shear (fibrous fracture) in the fracture surface is measured. The 50% FATT represents the temperature at 50% shear (50% fibrous). The 100% FATT would represent the temperature at 100% shear. Figure 33 shows a plot of percent shear versus test temperature for the same steel as in Fig. 31. From Fig. 33 the 50% FATT is 25 °C (75 °F). Note that this is the same temperature as determined from the data plotted in Fig. 31. In some steels the energy-established transition temperature and FATT may not be the same. In some steels it may be difficult to measure percent shear because of woody fracture surfaces caused by stringer-type inclusions, and so on. For these cases, it would be more appropriate to use the lateral expansion and absorbed-energy measurements to obtain a more accurate transition temperature.

Fig. 33 Charpy curve of percent shear versus test temperature for the same Ni-Cr-Mo steel in Fig. 31

Selection of the most appropriate method of measuring transition temperature for a given application is difficult and requires an understanding of both toughness testing and service behavior. Often, additional tests are needed to establish a correlation between the transition temperature determined using a certain method and the service behavior of a specific structure made of the same material.

## Effects of Composition

The composition of a steel, as well as its microstructure and processing history, significantly affects both the ductile-to-brittle transition temperature range and the energy absorbed during fracture at any particular temperature. The effect of the various alloying elements and those of microstructural and processing variables are intimately interrelated; in practice, it is difficult to change one variable without affecting another. Each individual alloying element contributes to notch toughness to varying degrees.

**Carbon.** Increasing carbon content increases transition temperature and decreases upper-shelf fracture energy primarily as a result of increased strength and hardness. These effects, measured by Charpy V-notch impact tests, are shown in Fig. 34. Carbon is one of the most potent alloying elements in its effect on notch toughness and strength. Consequently, for maximum toughness, the carbon content should be kept as low as possible, consistent with strength requirements. Low-carbon steels tend to have very steep transition curves.

Fig. 34 Variation in Charpy V-notch impact energy with temperature for normalized plain carbon steels of

various carbon contents

**Manganese** has a variety of effects on transition temperature. In low-carbon steels, it can substantially reduce the transition temperature, as shown in Fig. 35. In higher-carbon steels, manganese may be less beneficial. In a hardened and tempered steel, manganese can have the opposite effect, as illustrated in Fig. 36. Manganese can make the steel susceptible to temper embrittlement, and it may cause the formation of less tough upper bainite (rather than fine pearlite) during normalizing.

**Fig. 35** Variation in Charpy V-notch impact energy with temperature for furnace-cooled Fe-Mn-0.05C alloys containing various amounts of manganese

**Fig. 36** Variation in Charpy V-notch impact energy with temperature for alloy steels containing 0.35% C, 0.35% Si, 0.80% Cr, 3.00% Ni, 0.30% Mo, 0.10% V and the indicated amounts of manganese. The steels were hardened and tempered to a yield strength of approximately 1175 MPa (170 ksi). The microstructures of these steels contained tempered martensite.

**Sulfur.** The effect of sulfur on the notch toughness of steels is directly related to deoxidation practice. For rimmed, semi-killed, and silicon-killed steels, sulfur in amounts up to about 0.04% has a negligible effect on notch toughness. However, for silicon-aluminum-killed steels, a reduction in sulfur content can substantially increase upper-shelf energy.

**Phosphorus** has a strongly deleterious effect on the notch toughness of steel. It raises the 50% FATT about 7 °C (13 °F) for each 0.01% P and reduces upper-shelf energy. In addition, phosphorus increases the susceptibility of some steels to temper embrittlement.

**Silicon**, used in amounts of 0.15 to 0.30% to deoxidize steels, generally lowers the ductile-to-brittle fracture transition and raises upper-shelf energy. Compared to rimmed or semikilled steels, silicon-killed steels are cleaner and have more uniform ferrite grains. These effects are probably caused by variations in steelmaking practice characteristic of the deoxidation methods used, rather than by the silicon content.

**Nitrogen**, by itself, lowers the upper-shelf energy and raises the transition temperature. However, most nitrogenized steels are deoxidized with silicon and aluminum, both of which combine with nitrogen. Aluminum nitrides formed during deoxidation serve to stabilize grain size and thus improve the notch toughness of these steels.

**Nickel** is useful for improving the notch toughness of steels at low temperatures. Ferritic steels with high nickel content (2 <sup>1</sup>/<sub>4</sub> to 9% Ni) are used for applications involving exposure to temperatures from 0 to -195 °C (32 to -320 °F). Nickel is less effective in improving the toughness of medium-carbon steels than low-carbon steels. Some high-nickel alloy steels, such as maraging steels and austenitic stainless steels, do not exhibit the typical ductile-to-brittle transition (austenitic steels, being face-centered cubic, do not have a ductile-to-brittle transition). The high nickel content reduces upper-shelf fracture energy--but to a level that is still quite acceptable for most applications.

**Chromium** raises the transition temperature slightly. In steels having chromium contents in excess of 0.90%, it is very difficult to develop those microstructures and mechanical properties that are typical of plain carbon steels; therefore, impact test results are not comparable. Chromium is usually added to increase hardenability. The increase in hardenability is often sufficient to develop a martensitic microstructure that provides high upper-shelf energy. Medium-carbon, straight chromium alloy steels, such as 5140, are susceptible to embrittlement when quenched to martensite and tempered between 370 and 575 °C (700 and 1070 °F).

**Molybdenum** in the typical quantities in alloy steels (up to about 0.40%) raises the 50% FATT. Molybdenum is frequently used to increase hardenability, and it influences notch toughness primarily through its effect on microstructure. About 0.5 to 1.0% Mo can be added to alloy steels to reduce their susceptibility to temper embrittlement, but it is effective only for relatively short heating times at embrittling temperatures. Molybdenum appears to delay rather than eliminate temper embrittlement, because steels containing small amounts of this element have become embrittled upon prolonged exposure within the embrittling temperature range.

**Boron**. For quenched and tempered steels, a practical way of improving toughness without reducing strength is to use a boron-containing grade of steel with a lower carbon content. However, the benefit of boron is applicable only to quenched and tempered steels; boron reduces the toughness of as-rolled, as-annealed, and as-normalized steels.

**Copper** in steels that have not been subjected to precipitation hardening appears to be moderately beneficial to low-temperature notch toughness. However, copper promotes precipitation hardening in steel and, as a result, may adversely affect notch toughness, particularly if the tempering temperature is between 400 and 565 °C (750 and 1050 °F).

**Vanadium, niobium, and titanium** are most often used in steels that receive controlled thermomechanical treatment. Consequently, the toughness of steels containing these elements is largely a function of mill processing. When the steel is finished at temperatures below about 925 °C (1700 °F) (which is characteristic of certain HSLA steels), vanadium, niobium, and titanium improve toughness primarily by refining the ferrite grain size. At higher finishing temperatures, these elements may be detrimental to toughness.

**Zirconium, titanium, calcium, and the rare earths** can be used to control the shape of manganese sulfide inclusions, causing the inclusions to be spherical rather than elongated. Spherical inclusions raise upper-shelf energy and minimize the anisotropic nature of notch toughness; these effects are particularly useful in HSLA sheet and thin plate.

## Effects of Manufacturing Practices

**Deoxidation Practice.** The effect of deoxidation practice on the notch toughness of steels is directly traceable to the presence of those alloying elements and impurities characteristic of the deoxidation practice. Rimmed steels typically contain appreciable quantities of oxygen and nitrogen; soundness and homogeneity of rimmed steel ingots are often poor. These characteristics of rimmed steels account for their poor notch toughness. Killed steels, particularly silicon-aluminum-killed steels, have lower transition temperatures and higher upper-shelf energy values than rimmed steels. Semikilled steels have toughness properties between those of rimmed and killed steels. A comparison of the notch toughness of these three types of steel is shown in Fig. 37.

**Fig. 37** Effects of deoxidation practice on notch toughness. Charpy V-notch impact energy varies with temperature for (a) rimmed, (b) semikilled, and (c) killed plain carbon steels.

**Hot Deformation Temperature.** The effect of hot deformation on the notch toughness of steel can be directly related to the microstructure produced during hot rolling and forging. Steels deformed at temperatures above about 980 °C (1800 °F) undergo considerable recrystallization and grain growth during rolling; the structure thus obtained is only slightly affected by the rolling process. The notch toughness of steels deformed at such high temperatures is largely determined by the size to which the austenite grains grow after recrystallization. The influence of grain size on transition temperature is shown in Fig. 38. When steels are deformed at lower temperatures, recrystallization and growth of austenite grains cannot proceed to the extent possible at higher deformation temperatures. Thus, the transition temperature can be significantly lowered by deforming in the lower portion of the austenite temperature range. Figure 39 shows the effect of finishing temperature during hot rolling on the 54 J (40 ft · lbf) transition temperature of a carbon-manganese steel.

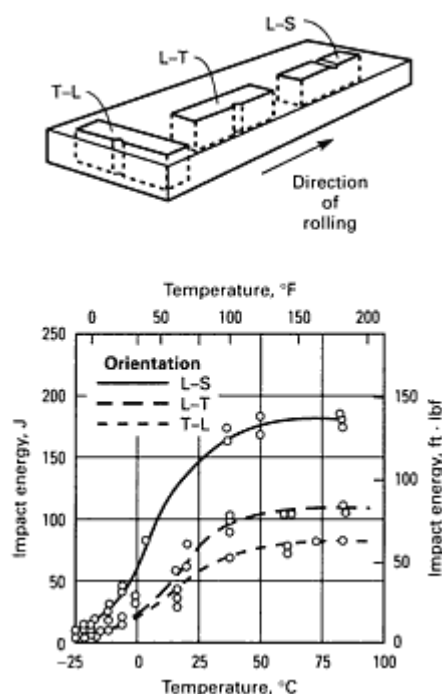

**Fig. 38** Effect of grain size on transition temperature. Variation in fracture appearance transition temperature with ferritic grain size for 0.11% C mild steel. Transition temperature varies linearly with  $\ln(d^{-1/2})$  and is lower for fine-grained steel.

**Fig. 39** Effect of finishing temperature on notch toughness. The 54 J (40 ft · lbf) Charpy V-notch transition temperature varies with hot-rolling finishing temperature for silicon-killed 0.24C-1.69Mn steel.

**Toughness Anisotropy.** Steels can acquire strongly anisotropic microstructures as a result of working. Anisotropic microstructures are often indicative of the anisotropy of mechanical properties, particularly notch toughness. Anisotropy, therefore, is an important consideration in the design and fabrication of rolled, forged, drawn, or extruded steel products.

The effect of anisotropy on the notch toughness of as-rolled low-carbon steel plate is shown in Fig. 40. Specimens parallel to the rolling direction (orientations L-S and L-T) show higher impact energies throughout the ductile-to-brittle fracture transition temperature range than do specimens perpendicular to the rolling direction (orientation T-L). Orientation L-T is the standard longitudinal specimen, and orientation T-L is the standard transverse specimen referred to in ASTM E 23. Therefore, when a part is to be cut from plate, it is essential to specify the orientation of the part relative to the rolling direction.

**Fig. 40** Variation of Charpy V-notch impact energy with notch orientation and temperature for steel plate containing 0.012% C

The rolling schedule during the fabrication of plate affects anisotropy. For example, if the steel had been cross rolled so that it received about the same amount of hot reduction in both directions, the curves for orientation would nearly coincide at a position between the L-T and T-L curves for material reduced by conventional rolling.

Regardless of the amount of cross rolling, specimens that are notched parallel to the plate surface (orientation L-S) absorb greater amounts of energy than those notched at right angles to the plate surface (orientation L-T). In the experiment described in Fig. 40, the temperature range over which transition occurred (and also the shear-fracture transition temperature) was the same regardless of notch or specimen orientation. In other experiments, transition temperatures for both energy absorption and fracture appearance were higher for transverse orientations than for longitudinal orientations.

**Section and Part Size.** Variations in fracture behavior can also result from differences in metallurgical structure between thin and thick stock of a given material. For example, the transition temperature of hot rolled low-carbon steel varies with plate thickness, as shown in Fig. 41. In these tests, specimen size was constant, yet ductile-to-brittle energy transition still increased with increasing plate thickness. Reduction of toughness with increasing plate thickness is not limited to low-carbon steel but apparently applies to all steels. Because of the characteristics of normal commercial processing, the metallurgical structure of thick stock is different from that of thin stock, resulting in inherently lower toughness for the thicker stock. More important, the probability that a given part will contain a crack or a flaw of critical size (or greater) increases with increasing stock thickness or part size. The lower inherent toughness of thick stock and the higher probability that thick stock contains a large crack or flaw, combined with the plane-strain conditions inherent in thick members, account for the fact that large structures are more susceptible to brittle fracture than small structures.

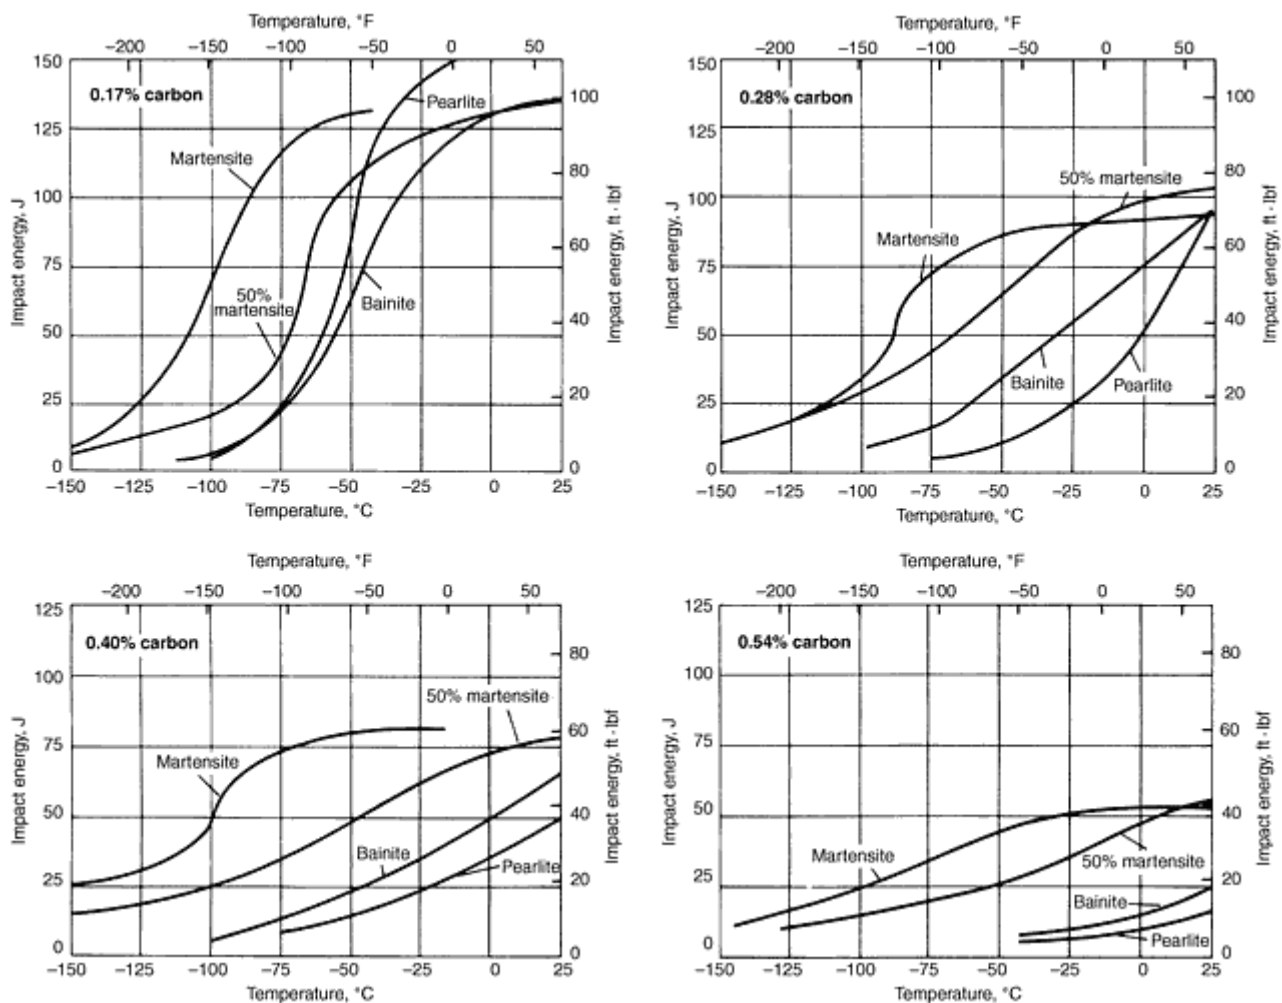

**Fig. 41** Effect of plate thickness on notch toughness for aluminum semikilled steel (0.14C-1.25Mn-0.007S-0.020P-0.021Nb)

## Effects of Microstructure

Like most mechanical properties, the notch toughness of steel can usually be traced directly to microstructure. Because the microstructures of steel are readily observed and classified, it is convenient to attribute the various mechanical properties to the microstructure, even though the properties might also be attributed to the composition of manufacturing history of the steel.

**Microstructural Constituents.** In general, of the major microstructural constituents found in steels, pearlite and ferrite have the highest transition temperature, followed by upper bainite and, finally, tempered martensite or lower bainite. Values of notch toughness for similar steels having different carbon contents and microstructural constituents are shown in Fig. 42. To facilitate comparison of the different microstructures, these steels were tempered to uniform strength levels before testing. In practice, the cooling or quenching rate determines the resulting microstructure or mixture of microstructures in a particular steel. The transformation characteristics are controlled by the cooling rate, alloy content, austenitizing temperature, and austenite grain size.

**Fig. 42** Effect of microstructure on notch toughness. Variation in Charpy V-notch impact energy with microstructure and carbon content for 0.70% Cr, 0.32% Mo steel. Pearlitic structure was formed by transformation at 650 °C (1200 °F). A structure with 50% martensite was formed by quenching in lead at 450 °C (850 °F) for 10, 19, 35, and 100 s for the 0.17 to 0.54% C steels, respectively. Fully martensitic structures were formed by quenching the 0.17 and 0.28% C grades in water and oil quenching the grades containing 0.40 and 0.54% C. Bainite was formed by quenching in lead at 450 °C (850 °F) and holding 1 h, except that the 0.54% C grade was held 3 h. All specimens were tempered to the same hardness level.

Generally, treatments that produce microstructures with inferior room-temperature toughness also raise transition temperature. Precipitates and second-phase particles are detrimental to toughness, especially if located at grain boundaries. A spheroidization treatment of pearlitic steels can improve toughness by reducing strength and eliminating ferrite lamellae (which have a platelike form and thus are paths of easy cleavage fracture). Spheroidization also improves toughness by changing the shape of the brittle cementite lamella of pearlite to innocuous spherical particles. In addition, steels can lose toughness because of various embrittlement phenomena such as temper embrittlement.

Steels having a tempered martensitic or a lower bainitic structure offer an optimum balance of strength and toughness. When observed under a light microscope, these two microconstituents are indistinguishable. Only by transmission electron microscopy can one distinguish tempered martensite from lower bainite. Which of these two microconstituents provides better notch toughness has been a subject of controversy.

Isothermally transformed lower bainite has superior toughness, and a slightly lower transition temperature, than tempered martensite of the same strength (see Fig. 43). However, mixed structures, which result from incomplete bainitic treatments causing partial transformation to martensite, have lower toughness and much higher transition temperatures than either 100% tempered martensite or 100% lower bainite. Thus, it is important that bainitic treatments be carried to completion to avoid the adverse effects of mixed structure.

**Fig. 43** Variation in Charpy V-notch impact energy with temperature for specimens of 4340 steel having 100% tempered martensite and 100% bainite microstructures. All specimens were austenitized for 30 min at 845 °C (1550 °F) in neutral salt. 100% bainite was produced by isothermal transformation for 1 h at 315 °C (600 °F) in agitated salt. 100% tempered martensite was produced by quenching in agitated oil at 50 to 55 °C (120 to 135 °F) and tempering at 315 °C (600 °F). All specimens had the same tensile strength.

Finally, the presence of austenite inhibits the fast propagation of cleavage fracture in some ferritic and martensitic steels.

## Fracture Toughness of Steels

FRACTURE-MECHANICS TECHNOLOGY has significantly improved the ability to design safe and reliable structures. The application of fracture-mechanics concepts has identified and quantified the primary parameters that affect structural integrity. These parameters include the magnitude and range of the applied stresses; the size, shape orientation, and rate of propagation of the existing crack; and the fracture toughness of the material.

Linear-elastic fracture-mechanics technology is based on an analytical procedure that relates the stress-field magnitude and distribution in the vicinity of a crack tip to the nominal stress applied to the structure; to the size, shape, and orientation of the crack or cracklike imperfection; and to the material properties. The stress-field equations show that the magnitude of the elastic stress field can be described by a single parameter,  $K$ , which is designated the "stress-intensity factor," as will be briefly described below.

## Fracture Toughness Properties

Because fracture mechanics properties are being examined for a broad spectrum of steels with extreme variations in strength, composition, and microstructure, this article will also attempt to present typical data for several classes of steels including:

- Ferrite-pearlite steels (plain carbon, carbon-manganese, and HSLA steels) with nominal yield strengths ranging from approximately 240 to 470 MPa (35 to 70 ksi)
- Quenched-and-tempered alloy steels (low and medium carbon content) with yield strength levels ranging from approximately 600 to 900 MPa (90 to 130 ksi)
- Ultrahigh-strength steels with yield strength levels approaching or exceeding approximately 1400 MPa (200 ksi) depending on the heat treatment. This group includes medium-carbon quenched-and-tempered steels, high fracture toughness Fe-Ni-Co steels, and 18% Ni maraging steels

Additional information on these steels, including compositions, applicable specifications, and minimum mechanical property requirements, can be found in other articles contained within this Section.

**Fracture Toughness versus Yield Strength.** The relationship between fracture toughness and yield strength for the three steel classes listed above is shown in Fig. 45. As this figure indicates, fracture toughness generally decreases with increasing yield strength for higher strength steels, and high-fracture-toughness steels have ductile (low-carbon) martensite and retained metastable austenite as dominant phases in the microstructure. Steels that contain predominantly ferritic and pearlitic structures have relatively low fracture toughness. Table 6 summarizes the effects of microstructure on toughness.

**Table 6 Effects of microstructural variables on fracture toughness of steels**

Microstructural parameter	Effect on toughness
Grain size	<b>Decrease in grain size increases <math>K_{Ic}</math> in austenitic and ferritic steels</b>
Unalloyed retained austenite	<b>Marginal increase in <math>K_{Ic}</math> by crack blunting</b>
Alloyed retained austenite	<b>Significant increase in <math>K_{Ic}</math> by transformation-induced toughening</b>
Interlath and intralath carbides	<b>Decrease <math>K_{Ic}</math> by increasing the tendency to cleave</b>
Impurities (P, S, As, Sn)	<b>Decrease <math>K_{Ic}</math> by temper embrittlement</b>
Sulfide inclusions and coarse carbides	<b>Decrease <math>K_{Ic}</math> by promoting crack or void nucleation</b>
High carbon content (>0.25%)	<b>Decrease <math>K_{Ic}</math> by easily nucleating cleavage</b>
Twinned martensite	<b>Decrease <math>K_{Ic}</math> due to brittleness</b>
Martensite content in quenched steels	<b>Increase <math>K_{Ic}</math></b>
Ferrite and pearlite in quenched steels	<b>Decrease <math>K_{Ic}</math> of martensitic steels</b>

**Effects of Alloy Chemistry.** The influence of alloying additions on fracture toughness can be appreciated by comparing the toughness values of the quenched-and-tempered steel (4340) with those of the maraging steel. The major alloying chemistry differences here are carbon content, which is low for the maraging steels (0.03%) but higher for the quenched-and-tempered steels (more than 0.25%); nickel content, which is 18% for maraging steels; and titanium content, which is added as a strengthener in maraging steels. As a generalization, it may be inferred that carbon and strong carbide formers tend to decrease toughness in ultrahigh-strength steels.

Because alloy chemistry affects other characteristics such as hardenability, tempering response, strength, and ductility (Ref 7), it is very difficult to separate the effects of chemistry on fracture toughness from the effects of other variables. In one series of experiments in which strength was held constant (Ref 8, 9), an increase in nickel content of about 5% increased fracture toughness by about 50% in the transition, temperature range, as shown in Fig. 46(a). Here, the yield strength was 1175 MPa (170 ksi) at room temperature. On the other hand, for lower-strength steels with yield strengths ranging from 500 to 700 MPa (73 to 102 ksi) at -100 °C (-150 °F), addition of 3.5% Ni increased fracture toughness by more than 100% (Ref 10). This is illustrated in Fig. 46(b). It should be noted that moderate additions of nickel mainly improve low-temperature fracture toughness through resistance to cleavage, and that little effect may be seen at higher temperatures at which microvoid coalescence is the fracture mode. Such is the case in Fig. 46(a) at temperatures in the upper-shelf region.

**Fig. 46** Effect of nickel content on fracture toughness of several steels. (a) High-strength steels containing 0.35% C, 0.65% Mn, 0.35% Si, 0.80% Cr, 0.30% Mo, 0.10% V, and various amounts of nickel; all steels hardened to a yield strength of 1175 MPa (170 ksi). Source: Ref 8, 9. (b) Lower-strength steels (those containing 0 and 0.5% Ni) with yield strengths ranging from 500 to 700 MPa (73 to 102 ksi) at -100 °C (-150 °F). Source: Ref 10

It is well known that decreasing the carbon content decreases the transition temperature in ferrite-pearlite steels. This trend is less prevalent in ultrahigh-strength steels if strength is maintained at a constant level by tempering. The effect of carbon content on the fracture toughness transition curves for alloy steels containing 0.28, 0.35, and 0.41% C, with strength maintained at 1175 MPa (170 ksi), is illustrated in Fig. 47. There is little effect in the transition temperature range; however, there is a substantial effect in the upper-shelf region, where microvoid coalescence (ductile rupture) is the fracture mode.

**Fig. 47** Effect of carbon content and testing temperature on fracture toughness of alloy steels. Data are for steels containing 0.65% Mn, 0.35% Si, 0.80% Cr, 3.00% Ni, 0.30% Mo, 0.10% V, and various amounts of carbon; all steels were hardened and tempered to a yield strength of approximately 1175 MPa (170 ksi). Source: Ref 8, 9

**Effects of Inclusion Content.** Nonmetallic inclusions (single inclusions or cluster of inclusions) reduce fracture toughness, particularly at high strength levels. The effect of sulfide inclusion content (which is a function of sulfur content) on fracture toughness of 4345 steel is shown in Fig. 48. Because of this effect, special melting and processing requirements are often specified when alloy steels are selected for certain critical applications, such as aircraft landing gear. Vacuum arc remelting (VAR), vacuum induction melting (VIM), and electroslag remelting (ESR) are three of the special processes that normally produce cleaner steels than more common steelmaking processes (see the article "Steelmaking Practices and Their Influence on Properties" in this Handbook).

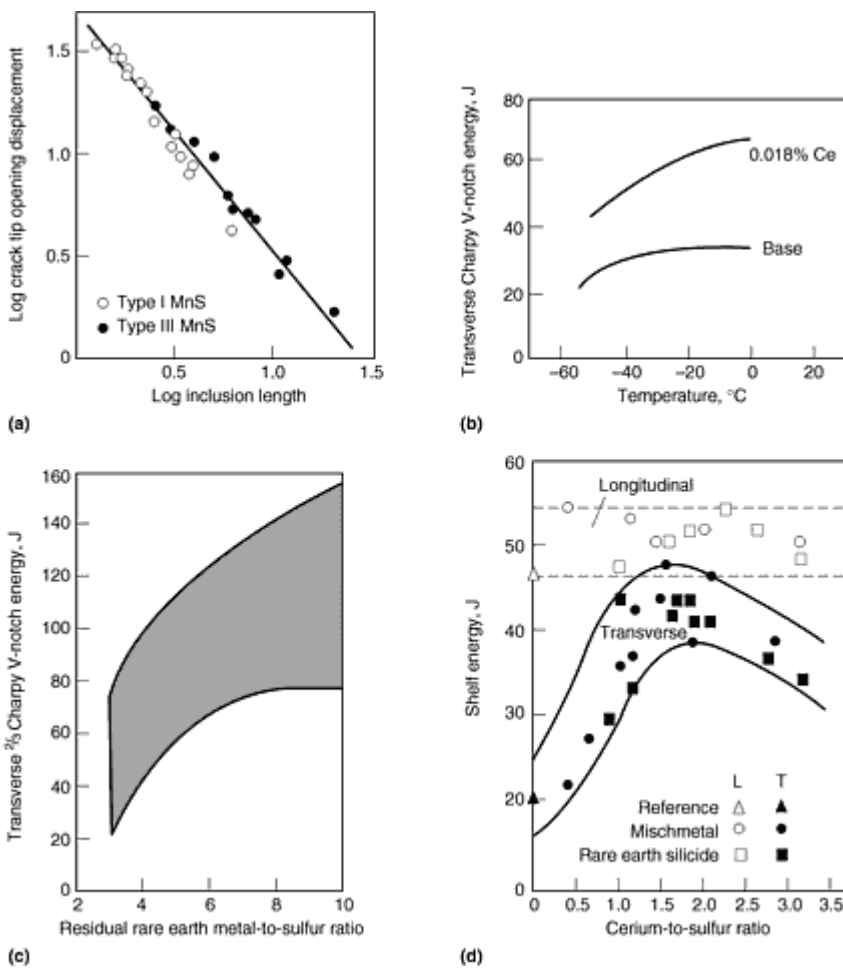

**Fig. 48** Effect of sulfur content on fracture toughness of 4345 steel hardened and tempered to various strength levels. Source: Ref 11

Not only does sulfur affect ultrahigh-strength steels, but it may also effect grades of low-to-medium strengths (Ref 12). This is largely a microvoid nucleation mechanism, and, if the sulfide inclusion length is plotted versus crack tip opening displacement (CTOD), an inverse relationship is revealed, as shown in Fig. 49(a). The critical crack tip opening displacement,  $\delta_c$ , is a measure of fracture toughness. Under plane-strain conditions, an approximate relation between  $\delta_c$  and  $K_{Ic}$  is:

$$\delta_c \equiv \frac{K_{Ic}^2}{2\sigma_{ys}E} \quad (\text{Eq 3})$$

where  $\sigma_{ys}$  is yield strength and  $E$  is Young's modulus. Thus, one means of improving toughness is to reduce the projected inclusion length by controlling the shape of the inclusions (Ref 12). This can be achieved by adding rare earths, which combine with manganese sulfide to form hard-to-deform particles comprised of sulfides, oxides, and/or oxysulfides. This means of shape control greatly improves transverse notch impact properties, as shown in Fig. 49(b) for X-65 pipeline steel (Ref 13). As shown in Fig. 49(c), notch toughness of a large heat of pipeline steel tended to increase with increasing rare earth metal additions (Ref 14). With regard to shape control, Luyckx et al. (Ref 15) demonstrated that when there was a complete change from elongated to globular sulfides, at a cerium-to-sulfur ratio of two, the upper-shelf impact energy became a maximum. This is seen in Fig. 49(d). As might be expected, there was little effect on rare earth metal additions on longitudinal properties, because the shape of sulfides is not particularly detrimental to longitudinal fracture toughness in steels of low to medium strength.

Source: Ref 12

**Effects of Trace Elements.** Other alloy chemistry effects are those that cause or influence temper embrittlement. As indicated in Table 6, impurities such as phosphorus, silicon, arsenic, and tin reduce  $K_{Ic}$  values because of their

contributing to temper embrittlement. Additional information on this embrittlement mechanism can be found elsewhere in this Handbook.

**Effects of Microstructure and Heat Treatment.** Typical microstructural changes on heat treatment of high-strength steels are accomplished by changing the austenitizing temperature and time at temperature, the quenching rate, and the tempering temperature and time at temperature. Increasing the austenitizing temperature and time has a two-fold effect in that it increases the grain size and/or increases the solutionizing of alloy carbide formers. The former effect may produce mixed results in that austenitizing at 1200 °C (2200 °F) can increase the sharp-crack fracture toughness of an AISI 4340 steel over that obtained using conventional heat treatments; however, the large prior austenite grains may produce a lower impact toughness (Ref 16). Increased prior austenite grain size in high-strength steels may also have a detrimental effect on resistance to fatigue cracking (Ref 17). On the other hand, it is well known that reasonable austenitizing temperatures and times are necessary to dissolve the carbide-forming elements prior to quenching.

Variations in quenching rates also influence fracture toughness of alloy steels by causing variations in the as-quenched microstructures. Quenching alloy steels in oil to obtain nearly 100% martensite on quenching will result in higher fracture toughness in the tempered condition than will slack quenching and tempering at the same temperature. This condition is discussed by Peterman and Jones (Ref 18) for heat-treated aircraft structures of D-6ac steel. Briefly, austenitizing at 900 °C (1650 °F), quenching in salt at 200 °C (400 °F), and tempering at 200 °C resulted in an average fracture toughness ( $K_{Ic}$ ) of 57 MPa $\sqrt{m}$  (52 ksi $\sqrt{in.}$ ), whereas austenitizing at 925 °C (1700 °F), quenching in oil at 60 °C (140 °F), and tempering at 200 °C (400 °F) resulted in an average fracture toughness of 101 MPa $\sqrt{m}$  (92 ksi $\sqrt{in.}$ ).

The effects of tempering ultrahigh-strength steels at temperatures in the upper portion of the tempering range are to increase fracture toughness and to reduce yield strength. In the intermediate tempering temperature regime between 200 and 400 °C (400 and 750 °F), these effects are not always apparent. This is shown in Fig. 50(a), where fracture toughness at 25 °C (75 °F) is relatively independent of tempering temperature for three different nickel additions. For tests at -73 °C (-100 °F), however, severe tempered martensite embrittlement results for the low-nickel steel tempered at 300 °C (570 °F). This embrittlement is partly reduced by addition of 3% Ni and completely suppressed by addition of 6% Ni, as indicated in Fig. 50(b).

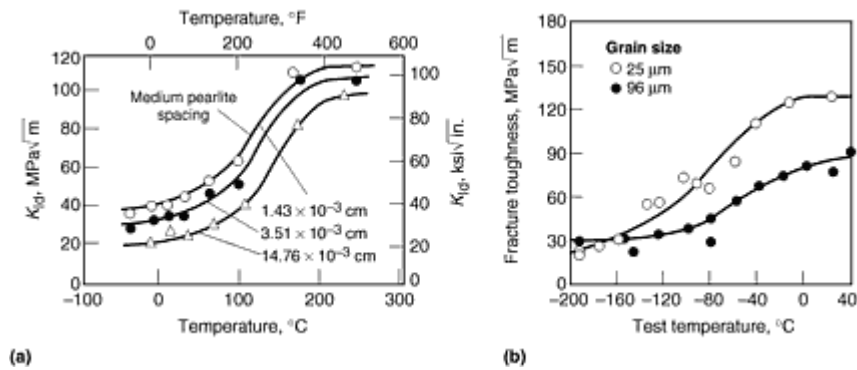

**Fig. 50** Variation of notch-bend fracture toughness with tempering temperature for steels containing 0.35% C, 0.65% Mn, 0.35% Si, 0.80% Cr, 0.30% Mo, 0.10% V, and various amounts of nickel. (a) Measurements made at 25 °C (75 °F). Source: Ref 9. (b) Measurements made at -73 °C (-100 °F). Source: Ref 8

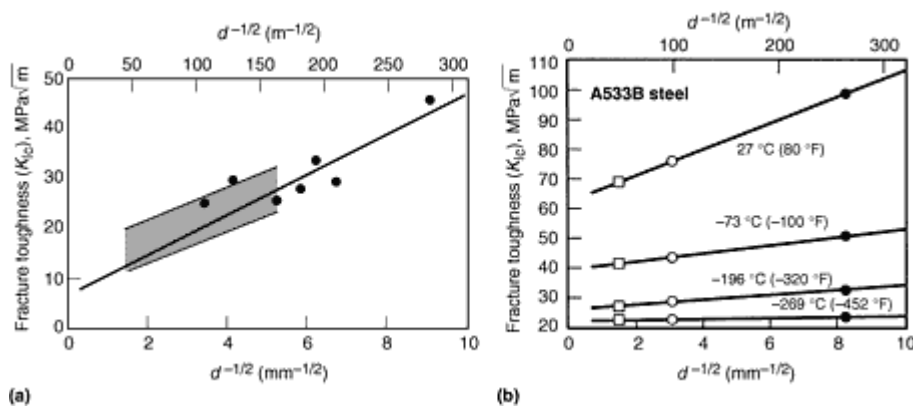

For lower-strength steels, useful microstructural modifications to improve low-temperature fracture toughness involve decreasing of the ferrite or prior austenite grain size. Results from two investigations presented in Fig. 51 show that, for

temperatures above  $-150\text{ }^{\circ}\text{C}$  ( $-240\text{ }^{\circ}\text{F}$ ), a substantial improvement in fracture toughness can be achieved through grain refinement (Ref 9, 19). Here, it is indicated that there may be a relationship between  $K_{Ic}$  and grain size,  $d$ . This is shown for both ferrite grain size (Ref 20) and prior austenite grain size (Ref 21) in Fig. 52(a) and 52(b) respectively. It is clear, then, that one goal for improved low-temperature fracture toughness in steels of low to medium strength is a refined grain size such as has been achieved in HSLA steels. The development of fine grain size in these steels through the use of minor alloying additions and lower hot rolling finishing temperatures has resulted in large improvements in fracture toughness.

(b) Dependence of fracture toughness on prior austenite grain size at four different temperatures. Source: Ref 21

**Effect of Strain Rate.** Not only does the fracture toughness temperature transition change with alloy composition and yield strength, but it also changes with loading rate. This is extremely important in low-strength and medium-strength steels, which are strain-rate sensitive. Such a result is shown in Fig. 53, where it is seen that A 36 steel undergoes a temperature transition shift as the strain rate increases from  $10^{-5}$  to  $10^{-3}$  to  $10^0\text{ s}^{-1}$ . Obviously, it would be very dangerous to select such a steel for dynamic conditions based on static fracture toughness unless the temperature shift could be adequately described. A series of studies (Ref 23, 24, 25) has shown that the magnitude of this shift is dependent on yield strength. Barsom (Ref 24) has described this relationship as:

$$T_{\text{shift}} (\text{in } ^{\circ}\text{C}) = 119 - 0.12\sigma_{ys} \quad (\text{Eq 4})$$

for steels with strengths given by  $250 \text{ MPa} < \sigma_{ys} < 965 \text{ MPa}$  ( $36 \text{ ksi} < \sigma_{ys} < 139 \text{ ksi}$ ). As can be seen in Fig. 54, there is no temperature transition shift for steels with yield strengths greater than about 965 MPa (139 ksi). This has also been verified by Priest (Ref 10) in a large number of tests of low-to-medium-strength steels, some of which are illustrated in Fig. 55. Here, up to six test temperatures and six orders of magnitude of loading rate ( $K, \text{MPa}\sqrt{\text{m}} \cdot \text{s}^{-1}$ ) were used to determine fracture toughness. It can be seen that there are substantial shifts for low-strength steels. However, for the steel with a yield strength of 970 MPa (140 ksi) in Fig. 55(d), although there is a change in fracture toughness with test temperature, there is no shift with loading rate. For steels with strengths less than 965 MPa (139 ksi), Barsom (Ref 22) has described the combined effect of yield strength and strain rate in the range of  $10^{-3} \text{ s}^{-1} \leq \dot{\epsilon} \leq 10 \text{ s}^{-1}$  by:

$$T_{\text{shift}} (\text{in } ^\circ\text{C}) = (83 - 0.08\sigma_{ys})\dot{\epsilon}^{0.17} \quad (\text{Eq 5})$$

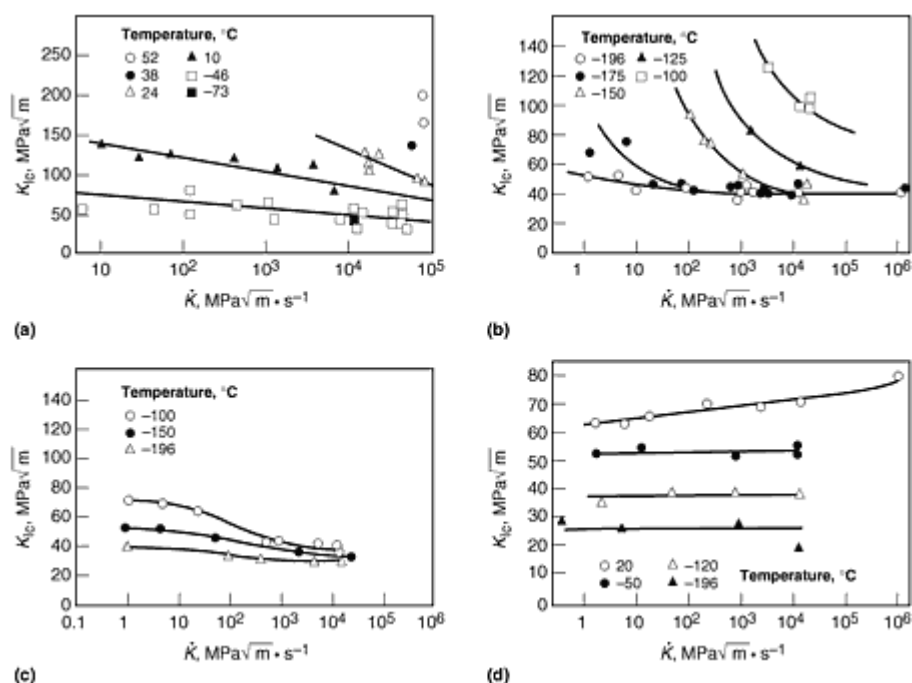

where  $\dot{\epsilon}$  is in  $\text{s}^{-1}$  units.

# Corrosion Characteristics of Carbon and Alloy Steels

---

## Types of Corrosive Environments

CORROSION OF METALS is defined as deterioration caused by chemical or electrochemical reaction of the metal with its environment. Usually, the corroding medium is a liquid, but gases and solids can also act as corroding media.

Corroding media are generally classified as aqueous or nonaqueous. Aqueous media include all types of water--natural, purified, and contaminated--ranging from deionized and distilled waters, which contain relatively few dissolved substances, through natural fresh waters, which may contain up to 10,000 ppm or more of various minerals or pollutants, to mine waters, deep-well brines, seawater, and certain process waters, which may contain several percent of one or more dissolved chemical substances such as acids, bases, salts, and gases.

Nonaqueous corrodents include dry gases, organic liquids, and liquid metals.

## Corrosion by Aqueous Media

Wherever water is involved, corrosion of iron and steel can be presumed to proceed by electrochemical action--that is, local anodic (active) and cathodic (noble) sites develop on the surface of the metal, and corrosion (oxidation) occurs at the anodic sites:  $\text{Fe}^0 \rightarrow \text{Fe}^{2+} + 2\text{e}^-$ . At the cathodic sites, a reduction reaction occurs which, depending on the pH of the environment, can be hydrogen evolution ( $2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2 \uparrow$ ) or oxygen reduction [ $\text{O}_2 + 2\text{H}_2\text{O} + 4\text{e}^- \rightarrow 4(\text{OH})^-$ ]. The electrodes liberated at the anode flow through the metal to the cathodic sites, where they are consumed by the cathodic reaction. In near-neutral or alkaline pH solutions, some dissolved oxygen or other reducible species must be present to support the cathodic reaction in order for appreciable corrosion to occur. The presence of dissolved salts generally increases corrosion rate, because it increases the conductivity of the solution and thus increases corrosion currents.

Galvanic cells can be set up by placing iron or steel in an aqueous solution while the ferrous metal is in electrical contact with another metal whose galvanic potential is more noble (more cathodic) than that of the ferrous metal. In this case a larger portion of the surface of the ferrous metal becomes anodic, and corrosion rate increases. Cells also can be set up when a local area of a ferrous metal is shielded from contact with water containing oxygen; this is called oxygen concentration-cell corrosion or crevice corrosion (because it is often seen in crevices, where oxygen is available at the edge of the crevice but is effectively absent within the crevice).

Water is the active corrodent even for some media that are not considered aqueous. Corrosion of ferrous metals in air increases when the surface is moistened regularly, as occurs in locations where dew regularly forms at night.

## **Corrosion by Nonaqueous Media**

Corrosion by most nonaqueous media except liquid metals occurs most often by direct chemical action resulting in loss of metal (e.g., high-temperature oxidation in air) or formation of a converted surface layer (e.g., carburization, nitriding). Most dry gases and organic liquids are noncorrosive to steel at ordinary temperatures, but can become corrosive at elevated temperatures.

Corrosion in liquid-metal systems almost always involves some form of dissolution or leaching, in which atoms leave the solid surface, and go into solution in the liquid metal. In a flowing system, particularly a recirculating system, the corrosion process is often controlled by the difference in temperature between the hottest and coldest points in the system, because solubility is greater as temperature increases.

Carbon and low-alloy steels can be embrittled by contact with liquid brass, aluminum bronze, copper, zinc, lead-tin solders, lithium, cadmium, and indium. The degree of embrittlement is greater for steels that have been heat treated or alloyed to produce higher strength.

## **Atmospheric Corrosion**

ALL UNPROTECTED carbon and alloy steels corrode to some extent when exposed to the atmosphere. The corrosion process can occur relatively rapidly for unalloyed iron, especially in moist air containing specific airborne contaminants. The addition of certain alloying elements--notably silicon, copper, chromium, and nickel--slows the rate of corrosion. The degree of effectiveness of each alloying element on slowing corrosion depends on both the climatic conditions of exposure and the amount of the alloying element present.

Atmospheric corrosion of ferrous metals proceeds by an electrochemical reaction in which the electrolyte is based on moisture from the air--either moisture that falls as precipitation or moisture that condenses as dew on exposed surfaces when the temperature of relatively humid air decreases.

## **Geographic and Meteorological Factors**

It is generally accepted that the principal environmental contaminants responsible for increased ferrous-metal corrosion in urban areas are the gaseous sulfur oxides that originate from the combustion of fossil fuels. The airborne seawater particles that originate in the ocean are responsible for accelerated corrosion in coastal areas. Airborne salts from arid soils of the western states and windborne fertilizer plus silicious and calcareous dust from midwestern rural areas likewise accelerate the atmospheric corrosion of ferrous metals. Complementing these ionic materials are nonionic dust particles that serve as nuclei for condensing dew.

## **Role of Dew**

Dew condensate can be a major factor in promoting corrosion. Condensed dew from a semi-industrial location was reported to have a pH of 4.5; rainwater plus dew collected from a gutter in an eastern industrial location had a pH of 3.5. Such values are sufficiently acidic to stimulate the corrosion of carbon steel through acid attack. Dew cleans the atmosphere by nucleating on particulate matter, dissolving gaseous contaminants, and subsequently clearing both from the air as it condenses on surfaces. Unfortunately, such condensed dew is damaging to both metals and concrete.

## Carbon Steels

For many years, Committee A-5 of ASTM (formerly the American Society for Testing and Materials) has exposed carbon steel specimens for the calibration of various test sites. From 1960 to 1964, specimens of carbon steel were exposed for periods of 1 and 2 years in 46 locations, 14 of which were in foreign countries. The locations ranged from tropical to polar, industrial to rural, and marine to arid. The average corrosion rates for two year exposures are given in Table 1 for 34 of the 46 locations. The greatest difference in corrosivity is the 1400-fold span between polar Norman Wells and near-tropical Cape Kennedy (beach site). The span between arid, rural Phoenix and rural State College shows a fivefold difference in corrosivity. A twofold difference exists between rural State College and industrial Newark. These data offer a preliminary appraisal of the atmospheric corrosion that might be expected when unprotected carbon steel structures are exposed in a particular location.

**Table 1 Corrosion rates of carbon steel at various locations**

## High-Strength Low-Alloy (HSLA) Steels

One of the significant observations that led to the development of high-strength low-alloy steels was the improved atmospheric corrosion resistance exhibited by carbon steel containing 0.05 to 0.2% copper. D.M. Buck performed one of the earliest systematic studies (1913), in which two levels of copper (0.15 and 0.25%) were added to corrugated carbon steel sheets used in 18° inclined roofs for outdoor structures. Weight-loss specimens were exposed simultaneously. The results from three environments--severe industrial, marine, and rural--indicated that copper reduced corrosion. In the industrial location, copper-bearing steel lost 40 to 48% less weight than did copper-free steel. In the marine environment, copper-bearing steel lost 51 to 61% less weight than copper-free steel.

**Effect of Composition.** Corrosion test results from a systematic study, involving 15.5 years of atmospheric exposure of 270 steels in three environments, were reported by Larrabee and Coburn. The alloying elements studied were copper, nickel, chromium, silicon, and phosphorus, all at levels of less than 1.3%. All these alloying elements were found to be beneficial, with the greatest change in corrosion resistance being caused by increasing copper content. The industrial site was at Kearny, NJ, the semirural site at South Bend, PA, and the marine site at Kure Beach, NC, about 240 m (800 ft) from the ocean. Some of the results of the study at the industrial site are summarized in Fig. 1. The "HSLA steel" (bottom curve) was comparable to ASTM A 242, which covers architectural grade copper-bearing weathering steels.

Fig. 1 Atmospheric corrosion versus time in a semi-industrial or industrial environment

**Corrosion in Selected Environments.** Table 2 compares carbon steel with copper-bearing steel and proprietary HSLA steels of the ASTM types A 242, A 588, A 514, and A 517 in various rural, industrial, and marine environments. A significant improvement in performance has been achieved by all of the high-strength low-alloy steels in comparison with structural copper steel and structural carbon steel.

## Soil Corrosion

SOIL CORROSION may be considered to encompass all corrosion taking place on buried structures. Soil corrosion has been ascribed to low pH, stray currents, reactive chemicals, low resistivity, and bacterial action; however, oxygen and water are considered to be the key factors necessary for corrosion.

## Soil Characteristics

Soil is a heterogeneous, porous material that ranges in character from soft spongy peats through soft clays, loams, and silts to coarse-grained sands and gravels. There are two large soil classes in the United States; west of the Mississippi River, soils generally accumulate lime and tend to be alkaline, whereas east of the Mississippi they do not and, therefore, tend to be acidic. Soil classes may be subdivided into texture groups containing varying amounts of clay, silt, and sand. Well-aerated soils are red, yellow, or brown due to the presence of ferric iron compounds; gray soils contain ferrous iron compounds. Dark soils contain decaying organic matter. Soil analysis in corrosion studies involves only substances present as water-soluble compounds, including base formers such as sodium, potassium, calcium, and magnesium, and acid formers such as carbonate, bicarbonate, chloride, nitrate, and sulfate.

Aeration and water-retention characteristics are the chief physical attributes of soil. Coarse soils (sands and gravels) that have good drainage and ample aeration corrode steel at a rate approaching that of the local atmosphere. Clay and silt soils are characterized by fine texture, high water retention, poor aeration, and poor drainage, all of which increase corrosion rates for steel. The most severe corrosion usually takes place at low elevations in poorly drained soils where there is minimal aeration.

**Differential Aeration.** Corrosion by differential aeration can result from various conditions. For example, when a pipe passes through two different soils that differ in oxygen permeability, a galvanic current will flow from the more poorly aerated (anodic) surface of the pipe through the soil to the better aerated (cathodic) surface. If the two surface conditions are widely separated, these galvanic currents, known as long-line currents, can be detected and used to locate the anodic areas.

**Dissolved Salts.** The most corrosive soils are those that contain large concentrations of soluble salts. Because of the presence of salts, such soils have relatively high electrical conductivities (or low electrical resistivities). The least-corrosive soils have low concentrations of soluble salts and high resistivities. Resistivity measurements can be obtained readily and provide as much information on corrosion characteristics as do measurements of any other single soil property. Consequently, resistivity is the property most often used to approximate the aggressiveness of a soil. Observations of soil drainage, and/or measurements of pH supplement resistivity measurements. The following table lists the general relationship that exists between soil resistivity and corrosion of ferrous metals; however, because of other factors this relationship may not always be valid.

Soil resistivity, $\Omega \cdot \text{m}$	Classification
<7	<b>Very corrosive</b>
7-20	<b>Corrosive</b>
20-50	<b>Moderately corrosive</b>
>50	<b>Mildly corrosive to noncorrosive</b>

## Bacterial Action

Bacterial action is another factor that influences underground corrosion. Of the various bacteria in soils, the anaerobic sulfate-reducing bacteria are of greatest concern. These bacteria can act as depolarizers for the cathodic reaction  $\text{H}_2\text{O} + \text{e}^- \rightarrow \text{H}^0 + \text{OH}^-$ , and thereby allow corrosion to proceed in oxygen-free soils. It should be noted that the conditions favorable to the activity of these bacteria (soluble sulfate) would be detected by the resistivity measurements mentioned above.

## Preventive Measures

Although other methods of corrosion control, such as the use of protective coatings, are often used to combat soil corrosion of steel, the cathodic protection method is regarded as the most economical and effective method available. Cathodic protection offers two important advantages. First, it can be retrofitted to existing structures, usually at a small fraction of the cost of replacing the structure and without major disruption of the facility or service; and second, the effectiveness of the cathodic protection in arresting corrosion can be measured by a simple, nondestructive electrical measurement.

## Corrosion in Concrete

THE CORROSION PROCESS in concrete is such that it tends to create conditions that increase the rate of attack. This phenomenon is related to the fact that the various corrosion products of iron and steel have a larger specific volume than the steel itself. The increase in volume of the corrosion products causes stresses that can lead to cracks in the concrete. These cracks allow easier access for the attacking medium and therefore more rapid attack. When the cracks are open to the exterior, corrosion products can be washed out and often lead to cosmetically objectionable stains. Of greater concern is the case of prestressed concrete. In this material, the corrosion process can lead to loss of structural strength and eventual failure.

The presence of chloride ions is one of the principal causes of steel corrosion in concrete. These result from airborne contaminants or deicing salts. Various attempts at reducing or eliminating the corrosion problem have focused on protective coatings for the steel members (galvanizing, painting, and so on), decreasing the concrete permeability, increasing the depth of concrete cover, or eliminating the chloride ion through the use of sealants, and so on. Although many of these approaches have shown some degree of success, the application of cathodic protection has been the most successful in arresting corrosion.

There does not appear to be any significant body of data relating the severity of corrosion to the composition of the steel reinforcing member. It is likely that alloying could reduce the overall rate of attack, but whether the reduction would be significant in light of the added cost is problematic. Some HSLA concrete-reinforcing bars covered in ASTM A 706 are used for special applications.

## Corrosion in Fresh Water

FRESH WATER includes all nonsaline natural waters, polluted or unpolluted, found in inland bodies such as streams, rivers, ponds, and lakes. In addition to nonsaline natural waters, which originate as precipitation such as rain or snow, fresh water includes well water, treated potable water, and various process waters that can or cannot be treated and can or cannot contain higher levels of contaminants than the natural waters from which they were derived. Data on the useful life of mild steel in contact with fresh water are incomplete without information on: (a) mineral quality of the water, (b) acidity, (c) presence or absence of dissolved oxygen, (d) velocity of flow, (e) temperature, and (f) environmental conditions such as nonuniformity of a corrosion-product deposit, contact with copper-bearing metals, and the existence of crevices, all of which can lead to severe localized corrosion.

### Effect of Dissolved Gases

Of all the characteristics of water that influence the rate of corrosion, dissolved gases are probably the most important.

**Oxygen.** The rate at which oxygen reaches a metal surface controls the rate of corrosion and can determine whether aerobic or anaerobic corrosion results. In addition, oxygen accelerates the action of carbon dioxide, hydrogen sulfide, and other dissolved gases and solids.

**Carbon dioxide** is only about one-tenth as corrosive as oxygen, and in natural waters the carbon dioxide concentration is important only as it affects the solubility and precipitation of calcium carbonate.

**Hydrogen sulfide** can cause rapid attack of steel, even in the absence of oxygen; it also produces severe graphitic corrosion of cast iron. The anaerobic corrosion products are sulfur and ferrous sulfide, both of which are cathodic to iron and tend to cause severe pitting. Most of the corrosion problems due to hydrogen sulfide arise when this chemical is produced by bacteria.

### Effect of pH

There is little difference in the corrosion rate of steel in natural waters having pH values between 4.5 and 9.5. This has been confirmed in both tap water and distilled water. In this range of pH, the corrosion products maintain a pH of 9.5 next to the steel surface, regardless of the pH of the solution. At a pH of 4 or below, hydrogen evolution begins and corrosion increases rapidly (Fig. 2).

**Fig. 2** Effect of pH on corrosion of steel in aerated water. Corrosion rates are normalized to a solution containing 1 mL O<sub>2</sub> per liter of water. To estimate corrosion rates at other concentration, multiply values derived from this graph by the oxygen concentration in mL/L.

### Effect of Dissolved Salts

Most salts dissolved in water tend to decrease the solubility of both oxygen and ferrous hydroxide. Therefore, rates of corrosion in concentrated salt solutions are usually less than those in dilute salt solutions. Some salts also tend to buffer

the pH value, which can overcome a tendency toward acidic corrosion. On the other hand, most dissolved salts become ionized and increase the conductivity of water which, in turn, tends to localize corrosion, thus leading to severe pitting. The increased conductivity permits cathodic areas to become larger and causes anode and cathode reaction products to combine in the water instead of at the corroding surface. Cations stimulate corrosion in the following order (magnesium ions having the least effect and ferric ions the greatest): magnesium, cadmium, manganese, calcium, strontium, barium, lithium, sodium, potassium, ammonium, trivalent chromium, and trivalent iron (ferric).

Ammonium salts and salts of trivalent elements such as chromium and iron greatly stimulate corrosion because they hydrolyze, creating acidic conditions. Corrosion then occurs by hydrogen evolution as well as by oxygen depolarization. Ammonium chloride is particularly active, even at concentrations as low as 10 ppm.

**Copper and Mercury Ions.** Certain soluble ions, especially copper and mercury, are capable of undergoing a reaction termed mutual replacement, in which the dissolved ions (which are more noble than iron) deposit on an iron or steel surface and an equal number of iron atoms go into solution. Mutual replacement can take place in the absence of oxygen, and there is no known inhibitor that can prevent this reaction.

**Alkali Metal Salts.** When salts of lithium, sodium, or potassium are added to aerated water, the corrosion rate varies with concentration. At low concentrations, addition of an alkali metal salt increases the corrosion rate; at higher concentrations, the corrosion rate reaches a maximum and then decreases with increasing concentration, as shown in Fig. 3.

Fig. 3 Effect of alkali metal salt concentration on corrosion of steel at 35 °C (95 °F)

## Corrosion in Potable Water Systems

Steel pipe is not used for domestic potable water. Other steel containers seldom are used for household or industrial water or for water distribution systems without protective coatings of zinc, cement, enamel, paint, coal tar, or a coal-tar-base product. Such coatings are necessary not only to reduce corrosion but also to avoid red water. Steels exposed to water at gaps (holidays) in coatings or at joints will not resist aggressive water but will remain unattacked in nonaggressive water, in water that has been treated with the proper inhibitor, or when placed under cathodic protection.

## Corrosion in Natural Waters

Steel is used for structures, pilings, and water-intake piping that are completely or partly submerged in various natural waters. In virtually all applications, the corrosion rate is influenced not only by the prevailing oxygen content of the natural water, but also by the presence of minerals or industrial pollutants, or both. The prevailing pH and degree of movement around an exposed steel structure (producing turbulent flow, laminar flow, or stagnation) also affect the corrosion rate. Frequently, it is impossible to predict useful life with any reasonable certainty without conducting corrosion tests at the site.

## Corrosion in Seawater

SEAWATER is a relatively uniform saline solution consisting predominantly of sodium and magnesium chlorides dissolved in water. Although many other soluble minerals are present in very small quantities, both the individual and cumulative effects of these minerals are so greatly overshadowed by the effect of the dominant chlorides that seawater can be considered equivalent to a 0.5*N* sodium chloride solution. At this concentration, a sodium chloride solution is at a peak in corrosivity, acting more aggressively toward steel than at either higher or lower concentrations. Factors other than chloride concentration that affect corrosion in seawater include oxygen concentration, biofouling, water velocity, and water temperature. These factors are discussed later in this article.

The corrosion rate most commonly cited for carbon steel immersed in seawater is 5 mils/year (130  $\mu$ m/year). This rate may be considered linear with time up to about eight years. After about eight years, the corrosion rate decreases to a steady, but slower, rate. In one instance, examination of steel H-piles exposed to unpolluted seawater in the Santa Barbara Channel indicated that the loss due to corrosion is about 1 mm (40 mils) over a 20 year interval, or a rate of about 50  $\mu$ m/year (2 mils/year), which can be reduced to about 25  $\mu$ m/year (1 mil/year) thereafter.

Corrosion in brackish waters, such as is found in bays and estuaries, parallels corrosion in seawater to a certain extent. However, because of the periodic reversal in flow typical of many brackish waters and because of certain other characteristics, the pattern of corrosion in brackish waters differs from the pattern in ordinary seawater.

## Effect of Mill Scale

Corrosion rates around the world are somewhat similar, regardless of whether they are measured in terms of weight loss or of maximum pit depth. However, in almost all instances, maximum pit depth is much greater in carbon steel specimens covered with mill scale than in specimens that are free of mill scale, as shown in Table 3. Mill scale is very cathodic to bare steel.

**Table 3 Corrosion of mill-scaled surface of carbon steel immersed in seawater versus corrosion of scale-free surface**

Location	Pickled surface				Mill-scaled surface			
	Corrosion loss		Max pit depth		Corrosion loss		Max pit depth	
	$\mu$ m/yr	mils/yr	mm	mils	$\mu$ m/yr	mils/hr	mm	mils
Halifax, Nova Scotia	120	4.8	1.9	75	110	4.3	1.7	<b>68</b>
Auckland, New Zealand	75	3.0	1.1	43	85	3.3	3.7	<b>147</b>
Plymouth, England	60	2.4	1.65	65	60	2.4	4.0	<b>156</b>
<b>Colombo, Sri Lanka</b>	<b>90</b>	<b>3.6</b>	<b>1.6</b>	<b>64</b>	<b>100</b>	<b>3.9</b>	<b>6.1</b>	<b>240</b>

## Effect of Oxygen Concentration

It is the cathodic depolarizing effect of oxygen that permits most corrosion reactions to proceed. In practice, the various natural forms of inhibition that prevent access of oxygen to a metal surface reduce the corrosion rate and often stifle corrosion completely.

In one instance, the effects of such parameters of the deep-sea environment as oxygen concentration, salinity, temperature, and pH were investigated. Some of the data from that study are given in Table 4. The corrosion rate for steel was determined to be a linear function of dissolved oxygen content.

**Table 4 Corrosion rates of carbon steel for near-surface and deep-sea immersion**

Immersion depth		Temperature, °C	Oxygen concentration, ppm	Immersion time, days	Corrosion rate	
m	ft				μm/yr	mils/yr

## Galvanic Corrosion

Galvanic corrosion in seawater is a matter of concern because the corroding medium has a fairly high conductivity. A practical version of the galvanic relationship of metals in seawater is shown in Table 5. Service conditions can differ considerably because of solution composition, solute concentration, agitation, aeration, temperature, and purity of the metals, as well as corrosion-product formation and biological growth, each of which can result in a different galvanic series.

## Basic Corrosion Rates in Seawater

Carbon steel and many of the low-alloy steels are frequently cited as having short-term corrosion rates of about 130  $\mu\text{m}/\text{year}$  (5 mils/year) when completely immersed in seawater. The long-term corrosion rates of these steels (after immersion for five to ten years) are somewhat lower.

It is generally conceded that steelmaking practice has no effect on corrosion in seawater; there is no substantial difference in behavior between rimmed and killed steel. Likewise, alloying with small amounts of either copper or chromium has no effect on corrosion. In one investigation, for example, seven different open-hearth steels, six copper-bearing steels, and several low-chromium copper-bearing steels were immersed in seawater for 203 days; the corrosion rates for all these steels were in the relatively narrow range of 135 to 150  $\mu\text{m}/\text{year}$  (5.4 to 5.8 mils/year).

**Effect of Velocity.** Increasing the velocity of seawater generally increases the rate of corrosion. For instance, one study showed that the corrosion rate in stagnant seawater was the same for both carbon steel and copper-bearing steel--about 70  $\mu\text{m}/\text{year}$  (2.8 mils/year)--for immersion periods of 5 to 10 years. In seawater flowing at low velocity, the corrosion rate for carbon steel was about 95  $\mu\text{m}/\text{year}$  (3.8 mils/year), but at higher velocity the corrosion rate was 380  $\mu\text{m}/\text{year}$  (15 mils/year). The corrosion rate for copper-bearing steel in high-velocity seawater was only about 120  $\mu\text{m}/\text{year}$  (5.5 mils/year), which indicates a possible benefit from alloying with small amounts of copper. Most investigators consider the effect of velocity on corrosion rates to be an erosion effect, whereby corrosion products are continually removed from the surface as they form, which reduces their effectiveness in stifling further corrosion.

**Pitting.** Where pitting is a serious consideration, steels containing up to 3% Ni or 3% Cr may be used. Both nickel steels and chromium steels pit at about half the rate of carbon steel. For instance, in one six year immersion test, a 2% Ni steel pitted to an average depth of about 2 mm (80 mils), compared to a depth of 5 mm (200 mils) for carbon steel. Increasing the amount of chromium above 3% changes the mode of corrosion to an increasingly more localized attack with deeper pits. For instance, a 3% Cr steel typically exhibits pitting rates of about 0.2 mm/year (8 mils), compared to about 0.9 mm/year (37 mils) for a 13% Cr steel and a 1.75 mm/year (69 mils/year) for a 17% Cr steel.

**Corrosion in Tropical Waters.** The higher temperature of seawater in tropical climates than in temperate or arctic climates results in higher rates of corrosion. Results of a systematic study conducted in both fresh water and seawater in a tropical climate are given in Table 6; in this climate, as in more temperate climates, the average corrosion rates for both carbon and HSLA steels decrease with time in both fresh and salt water. Furthermore, the average depth of the 20 deepest pits is about the same for both carbon and copper-bearing steels, higher after long-term exposure for Ni steels, and slightly lower for long-term exposure only for 5% Cr steel. Besides the results given in Table 6, a 3% Cr steel and several HSLA steels containing various amounts of Ni, Cr, P, Cu, and Si were subjected to the same conditions and gave about the same results, as those reported for similar steels in Table 6.

**Table 6 Typical corrosion rates in tropical waters**

## Preventive Measures

The use of organic coatings in conjunction with cathodic protection offers the most economical and effective method of corrosion prevention in seawater. Offshore oil rigs, pipelines, and other underwater equipment make use of this combination. The less porous the coating, the less current needed for cathodic protection and the more economical the system. Aluminum anodes, with their high current efficiency, are most often used in seawater. However, zinc anodes also have been used extensively in seawater applications, while magnesium anodes have been used less extensively. The slight advantage of low-alloy steels over carbon steels usually is lost in the final economic analysis of corrosion prevention.

Inhibitors are sometimes used in seawater cooling equipment. Wherever possible, all equipment in contact with seawater should be designed without galvanic couples.

## Stress-Corrosion Cracking of Steels

STRESS CORROSION CRACKING (SCC) is slow, environmentally induced crack propagation in engineering materials that results from the combined interaction of mechanical stress and corrosion reactions. Generally, steels with lower strengths are susceptible to SCC only upon exposure to a small number of specific environments, such as the hot caustic solutions encountered in steam boilers, hot nitrate solutions, anhydrous ammonia, and hot carbonate-bicarbonate solutions.

For steels with yield strengths greater than about 690 MPa (100 ksi)--such as quenched-and-tempered alloy steels, hot-work die steels, maraging steels, and martensitic and precipitation-hardenable stainless steels--the environments that cause SCC are not specific. In many alloy systems, the phenomena of SCC and hydrogen embrittlement cracking are indistinguishable. This is particularly the case in environments that contain sulfides or other promoters of hydrogen entry.

Environments of major concern are natural waters--for example, rainwater, seawater, and atmosphere moisture. Any of these environments may become contaminated, which significantly increases the likelihood of SCC. Contamination with hydrogen sulfide is particularly serious: consequently, the presence of hydrogen sulfide in high concentrations in salt water associated with certain deep oil wells (termed sour wells) places an upper limit of approximately 620 MPa (90 ksi) on the yield strength that can be tolerated in stressed steel in such environments without cracking.

## Protection of Steel from Corrosion

CORROSION PROTECTION is often an essential consideration in selection of carbon or alloy steel for a given structural application. Corrosion can reduce the load-carrying capacity of a component either by generally reducing its size (cross section) or by pitting, which not only reduces the effective cross section in the pitted region, but also introduces stress raisers that may initiate cracks. Obviously, any measure that reduces or eliminates corrosion will extend the life of a component and increase its reliability (Table 7).

**Table 7 Guide to corrosion prevention for carbon steels in various environments**

Preventive method	Atmosphere	Soil	Fresh water	Seawater	Steam systems	Acids and pickling baths
Metal coatings: electroplating, galvanizing, thermal spraying	Galvanizing very effective; plating with other metals used for both decorative appearance and corrosion protection	Not recommended	Galvanizing used in potable water	Not recommended	Not recommended	<b>Not recommended</b>
Painting: chemical treatment, priming and painting	Most economical and effective corrosion prevention	Seldom used	Fairly effective	Special paint systems used	Not recommended	<b>Not recommended</b>
Cathodic protection	Not recommended	Most economical and effective method, especially with organic coatings	Fairly effective with organic coatings	Very effective	Not recommended	<b>Effective under special conditions</b>

		other than paint				
Inhibitors: liquid and vapor	Not recommended	Not recommended	Effective in some applications, especially cooling waters	Fairly effective in some applications	Very effective	<b>Very effective</b>
Alloying additions to steel	Very effective, especially copper-bearing and HSLA steels	Not effective	Not effective	Only effective with much alloying	Chromium-molybdenum steels are very effective	<b>Only effective with much alloying</b>
Removal of oxygen from environment	Not recommended	Not recommended	Seldom used	Very effective, especially in desalination and hot seawater	Very effective	<b>Not recommended</b>
Removal of more noble metals; elimination of galvanic couples	Usually not necessary	Fairly effective	Effective	Necessary	Advisable	<b>Not effective</b>
<b>Organic coatings other than paint</b>	<b>Seldom used to replace painting</b>	<b>Used to advantage with cathodic protection</b>	<b>Fairly effective with cathodic protection</b>	<b>Used to advantage with cathodic protection</b>	<b>Not recommended</b>	<b>Have been used</b>

Overall economics, environmental conditions, degree of protection needed for the projected life of the part, consequences of unexpected service failure, and importance of appearance are the chief factors that determine not only whether a steel part needs to be protected against corrosion, but the most effective and economic method of achieving that protection as well. Protection against corrosion can be done by (a) providing an impervious barrier between the steel and the corroding medium, (b) introducing a substance that inhibits the chemical action, or (c) inducing galvanic activity that counteracts the galvanic activity involved in corrosion.

## Coatings

The types of coatings available seem endless, varying from simply oiling the surface for low-cost temporary protection to electroplating with a multilayer copper-nickel-chromium coating to obtain a high-gloss metallic appearance and superior corrosion protection. For economic reasons, the desired degree of protection must be determined before a coating is selected.

**Temporary protection** during storage or shipment usually can be done effectively by coating the steel with mineral oil, solvents combined with inhibitors and film formers, emulsions of petroleum-based coatings, or water plus waxes. These coatings are applied (a) after acid pickling to remove mill scale or (b) between coating sequences and are not expected to give long-term corrosion protection.

**Cleaning** is the most important prerequisite for any coating process. Any oxides on a steel surface must be removed by acid pickling or sand blasting. Degreasing is necessary after oxide removal or when the steel has been given a temporary coating. Degreasing can be accomplished by alkaline cleaning, vapor degreasing, or emulsion cleaning.

**Hot dip coating** processes are particularly well suited for applying coatings of aluminum, lead, tin, zinc, and some of their alloys. Hot dipping consists of immersing the steel in a bath of molten metal that usually is covered with a layer of

molten flux. Zinc coating (galvanizing) protects steel galvanically because the zinc is anodic to the steel base metal and therefore corrodes preferentially in most environments.

**Electroplating** is perhaps the most expensive of all processes for coating steel. Electrodeposits, therefore, are used when appearance, solderability, or some other requirement demands a metal coating. If only corrosion protection is needed, many nonmetallic coatings will give better protection at lower cost. All conventional electroplates can be applied to steel.

**Thermal spray coatings** provide effective long-term corrosion protection for steels in a wide range of corrosive environments. They are applied by one of several processes, including wire flame spraying, powder flame spraying, and electric arc spraying. Zinc, aluminum, and zinc-aluminum alloys are the most common coating materials applied by thermal spray techniques.

**Conversion coatings** offer only mild corrosion protection to steel if not covered with another system but become very protective when used with paints. Phosphate coatings and chromate conversion coatings are widely used as paint bases on both uncoated and galvanized steel.

**Thin organic coatings** (paints) are used more often for corrosion protection than any of the other coatings because the cost is low for the degree of protection afforded. A good paint system includes proper cleaning, a conversion coating, a primer, and a compatible top coat. Application of the various coats can be accomplished by spraying, dipping, flow coating, roller coating, or electrophoretic deposition.

## **Inhibitors**

An inhibitor is a chemical substance or combination of substances that, when present in the environment, prevents or reduces corrosion without significant reaction with the components of the environment. Inhibitors find their major uses in acid-pickling solutions, acidic service environments, steam systems, and neutral and near-neutral aqueous solutions. Inhibitors may be organic or inorganic compounds, and they are usually dissolved in aqueous environments. Inhibitors have been added to chemical conversion treatment baths and to paint primers. A few vapor-phase inhibitors are used in confined atmospheres (for example, packaging applications).

# Basic Metallurgy of Cast Iron

## Introduction

CAST IRON, like the term steel, identifies a large family of ferrous alloys. Cast irons primarily are iron alloys that contain more than 2% carbon and from 1 to 3% silicon. Wide variations in properties can be achieved by varying the balance between carbon and silicon, by alloying with various metallic elements, and by varying melting, casting, and heat treating practices.

The five types of commercial cast iron are gray, ductile, malleable, compacted graphite, and white iron. With the exception of a white cast iron, all cast irons have in common a microstructure that consists of graphite phase in a matrix that may be ferritic, pearlitic, bainitic, tempered martensitic, or combinations thereof. The four types of graphitic cast irons are roughly classified according to the morphology of the graphite phase. Gray iron has flake-shaped graphite, ductile iron has nodular or spherically shaped graphite, compacted graphite iron (also called vermicular graphite iron) is intermediate between these two, and malleable iron has irregularly shaped globular or "popcorn-shaped" graphite that is formed during tempering of white cast iron. Table 1 shows the correspondence between commercial and microstructural classification, as well as final processing stage in obtaining common cast irons.

**Table 1 Classification of cast irons by commercial designation, microstructure, and fracture**

Commercial designation	Carbon-rich phase	Matrix <sup>(a)</sup>	Fracture	Final structure after
Gray iron	Lamellar graphite	P	Gray	<b>Solidification</b>
Ductile iron	Spheroidal graphite	F, P, A	Silver-gray	<b>Solidification or heat treatment</b>
Compacted graphite iron	Compacted (vermicular) graphite	F, P	Gray	<b>Solidification</b>
White iron	Fe <sub>3</sub> C	P, M	White	<b>Solidification and heat treatment<sup>(b)</sup></b>
Mottled iron	Lamellar Gr + Fe <sub>3</sub> C	P	Mottled	<b>Solidification</b>
Malleable iron	Temper graphite	F, P	Silver-gray	<b>Heat treatment</b>
<b>Austempered ductile iron</b>	<b>Spheroidal graphite</b>	<b>At</b>	<b>Silver-gray</b>	<b>Heat treatment</b>

(a) F, ferrite; P, pearlite; A, austenite; M, martensite; At, austempered (bainite).

(b) White irons are not usually heat treated, except for stress relief and to continue austenite transformation.

White cast irons, so named because of the characteristically white fracture surfaces, do not have any graphite in the microstructures. Instead the carbon is present in the form of carbides, chiefly of the types Fe<sub>3</sub>C and Cr<sub>7</sub>C<sub>3</sub>. Often, complex carbides are also present, such as (Fe,Cr)<sub>3</sub>C from additions of 3 to 5% Ni and 1.5 to 2.5% Cr, (Cr,Fe)<sub>7</sub>C<sub>3</sub> from additions of 11 to 35% Cr, or those containing other carbide-forming elements.

Cast irons may also be classified as either unalloyed cast irons or alloy cast irons. Unalloyed cast irons are essentially iron-carbon-silicon alloys containing small amounts of manganese, phosphorus, and sulfur. The range of composition for typical unalloyed cast irons is given in Table 2. Figure 1 shows the range of carbon and silicon for common cast irons as compared with steel.

**Table 2 Range of compositions for typical unalloyed common cast irons**

Type of iron	Composition, %				
	C	Si	Mn	P	S
Gray	2.5-4.0	1.0-3.0	0.2-1.0	0.002-1.0	<b>0.02-0.25</b>
Compacted graphite	2.5-4.0	1.0-3.0	0.2-1.0	0.01-0.1	<b>0.01-0.03</b>
Ductile	3.0-4.0	1.8-2.8	0.1-1.0	0.01-0.1	<b>0.01-0.03</b>
White	1.8-3.6	0.5-1.9	0.25-0.8	0.06-0.2	<b>0.06-0.2</b>
Malleable	<b>2.2-2.9</b>	<b>0.9-1.9</b>	<b>0.15-1.2</b>	<b>0.02-0.2</b>	<b>0.02-0.2</b>

**Fig. 1** Approximate ranges of carbon and silicon for steel and various cast irons

## The Iron-Iron Carbide-Silicon System

A section through the ternary Fe-Fe<sub>3</sub>C-Si diagram at 2% Si (which approximates the silicon contents of many cast irons) provides a convenient reference for discussing the metallurgy of cast iron. The diagram in Fig. 2 resembles the binary Fe-Fe<sub>3</sub>C diagram but exhibits important differences characteristic of ternary systems. Eutectic and eutectoid temperatures change from single values in the Fe-Fe<sub>3</sub>C system to temperature ranges in the Fe-Fe<sub>3</sub>C-Si system; the eutectic and eutectoid points shift to lower carbon contents.

Fig. 2 Section through the Fe-Fe<sub>3</sub>C-Si ternary equilibrium diagram at 2% Si

Figure 2 represents the metastable equilibrium between iron and iron carbide (cementite), a metastable system. The silicon that is present remains in solid solution in the iron, in both ferrite and austenite, and so does not affect the composition of the carbide phase but only the conditions and the kinetics of the carbide formation on cooling. The designations  $\alpha$ ,  $\gamma$ , and Fe<sub>3</sub>C, therefore, are used in the ternary system to identify the same phases that occur in the Fe-Fe<sub>3</sub>C binary system. Some of the silicon may precipitate along with the carbide, but it cannot be distinguished as a different phase. The solidification of certain compositions does not occur in the metastable system, but rather in the stable system, where the products are iron and graphite rather than iron and carbide. These compositions encompass the gray, ductile, and compacted graphite cast irons.

If the section through the ternary diagram at 2% Si is to be used in tracing the phase changes that occur, its use can be justified only on the assumption that silicon concentration remains at 2% in all parts of the alloy under all conditions. This obviously is not strictly true, but there is little evidence that silicon segregates to any marked degree in cast iron.

## Carbon Equivalence

Both carbon and silicon influence the nature of iron castings, so it is necessary to develop an approximation of their impact on solidification. This has been accomplished through development of the concept of carbon equivalence,  $CE$ . Using this approach, carbon equivalence is calculated as:

$$CE = \%C + \frac{\%Si}{3}$$

or more precisely, taking phosphorus into consideration:

$$CE = \%C + \frac{\%Si + \%P}{3}$$

Comparison of  $CE$  with the eutectic composition in the Fe-C system (4.3% C) will indicate whether a cast iron will behave as a hypoeutectic or hypereutectic alloy during solidification. When  $CE$  is near the eutectic value, the liquid state persists to a relatively low temperature and solidification takes place over a small temperature range. The latter characteristic can be important in promoting uniformity of properties within a given casting.

In hypereutectic irons ( $CE$  greater than about 4.3%), there is a tendency for kish graphite--proeutectic graphite that forms and floats free in the molten iron--to precipitate on solidification under normal cooling conditions. In hypoeutectic irons, the lower the  $CE$ , the greater the tendency for white or mottled iron to form on solidification.

## Characteristics of Cast Irons

**White Cast Iron.** White iron is formed when the carbon in solution in the molten iron does not form graphite on solidification but remains combined with the iron, often in the form of massive carbides. White irons are hard and brittle and produce white, crystalline fracture surfaces.

White cast irons have high compressive strength and good retention of strength and hardness at elevated temperature, but they are most often used for their excellent resistance to wear and abrasion. The massive carbides in the microstructure are chiefly responsible for these properties.

**Gray Cast Iron.** When the composition of the iron and the cooling rate at solidification are suitable, a substantial portion of the carbon content separates out of the liquid to form flakes of graphite. When a piece of the solidified alloy is broken, the fracture path follows the graphite flakes, and the fracture surfaces appear gray because of the predominance of exposed graphite.

Gray cast iron has several unique properties that are derived from the existence of flake graphite in the microstructure. Gray iron can be machined easily at hardnesses conducive to good wear resistance. It resists galling under boundary-lubrication conditions (conditions wherein the flow of lubricant is insufficient to maintain a full fluid film). It has outstanding properties for applications involving vibrational damping or moderate thermal shock.

**Ductile Cast Iron.** Ductile iron, which is also known as nodular iron or spheroidal graphite cast iron, is very similar to gray iron in composition, but during casting of ductile iron the graphite is caused to nucleate as spherical particles, or spherulites, rather than as flakes. This is accomplished through the addition of a very small but definite amount of magnesium and/or cerium to the molten iron in a process step called nodulizing.

Ductile iron is produced from the same types of raw material as gray iron, but usually requires slightly higher purity, especially in regard to sulfur. Casting properties of ductile iron, such as fluidity, are comparable to those of gray iron.

The chief advantage of ductile iron over gray iron is its combination of high strength and ductility--up to 18% minimum elongation for ferritic ductile iron with a tensile strength of 415 MPa (60 ksi) as opposed to only about 0.6% elongation for a gray iron of comparable strength. Martensitic ductile irons with tensile strengths of about 830 MPa (120 ksi) exhibit

at least 2% elongation, and the newer austempered ductile irons exhibit in excess of 5% elongation at even higher tensile strengths (1000 MPa, or 145 ksi).

For most applications, some deviation from true spherical shape can be tolerated without unacceptable loss of properties. However, the quasi-flake and crab form (see Table 3) are unacceptable for most applications.

**Table 3 Summary and description of ASTM and equivalent ISO classification of graphite shapes in cast iron**

ASTM type <sup>(a)</sup>	Equivalent ISO form <sup>(b)</sup>	Description
I	VI	<b>Nodular (spheroidal) graphite</b>
II	VI	<b>Nodular (spheroidal) graphite, imperfectly formed</b>
III	IV	<b>Aggregate, or temper carbon</b>
IV	III	<b>Quasi-flake graphite</b>
V	II	<b>Crab-form graphite</b>
VI	V	<b>Irregular or "open" type nodules</b>
VII <sup>(c)</sup>	I	<b>Flake graphite</b>

(a) As defined in ASTM A 247.

(b) As defined in ISO/R 945-1969 (E).

(c) Divided into five subtypes; uniform flakes; rosette grouping; superimposed flake size; interdendritic, random orientation; and interdendritic, preferred orientation

**Compacted graphite (CG) cast iron**, also known as vermicular graphite cast iron, is characterized by graphite that is interconnected within eutectic cells as is the flake graphite in gray iron. Compared with the graphite in gray iron, however, the graphite in CG iron is coarser and more rounded, similar in metallographic appearance to ASTM type IV, quasi-flake graphite (Table 3). The structure can be considered intermediate between those of gray iron and ductile iron. Individual properties can also be considered intermediate between those of gray and ductile irons, but the unique combinations of properties obtainable in CG irons make them superior to either gray or ductile iron in applications such as disc-brake rotors and diesel-engine heads.

Compacted graphite cast iron can be obtained by very carefully controlling the amount of magnesium added as an inoculant in a process very similar to the process used to make ductile iron. Unfortunately, either undertreatment, resulting in a gray iron structure, or overtreatment, resulting in a ductile iron structure, can occur if the ideal quantity of magnesium is missed by as little as 50 ppm. Current commercial production of CG iron is accomplished by inoculation with magnesium to give a residual content of 50 to 600 ppm in the presence of 0.15 to 0.5% titanium and 10 to 150 ppm of rare earths, such as cerium. In effect, the process is one in which the nodulizing reaction due to the addition of magnesium is poisoned by the presence of a controlled amount of titanium, and in which cerium is added to eliminate a need to control sulfur at a low concentration.

**Malleable cast iron** encompasses yet another form of graphite called temper carbon. This form of graphite is produced by the heat treatment of white cast iron, which does not contain graphite, but does contain a high percentage of cementite. When a white cast iron is heated for an extended period of time (about 60 h) at a temperature of 960 °C (1760 °F), the cementite decomposes into austenite and graphite. By slow cooling from 960 °C (1760 °F), the austenite transforms into ferrite or pearlite, depending on the cooling rate and the diffusion rate of carbon. The ductility and toughness of malleable iron falls between that of ductile cast iron and gray cast iron. Because white iron can only be produced in cast sections up to about 100 mm (4 in.) thick, malleable iron is limited in section size. In recent years, malleable irons have been replaced by the more economically processed ductile irons for many applications.

---

# Gray Iron

## Introduction

GRAY IRON refers to a broad class of ferrous casting alloys normally characterized by a microstructure of flake graphite in a ferrous matrix. Gray irons are in essence iron-carbon-silicon alloys that usually contain 2.5 to 4% C, 1 to 3% Si, and additions of manganese, depending on the desired microstructure (as low as 0.1% Mn in ferritic gray irons and as high as 1.2% Mn in pearlitics). Sulfur and phosphorus are also present in small amounts as residual impurities. More highly alloyed (>4% alloy content) austenitic nickel-alloyed gray irons can also be produced, as well as high-silicon-content gray irons used for corrosion-resistant and/or heat-resistant applications. These materials are described in the article "Alloy Cast Irons" in this Section.

## Classes of Gray Iron

A simple and convenient classification of the gray irons is found in ASTM specification A 48, which classifies the various types in terms of tensile strength expressed in ksi. The ASTM classification by no means connotes a scale of ascending superiority from class 20 (minimum tensile strength of 140 MPa or 20 ksi) to class 60 (minimum tensile strength of 410 MPa, or 60 ksi). In many applications, strength is not the major criterion for the choice of grade. For example, for parts such as clutch plates and brake drums, where resistance to heat checking is important, low-strength grades of iron are the superior performers. Similarly, in heat-shock applications such as ingot or pig molds, a class 60 iron would fail quickly whereas good performance is shown by class 25 iron. In machine tools and other parts subject to vibrations, the better damping capacity of low-strength irons is often advantageous.

Generally, it can be assumed that the following properties of gray cast irons increase with increasing tensile strength from classes 20 to 60:

- All strengths, including strength at elevated temperature
- Ability to be machined to a fine finish
- Modulus of elasticity
- Wear resistance

On the other hand, the following properties decrease with increasing tensile strength, so that low-strength irons often perform better than high-strength irons when these properties are important:

- Machinability
- Resistance to thermal shock
- Damping capacity
- Ability to be cast in thin sections

**Composition.** The major elements in gray iron are carbon, silicon, and iron. Carbon and silicon levels found in commercial irons vary widely:

Type of iron	Total carbon, %	Silicon, %
Class 20	3.40-3.60	<b>2.30-2.50</b>
Class 30	3.10-3.30	<b>2.10-2.30</b>
Class 40	2.95-3.15	<b>1.70-2.00</b>
Class 50	2.70-3.00	<b>1.70-2.00</b>
<b>Class 60</b>	<b>2.50-2.85</b>	<b>1.90-2.10</b>

### Castability

Successful production of a gray iron casting depends on the fluidity of the molten metal and on the cooling rate, which is influenced by the minimum section thickness and by section thickness variations. As described below, casting design is often described in terms of section sensitivity. This is an attempt to correlate properties in critical sections of the casting with the combined effects of composition and cooling rate. All of these factors are related and may be condensed into a single term, *castability*, which for gray iron can be defined as the minimum section thickness that can be produced in a mold cavity with a given volume/area ratio and mechanical properties consistent with the type of iron being poured.

**Fluidity.** Scrap losses resulting from misruns, cold shuts, and round corners are often attributed to the lack of fluidity of the metal being poured.

Mold conditions, pouring rate, and other process variables being equal, the fluidity of commercial gray irons depends primarily on the amount of superheat above the freezing temperature (liquidus). As the total carbon (TC) content decreases, the liquidus temperature increases, and the fluidity at a given pouring temperature therefore decreases. Fluidity is commonly measured as the length of flow into a spiral-type fluidity test mold. The relation between fluidity and superheat is shown in Fig. 1 and Table 1 for unalloyed gray irons of different carbon contents.

**Table 1 Superheat above liquidus for 2% Si irons of various carbon contents poured at 1455 °C (2650 °F)**

Carbon, %	Liquidus temperature		Superheat above liquidus	
	°C	°F	°C	°F
2.52	1295	2360	160	<b>290</b>
3.04	1245	2270	210	<b>380</b>

3.60	1175	2150	280	500
------	------	------	-----	-----

Fig. 1 Fluidity versus degree of superheat for four gray irons of different carbon contents

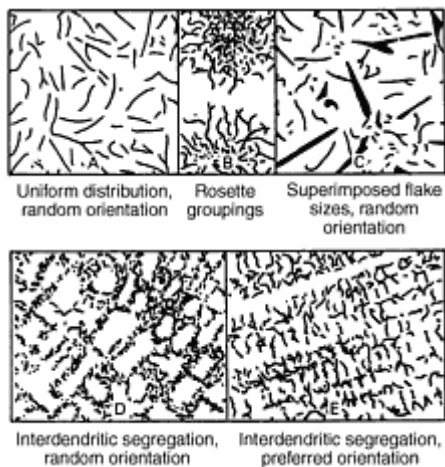

### Microstructure

The usual microstructure of gray iron is a matrix predominantly of pearlite, with graphite flakes dispersed throughout (Fig. 2). Foundry practice can be varied so that nucleation and growth of graphite flakes occur in a pattern that enhances the desired properties. The amount, size, and distribution of graphite are important. Cooling that is too rapid may produce "mottled iron," in which carbon is present in the form of both primary cementite (iron carbide) and graphite. Very slow cooling of irons that contain large percentages of silicon and carbon is likely to produce a matrix predominantly of ferrite, together with coarse graphite flakes.

Fig. 2 Class 30 gray iron, as-cast. Structure consists of type A graphite in a pearlitic matrix.

**Graphite Morphology.** The mechanical and physical properties of gray iron are governed in part by the shape, size, amount, and distribution of the graphite flakes. A method for evaluating graphite-flake distribution and size is given in ASTM A 247. There are five graphite-flake distributions: A to E (Fig. 3 ).

**Fig. 3 Graphite distributions specified in ASTM A 247**

Type A graphite flakes are randomly distributed and oriented throughout the iron matrix (Fig. 2). This type of graphite is found in irons that solidify with a minimum amount of undercooling, and type A is the structure desired if mechanical properties are to be optimized.

Type B graphite (rosette pattern) is formed in irons of near-eutectic composition that solidify with a greater amount of undercooling than that associated with type A graphite. Type B flake graphite is common with moderately thin sections (about 10 mm, or  $\frac{3}{8}$  in.) and along the surface of thicker sections.

Types D and E graphite form when the amount of undercooling is high but is not sufficient to cause carbide formation. Both types are found in interdendritic regions. Type D graphite is randomly distributed while type E flakes have a preferred orientation. The manner in which the plane of polish intersects the graphite flakes may be responsible for this difference in orientation. Elements such as titanium and aluminum promote undercooled graphite structures. The iron matrix associated with undercooled graphite is usually ferrite, because formation of the fine, highly branched flakes reduces carbon diffusion distances and results in a low-carbon matrix. Because ferrite has a lower tensile strength than pearlite, there is a reduction in the anticipated strength of the iron.

Type C graphite occurs in hypereutectic irons, particularly those with a high carbon content. Type C graphite precipitates during the primary freezing of the iron. Kish graphite, as it is often called, appears as straight, coarse plates. It greatly reduces the mechanical properties of the iron and produces a rough surface finish when machined. However, type C graphite is desirable in applications requiring a high degree of heat transfer.

Graphite-flake sizes also influence properties. Large flakes are associated with irons having high *CE* values and slow cooling rates. Strongly hypoeutectic irons and irons subjected to rapid solidification generally exhibit small, short flakes. The large flakes are desirable in applications requiring high-thermal conductivity and damping capacity. Small flakes, because they disrupt the matrix to a lesser extent, are desired when maximum tensile properties and a fine, smooth surface finish are needed.

## Section Sensitivity

In practice, the minimum thickness of section in which any given class of gray iron may be poured is more likely to depend on the cooling rate of the section than on the fluidity of the metal. For example, although a plate 300 mm (12 in.) square by 6 mm (0.25 in.) thick can be poured classes 50 and 25 iron, the class 50 casting would not be gray iron, because the cooling rate would be so rapid that massive carbides would be formed. Yet it is entirely feasible to use class 50 iron for a diesel-engine cylinder head that has predominantly 6 mm (0.25 in.) wall sections in the water jackets above the firing deck. This is simply because the cooling rate of the cylinder head has been reduced by the "mass effect" resulting from enclosed cores and the proximity (often less than 12 mm, or 0.50 in.) of one 6 mm (0.25 in.) wall to the other.

It should be recognized that the smallest section that can be cast gray, without massive carbides, depends not only on metal composition but also on foundry practices. For example, by adjusting silicon content or by adding inoculants (graphitizing agents) to the ladle (or, more effectively, to the stream as the mold is poured), the foundryman may decrease the minimum section size for freedom from carbides for a given basic composition of gray iron.

**Typical Effects of Section Size.** When a wedge-shape bar with about 10° taper cast in a sand mold and sectioned near the center of its length, and Rockwell hardness determinations are made on the cut surface from the point of the wedge progressively into the thicker sections, the curves so determined to show what extent continually increasing section size will affect hardness, as shown in Fig. 4

**Fig. 4** Effect of section thickness and structure. Hardness readings were taken at increasing distance from the tip of a cast wedge section, as shown by inset. Composition of iron: 3.52% C, 2.55% Si, 1.01% Mn, 0.215% P, and 0.086% S

Progressing along the curve from the left in Fig. 4, the following metallographic constituents occur. The tip of the wedge is white iron (a mixture of carbide and pearlite) with hardness greater than 50 HRC. As the iron becomes mottled (a mixture of white iron and gray iron), the hardness decreases sharply. A minimum is reached because of the occurrence of fine type D flake graphite, which usually has large amounts of ferrite. With a slightly lower cooling rate, the structure becomes fine type A flake graphite in a pearlite matrix, and the hardness rises to another maximum on the curve. This structure usually is the most desirable for resistance and strength. With increasing section thickness beyond this point, the graphite flakes become coarser and the pearlite lamellae more widely spaced, resulting in slightly lower hardness. With further increase in wedge thickness and decrease in cooling rate, pearlite decomposes progressively into a mixture of ferrite and graphite, resulting in softer and weaker iron.

The structures of most commercial gray iron castings are represented by the right-hand downward-sloping portion of the curve in Fig. 4, beyond 5 mm (0.20 in.) wedge thickness, and normally increasing section size is reflected by gradual lowering of hardness and strength. However, thin sections may be represented by the left-hand downward-sloping portion.

Figure 5 shows the effect of varying section size of tensile strength for various classes of iron. Tensile strength decreases with increasing section size for all classes of gray iron. For example, an iron with a tensile strength of 310 MPa (45 ksi) in a 25 mm (1 in.) section will develop only 207 MPa (30 ksi) in a 75 mm (3 in.) section because of the decreased cooling rate associated with the larger section. This reduction in tensile strength is caused by the presence of larger graphite flakes and by a reduction in combined carbon. Decreasing combined carbon results in an increase in the amount of ferrite found, either a coarser pearlite spacing or the appearance of a ferrite phase.

Fig. 5 Effect of section size on tensile strength of specimens cast from five classes of gray iron

The maximum strength of class 20 iron occurs at a smaller section size than for class 60 iron. Each class has a minimum section size that can be cast without the formation of iron carbide. Recommended minimum section sizes are listed in Table 2 for each class of unalloyed gray iron. It is important for both the foundryworker and the designer to recognize that each class of iron has a minimum section size in which it can be cast without the presence of chill and that this minimum increases with higher classes of gray iron.

Table 2 Minimum recommended section sizes for unalloyed gray irons

Class	Minimum section thickness		Volume-to-surface-area ratio <sup>(a)</sup>	
	mm	in.	mm	in.
20	3.2	$\frac{1}{8}$	1.5	<b>0.06</b>
25	6.4	$\frac{1}{4}$	3.0	<b>0.12</b>
30	9.5	$\frac{3}{8}$	4.3	<b>0.17</b>
35	9.5	$\frac{3}{8}$	4.3	<b>0.17</b>
40	15.9	$\frac{5}{8}$	7.1	<b>0.28</b>
50	19.0	$\frac{3}{4}$	8.4	<b>0.33</b>

(a) Volume-to-surface-area ratios are for square plates.

## Prevailing Sections

Although the ASTM size B test bar (30.5 mm, or 1.2 in., diameter) is the bar most commonly used for all gray irons from classes 20 to 60, ASTM A 48 provides a series of bar sizes, and the user can select the bar sizes that best approximates the cooling rate in the critical section of the casting. In practice, it is customary to be somewhat more definite about the recommended values of minimum prevailing casting section for the various ASTM classes of cast iron (Table 2). The prevailing sections should be free of carbidic areas. In a platelike section, occasional thinner walls (such as ribs) are of no importance unless they are very thin or are appended to the outer edges of the casting.

Figure 6 shows mechanical properties of classes 30 and 50 gray irons in various sections. For class 30 iron, the combined carbon content and hardness are still at a safe level in sections equivalent to a 10 mm (0.4 in.) plate, which has a volume-to-area ( $V/T$ ) ratio of about 5 mm (0.20 in.). For class 50 iron, however, both combined carbon and Brinell hardness (HB) show marked increases when the thickness of the equivalent plate section is decreased to about 15 mm (0.6 in.), with  $V/A$  ratio  $\sim 7$  mm (0.27 in.). These results are consistent with the recommendations in Table 2.

**Fig. 6** Mechanical properties of class 30 and class 50 gray iron as a function of section size. Composition of the class 30 iron: 3.40% C, 2.38% Si, 0.71% Mn, 0.423% P, and 0.152% S. Composition of the class 50 iron: 2.96% C, 1.63% Si, 1.05% Mn, 0.67% Mo, 0.114% P, and 0.072% S

The hazards involved in pouring a given class of gray iron in a plate section thinner than recommended are discovered when the casting is machined. Typical losses are a result of specifying too high a strength for a prevailing section of 9.5 mm ( $\frac{3}{8}$  in.) are:

Class	Rejections, %
-------	---------------

35	<b>Negligible</b>
45	<b>25</b>
55	<b>80-100</b>

Rejections were for "hard spots" that made it impossible to machine the castings by normal methods.

In marginal applications, a higher class of iron can sometimes be used if the casting is cooled slowly (in effect, increasing the section thickness) by judicious placement of flowoffs and risers.

## Test Bar Properties

Mechanical property values obtained from test bars are sometimes the only available guides to the actual mechanical properties of the metal in production castings. When test bars and castings are both poured from the same metal and have subsequent thermal histories that are nearly identical, the strength of the test bars gives a general indication of strength of the metal in the castings. However, test bar results cannot be assumed to represent accurately the properties of the metal in every section of every casting, because of differences in section size and cooling rate.

**Usual Tests.** Tension and transverse tests on bars cast specifically for such tests are the most common for evaluating the strength of gray iron.

Yield strength, elongation, and reduction of area are seldom determined for gray iron in standard tension tests. The transverse test measures strength in bending and has the additional advantage that a deflection value may be obtained readily. Table 3 gives minimum specification values. Data usually can be obtained faster from the transverse test than from the tension test because machining of the specimen is unnecessary in transverse testing. The surface condition of the bar will affect the transverse test but not the tension test made on a machined specimen. Conversely, the presence of coarse graphite in the center of the bar, which can occur in an iron that is very section sensitive, will affect the tension test but not the transverse test.

**Table 3 Transverse breaking loads of gray irons tested per ASTM A 438**

ASTM class <sup>(a)</sup>	Approximate tensile strength		Corrected transverse breaking load <sup>(a)</sup>					
			A bar <sup>(b)</sup>		B bar <sup>(c)</sup>		C bar <sup>(d)</sup>	
	MPa	ksi	kN	lbf	kN	lbf	kN	lbf
20	138	20	4.00	900	8.01	1800	26.69	<b>6,000</b>
25	172	25	4.56	1025	8.90	2000	30.25	<b>6,800</b>
30	207	30	5.12	1150	9.79	2200	33.81	<b>7,600</b>
35	241	35	5.67	1275	10.68	2400	36.92	<b>8,300</b>
40	276	40	6.23	1400	11.57	2600	40.48	<b>9,100</b>

45	310	45	6.85	1540	12.46	2800	43.15	<b>9,700</b>
50	345	50	7.45	1675	13.34	3000	48.04	<b>10,300</b>
<b>60</b>	<b>414</b>	<b>60</b>	<b>8.56</b>	<b>1925</b>	<b>15.12</b>	<b>3400</b>	<b>55.60</b>	<b>12,500</b>

- (a) For separately cast test specimens produced in accordance with ASTM A 48, ASTM A 278, ASME SA278, FED QQ-1-652, or any other specification that designates ASTM A 438 as the test method. Included in specifications only by agreement between producer and purchaser.
- (b) 22.4 mm (0.88 in.) diam; 305 mm (12 in.) between supports.
- (c) 30.5 mm (1.20 in.) diam; 457 mm (18 in.) between supports.
- (d) 50.8 mm (2.00 in.) diam; 610 mm (24 in.) between supports

**Typical Specifications.** ASTM A 48 is typical of specifications based on test bars. In practice, separately cast test bars in one of three different standard sizes are used to evaluate the properties in the controlling section of the castings. After manufacturer and purchaser agree on a controlling section of the casting, the size of test bar that corresponds, approximately to the cooling rate expected in that section is specified by letter (see Table 4).

**Table 4 Test bars designed to match controlling sections of castings (ASTM A 48)**

Controlling section		Test bar	Diameter of as-cast test bar	
in.	mm		mm	in.
<0.25	<6	S	(a)	(a)
0.25-0.50	6-12	A	22.4	<b>0.88</b>
0.51-1.00	13-25	B	30.5	<b>1.20</b>
1.01-2.00	26-50	C	50.8	<b>2.00</b>

- (a) All dimensions of test bar by agreement between manufacturer and purchaser

Most gray iron castings for general engineering use are specified as class 25, 30, or 35. Specification A 48 is based entirely on mechanical properties, and the composition that provides the required properties can be selected by the individual producer. A manufacturer whose major production is medium-section castings of class 35 iron will find, for

heavy-section castings where the 50 mm (2 in.) test bar is required for qualifying, that the same composition will not meet the requirements for class 35. It will qualify only for a lower class, such as 25 or 30. As thickness of the controlling section increases, the composition must be adjusted to maintain the same tensile strength.

ASTM specifications other than A 48 include A 159 (automotive), A 126 (valves, flanges, and pipe fittings), A 74 (soil pipe and fittings), A 278 (pressure-containing parts for temperatures up to 340 °C, or 650 °F), A 319 (nonpressure-containing parts for elevated-temperature service), A 823 (permanent-mold cast gray irons), and A 436 (austenitic gray irons for heat, corrosion, and wear resistance). Gray irons used for automotive applications are also described in SAE standard J 431.

**Compressive Strength.** When gray iron is used for structural applications such as machinery foundations or supports, the engineer is usually designing to support weight only, and bases calculations on the compressive strength of materials. Table 5, which summarizes typical values for mechanical properties of the various grades, shows the high compressive strength of gray irons. If loads other than dead weights are involved (unless these loads are constant), the problem is dynamic stresses, which are discussed later in this article.

**Table 5 Typical mechanical properties of as-cast standard gray iron test bars**

ASTM A48 class	Tensile strength		Torsional shear strength		Compressive strength		Reversed bending fatigue limit		Transverse load on test bar B		Hardness, HB
	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	kN	lbf	
20	152	22	179	26	572	83	69	10	8.23	1850	<b>156</b>
25	179	26	220	32	669	97	79	11.5	9.67	2175	<b>174</b>
30	214	31	276	40	752	109	97	14	11.23	2525	<b>210</b>
35	252	36.5	334	48.5	855	124	110	16	12.68	2850	<b>212</b>
40	293	42.5	393	57	965	140	128	18.5	14.12	3175	<b>235</b>
50	362	52.5	503	73	1130	164	148	21.5	16.01	3600	<b>262</b>
<b>60</b>	<b>431</b>	<b>62.5</b>	<b>610</b>	<b>88.5</b>	<b>1293</b>	<b>187.5</b>	<b>169</b>	<b>24.5</b>	<b>16.46</b>	<b>3700</b>	<b>302</b>

**Tensile strength** is considered in selecting gray iron for parts intended for static load in direct tension or bending. Such parts include pressure vessels, autoclaves, housings, and other enclosures, valves, fittings, and levers. Depending on the uncertainty of loading, safety factors of 2 to 12 have been used in figuring allowable design stresses. Typical tensile strength values are given in Tables 3 and 5.

**Transverse Strength and Deflection.** When an arbitration bar is loaded as a simple beam and the load and deflection required to break it are determined, the resulting value is converted into a nominal index of strength by using the standard beam formula. The value so determined is arbitrarily called the "modulus of rupture." The values for modulus of rupture are useful for production control, but cannot be used in the design of castings without further analysis and interpretation. Typical transverse breaking loads for gray irons are given in Tables 3 and 5.

**Elongation of gray iron at fracture** is very small (on the order of 0.6%) and hence is seldom reported. The designer cannot use the numerical value of permanent elongation in any quantitative manner.

**Torsional Shear Strength.** As shown in Table 5, most gray irons have high-torsional shear strength. Many grades have torsional strength greater than some grades of steel. This characteristic, along with low-notch sensitivity, make gray iron a suitable material for shafting of various types, particularly in the grades of higher tensile strength.

**Modulus of Elasticity.** Typical stress-strain curves for gray iron are shown in Fig. 7. Gray iron does not obey Hooke's law, and the modulus in tension is usually determined arbitrarily as the slope of the line connecting the origin of the stress-strain curve with the point corresponding to  $\frac{1}{4}$  of the tensile strength (secant modulus). Some engineers use the slope of the stress-strain curve near the origin (tangent modulus).

Fig. 7 Typical stress-strain curves for three classes of gray iron in tension

**Hardness** of gray iron, as measured by Brinell or Rockwell testers, is an intermediate value between the hardness of the soft graphite in the iron and that of the harder metallic matrix. Variations in graphite size and distribution will cause wide variations in hardness (particularly Rockwell hardness) even though the hardness of the metallic matrix is constant. To illustrate this effect, matrix microhardness measurements for five types of hardened iron, as compared with Rockwell C measurements on the same iron, are shown in Table 6.

Table 6 Influence of graphite type and distribution on the hardness of hardened gray irons

Type of graphite	Total carbon, %	Conventional hardness, HRC <sup>(a)</sup>	Matrix hardness, HRC <sup>(b)</sup>
A	3.06	45.2 <sup>(c)</sup>	61.5
A	3.53	43.1	61.0
A	4.00	32.0	62.0
D	3.30	54.0	62.5
D	3.60	48.7	60.5

(a) Measured by conventional Rockwell C test.

- (b) Hardness of matrix, measured with superficial hardness tester and converted to Rockwell C.
- (c) Although this value was obtained in the specific test cited, it is not typical of gray iron of 3.06% C. Ordinarily the hardness of such iron is 48 to 50 HRC.

If any hardness correlation is to be attempted, the type and amount of graphite must be constant in the irons being compared. Rockwell hardness tests are considered appropriate only for hardened castings (camshafts, for example), and even hardened castings, Brinell tests are preferred. Brinell tests must be used when attempting any strength correlations for unhardened castings.

## Fatigue Limit in Reversed Bending

Because fatigue limits are expensive to determine, the designer usually has incomplete information on this property. Figure 8 shows fatigue-life curves at room temperature for a gray iron under completely reversed cycles of bending stress. Each point represents the data from one specimen. Table 5 list additional data.

**Fig. 8** Reversed bending fatigue life at room temperature for gray iron containing 2.84% C, 1.52% Si, 1.05% Mn, 0.07% P, 0.12% S, 0.31% Cr, 0.20% Ni, and 0.37% Cu. Open circles represent notched specimens; closed circles represent unnotched specimens.

Axial loading or torsional loading cycles are frequently encountered in designing parts of cast iron, and in many instances these are not completely reversed loads. Types of regularly repeated stress variation can usually be expressed as a function of a mean stress and a stress range. Whenever possible, the designer should use actual data from the limited information available.

If precisely applicable test data are not available, the reversed bending fatigue limit of machined parts may be estimated as about 35% of the minimum specified tensile strength of the particular grade of gray iron being considered. This value is probably more conservative than an average of the limited data available on the fatigue limit for gray iron.

# Ductile Iron

## Introduction

DUCTILE CAST IRON, also known as nodular iron or spheroidal-graphite (SG) cast iron, is cast iron in which the graphite is present as tiny spheres (nodules) (see Fig. 1). In ductile iron, eutectic graphite separates from the molten iron

during solidification in a manner similar to that in which eutectic graphite separates in gray cast iron. However, because of additives introduced in the molten iron before casting, the graphite grows as spheres, rather than as flakes of any of the forms characteristic of gray iron. Cast iron containing spheroidal graphite is much stronger and has higher elongation than gray iron or malleable iron. It may be considered a natural composite in which the spheroidal graphite imparts unique properties to ductile iron.

**Fig. 1** Spheroidal graphite in an unetched ductile iron matrix shown at 75 $\times$  (a) and in the etched (picral) condition shown at 300 $\times$  (b). Etching reveals that the matrix consists of ferritic envelopes around the graphite nodules (bull's-eye structure) surrounded by a pearlitic matrix.

The relatively high strength and toughness of ductile iron give it an advantage over gray iron or malleable iron in many structural applications. Also, because ductile iron does not require heat treatment to produce graphite nodules (as malleable iron does to produce temper-carbon nodules), it can compete with malleable iron even though it requires a melt treatment and inoculation process. The mold yield is normally higher than with malleable iron. Ductile iron can be produced to x-ray standards because porosity stays in the thermal center. Malleable iron cannot tolerate porosity because voids migrate to the surface of hot spots such as fillets and appear as cracks.

## General Characteristics of Ductile Irons

Typically, the composition of unalloyed ductile iron differs from that of gray iron or malleable iron (Table 1). The raw materials used for ductile iron must be of higher purity. Like gray iron, ductile iron can be melted in cupolas, electric arc furnaces, or induction furnaces. Ductile iron, as a liquid, has high fluidity, excellent castability, but high surface tension. The sands and molding equipment used for ductile iron must provide rigid molds of high density and good heat transfer.

**Table 1 Typical composition ranges for unalloyed cast irons**

Type	Composition, %										
	TC <sup>(a)</sup>	Mn	Si	Cr	Ni	Mo	Cu	P	S	Ce	Mg
Gray iron	3.25-3.50	0.50-0.90	1.80-2.30	0.05-0.45	0.05-0.20	0.05-0.10	0.15-0.40	0.12 max	0.15 max	...	...
Malleable iron	2.45-2.55	0.35-0.55	1.40-1.50	0.04-0.07	0.05-0.30	0.03-0.10	0.03-0.40	0.03 max	0.05-0.07	...	...
Ductile iron	<b>3.60-3.80</b>	<b>0.15-1.00</b>	<b>1.80-2.80</b>	<b>0.03-0.07</b>	<b>0.05-0.20</b>	<b>0.01-0.10</b>	<b>0.15-1.00</b>	<b>0.03 max</b>	<b>0.002 max</b>	<b>0.005-0.20<sup>(b)</sup></b>	<b>0.03-0.06</b>

(a) TC, total carbon.

(b) Optional

**Solidification and Shrinkage Characteristics.** The formation of graphite during solidification causes an attendant increase in volume, which can counteract the loss in volume due to the liquid-to-solid phase change in the metallic constituent. Ductile iron castings typically require only minimal use of risers (reservoirs in the mold that feed molten metal into the mold cavity to compensate for liquid contraction during cooling and solidification). Gray irons often do not require risers to ensure shrinkage-free castings. On the other hand, steels and malleable iron generally require heavy risering. Thus, the mold yield of ductile iron castings (the ratio of the weight of usable castings to the weight of metal poured) is much higher than the mold yield of either steel castings or malleable iron castings, but not as high as that of gray iron. In some cases, ductile iron castings have been made without risers.

Often designers must compensate for the shrinkage of cast iron (during both solidification and subsequent cooling to room temperature) by making patterns with dimensions larger than those desired in the finished castings. Typically, ductile iron requires less compensation than any other cast ferrous metal. The allowances in patternmaker rules (shrink rules) are usually:

Type of cast metal	Shrinkage allowance, %
Ductile iron	<b>0-0.7</b>
Gray iron	<b>1.0</b>
Malleable iron	<b>1.0</b>
Austenitic alloy iron	<b>1.3-1.5</b>

White iron	2.0
Carbon steel	2.0
Alloy steel	2.5

Shrinkage allowance can vary somewhat from the percentages given above, and different percentages must often be used for different directions in one casting because of the influence of the solidification pattern on the amount of contraction that takes place in different directions. Shrinkage is volumetric, and the ratio of dimensions to volume influences each dimension. As ductile iron approaches a condition of shrinkage porosity, the graphite nodules tend to become aligned and can result in lower fatigue strength.

**As-Cast versus Heat Treated.** Most ductile iron castings are used as-cast, but in some foundries, some castings are heat treated before being shipped. Heat treatment varies according to the desired effect on properties. Any heat treatment, with the exception of austempering, reduces fatigue properties. Holding at subcritical (705 °C, or 1300 °F) temperature for no more than 4 h improves fracture resistance. Heating castings above 790 °C (1450 °F) followed by fast cooling (oil quench or air quench) significantly reduces fatigue strength and fracture resistance at temperatures above room temperature. Ferritizing by heating to 900 °C (1650 °F) and slow cooling has the same effects. Heating to above the critical temperature also reduces the combined carbon content of quenched and tempered microstructures and produces lower tensile strength and wear resistance than the same hardness produced as-cast. Some castings may be given hardening treatments (either localized surface or through hardened) that produce bainitic or martensitic matrices.

As the matrix structure is varied progressively from ferrite to ferrite and pearlite to pearlite to bainite and finally to martensite, hardness, strength, and wear resistance increase, but impact resistance, ductility, and machinability decrease. An exception to this is austempered ductile iron, in which considerable elongation (as high as 10%) can be obtained even at high strengths (1000 MPa, or 145 ksi). Austempered ductile iron (ADI) has a matrix that is a combination of acicular (bainitic) ferrite and stabilized austenite (Fig. 2).

**Fig. 2** Austempered ductile iron structure consisting of spheroidal graphite in a matrix of bainitic ferritic plates (dark) and interplate austenite (white)

**Alloying.** Ductile iron can be alloyed with small amounts of nickel, molybdenum, or copper to improve its strength and hardenability. The addition of molybdenum is done with caution because of the tendency for intercellular segregation. Larger amounts of silicon, chromium, nickel, or copper can be added for improved resistance to corrosion, oxidation or abrasion, or for high-temperature applications.

## Specifications

Most of the specifications for standard grades of ductile iron are based on properties. That is, strength and/or hardness is specified for each grade of ductile iron, and composition is either loosely specified or made subordinate to mechanical

properties. Tables 2 and 3 list compositions, properties, and typical applications for most of the standard ductile irons that are defined by current standard specifications (except for the high-nickel, corrosion-resistant, and heat-resistant irons defined in ASTM A 439). As shown in Table 3, the ASTM system for designating the grade of ductile iron incorporates the numbers indicating tensile strength in ksi, yield strength in ksi, and elongation in percent. This system makes it easy to specify nonstandard grades that meet the general requirements of ASTM A 536. For example, grade 80-60-03 (552 MPa, or 80 ksi, minimum tensile strength; 414 MPa, or 60 ksi, yield strength; and 3% elongation) is widely used in applications for which relatively high ductility is not important. Grades 65-45-12 and 60-40-18 are used in areas requiring high ductility and impact resistance. Grades 60-42-10 and 70-50-05 are used for special applications such as annealed pipe or cast fittings. Grades other than those listed in ASTM A 536 or mentioned above can be made to the general requirements of A 536, but with the mechanical properties specified by mutual agreement between purchaser and producer.

**Table 2 Compositions and general uses for standard grades of ductile iron**

Specification No.	Grade or class	UNS	TC <sup>(a)</sup>	Typical composition, %				Description	General uses

Note: For compositions, descriptions, and uses, see Table 2.

(a) Measured at a predetermined location on the casting.

(b) Determined using a standard specimen taken from a separately cast test block, as set forth in the applicable specification.

(c) Range specified by mutual agreement between producer and purchaser.

(d) Value must be compatible with minimum hardness specified for production castings.

The Society of Automotive Engineers (now SAE International) uses a method of specifying iron for castings produced in larger quantities that is based on the microstructure and Brinell hardness of the material in the castings themselves. Both ASTM and SAE specifications are standards for tensile properties and hardness. The tensile properties are quasistatic and may not indicate the dynamic properties such as impact or fatigue strength.

Specifications for the highest-strength grades usually mention the possibility of hardened and tempered structures, but ASTM A 897 (Table 4) should be consulted for the most recently reported austempered ductile irons, which have the highest combinations of tensile strength and ductility.

**Table 4 ASTM standard A 897-90 and A 897M-90 mechanical property requirements of austempered ductile iron**

Grade	Tensile (min)		Yield (min)		Elongation, %	Impact <sup>(a)</sup>		Hardness, HB <sup>(c)</sup>
	MPa	ksi	MPa	ksi		J	ft · lbf	
125-80-10	...	125	...	80	10	...	75	<b>269-321</b>
850-550-10	850	...	550	...	10	100	...	<b>269-321</b>
150-100-7	...	150	...	100	7	...	60	<b>302-363</b>
1050-700-7	1050	...	700	...	7	80	...	<b>302-363</b>
175-125-4	...	175	...	125	4	...	45	<b>341-444</b>
1200-850-4	1200	...	850	...	4	60	...	<b>341-444</b>
200-155-1	...	200	...	155	1	...	25	<b>388-477</b>
1400-1100-1	1400	...	1100	...	1	35	...	<b>388-477</b>
230-185	...	230	...	185	<sup>(b)</sup>	...	<sup>(b)</sup>	<b>444-555</b>
<b>1600-1300</b>	<b>1600</b>	...	<b>1300</b>	...	<sup>(b)</sup>	<sup>(b)</sup>	...	<b>444-555</b>

(a) Unnotched Charpy bars tested at  $72 \pm 7$  °F ( $22 \pm 4$  °C). The values in the table are a minimum for the average of the highest three test values

of four tested samples.

(b) Elongation and impact requirements are not specified. Although grades 200-155-1, 1400-1100-1, 230-185, and 1600-1300 are primarily used for gear and wear resistance applications, grades 200-155-1 and 1400-1100-1 have applications where some sacrifice in wear resistance is acceptable in order to provide a limited amount of ductility and toughness.

(c) Hardness is not mandatory and is shown for information only.

## Manufacture and Metallurgical Control

Greater metallurgical and process control is required in production of ductile iron than in production of other cast irons. Frequent chemical, mechanical, and metallurgical testing is needed to ensure that the required quality is maintained and that specifications are met.

Manufacture of high-quality ductile iron begins with careful selection of charge materials that will yield a relatively pure cast iron free of undesirable residual elements sometimes found in other cast irons. Carbon, manganese, silicon, phosphorus, and sulfur must be held at specified levels. Magnesium, cerium, and certain other elements must be controlled in order to attain the desired graphite shape and to offset the deleterious effects of subversive elements; elements such as antimony, lead, titanium, tellurium, bismuth, and zirconium interfere with the nodulizing process, and must be either eliminated or restricted to very low concentrations.

Reduction of the sulfur content to less than 0.02% is necessary prior to the nodulizing process; this can be accomplished through basic melting alone, by use of low-sulfur charge material, or desulfurization of the base metal before the magnesium-nodulizing alloy is added. If base sulfur is not so reduced, excessive amounts of costly nodulizing alloys will be required and melting efficiency will be impaired.

**Graphite Shape and Distribution.** There are three major types of nodulizing agents, all of which contain magnesium: unalloyed magnesium, nickel-base nodulizers, and magnesium-ferrosilicon nodulizers. Unalloyed magnesium has been added to molten iron as wire, ingots, or pellets; as briquets, in combination with sponge iron; or in the cellular pores of metallurgical coke. The method of introducing the alloy has varied from an open-ladle method (in which the alloy is placed at the bottom of the ladle and iron is poured rapidly over the alloy) to a pressure-container method (in which unalloyed magnesium is placed inside a container is rotated so that the iron flows over the magnesium). In all cases, magnesium is vaporized and the vapors travel through the molten iron, lowering the sulfur content, and promoting formation of spheroidal graphite.

**Testing and Inspection.** Various tests are used to control the processing of ductile iron, starting with analyses of raw materials and of the molten metal both before and after the nodulizing treatment. Rapid thermal-arrest methods are used to determine carbon, silicon, and carbon equivalence in the molten iron. Silicon content is also determined by thermoelectric and spectrometric techniques. Chill tests are used for production-line testing for silicon.

After the nodulizing step, a standard test coupon for microscopic examination should be poured from each batch of metal, as recommended by AFS and as specified in ASTM A395. One ear of the test coupon is broken off and polished to reveal graphite shape and distribution, plus matrix structure. These characteristics are evaluated by comparison with standard ASTM/AFS photomicrographs, and acceptance or rejection of castings is based on this comparison.

Tensile-test specimens are machined from separately cast keel blocks, Y blocks, or modified keel blocks, as described in ASTM A 395. If the terms of purchase require tensile specimens to be taken from castings, the part drawing must identify the area of the casting and the size of the test specimens. These terms also must be mutually acceptable to both producer and purchaser.

Hardness testing of production castings also is used to evaluate conformance to specified properties. Some standard specifications, such as SAE J434b, relate strength and hardness, as shown in Table 3.

**Heat Treatment.** When the properties desired are difficult to obtain in the as-cast metal, ductile iron can be heat treated. Heat-treated ductile iron usually has more uniform mechanical properties than as-cast ductile iron, particularly in casts with wide variations in section thickness.

Ductile iron castings of large or nonuniform cross section occasionally are stress relieved at 540 to 660 °C (1000 to 1100 °F), which reduces warping and distortion during subsequent machining. Mechanical properties of castings are essentially unchanged by the stress-relieving process.

Full ferritizing annealing produces grade 60-40-18 for applications requiring maximum impact resistance and ductility. This heat treatment usually involves heating to 900 °C (1650 °F) and holding, then cooling to about 700 °C (1300 °F) and holding, following by controlled cooling to near room temperature.

Subcritical annealing produces either grade 60-40-18 or grade 65-45-12 for applications requiring high toughness and ductility. Subcritical annealing is usually done by heating to 730 °C (1350 °F) and holding until a ferritic structure is obtained, followed by controlled cooling to near room temperature.

Normalizing and tempering produces pearlitic grade 100-70-03, which is widely used for applications requiring good strength and wear resistance. Casting are heated to about 900 °C (1650 °F), held there long enough to stabilize the structure, and rapidly cooled with a fan or air blast. Then the castings are reheated to 540 to 675 °C (1000 to 1250 °F), which provides both stress relief and control of final hardness.

Martensitic ductile iron (grade 120-90-02) is produced by heating to about 900 °C (1650 °F) and holding, then quenching in agitated oil. This treatment produces castings of the highest strength and best wear resistance. Stress relief and control of final hardness are accomplished by tempering at 510 to 565 °C (950 to 1050 °F).

Austempered ductile iron (see Table 4) requires a two-stage heat treatment. The first stage, austenitizing, requires heating to and holding at about 900 °C (1650 °F). This is followed by the second stage, which requires quenching and isothermally holding at the required austempering temperature, usually in a salt bath. The properties of ADI depend principally on austempering temperature and time, and typical austempering treatment fall into two categories:

- Heat to 875 to 925 °C (1605 to 1695 °F), hold for 2 to 4 h, quench in a salt bath at 400 to 450 °C (750 to 840 °F), hold for 1 to 6 h, and cool to room temperature
- The same as the previous method but hold for 1 to 6 h at 235 to 350 °C (455 to 660 °F)

The first treatment listed above would yield high ductility and high strength with medium hardness but a very good ability to work harden. The second treatment would yield very high strength with some ductility and a fairly high hardness.

Figure 3 compares the strength and ductility of as-cast ductile iron with ductile irons subjected to the heat treatments described above. Further information is found in the Section "Heat Treating" in this Handbook.

Fig. 3 Strength and ductility ranges of as-cast and heat-treated ductile irons

## Mechanical Properties

Most of the standard specifications for ductile iron require minimum strength and ductility, as determined using separately cast standard ASTM test bars. The various specification limits have been established by evaluating the results from thousands of these test bars. Properties of test bars are useful approximations of the properties of finished castings. Test bar properties also make it possible to compare many different batches of metal without accounting for variations due to differences in the shapes being cast or differences in the production practices used in different foundries.

Test bars are machined from keel blocks, Y blocks, or modified keel blocks (see ASTM A 395 for details and dimensions). The test blocks are designed for ideal feeding from heavy molten metal heads over the mold and for controlled cooling at optimum rates. In practice, these characteristics may not be economically feasible, or may be impossible because of the configuration of the casting. As a result, actual properties of production castings may differ from those of test bars cast from the same heat of molten metal, a fact that sometimes is overlooked.

**Effect of Composition.** The properties of ductile iron depend first on composition. Composition should be uniform within each casting and among all castings poured from the same melt. Many elements influence casting properties, but those of greatest importance are the elements that exert powerful influences on matrix structure or on shape and distribution of graphite nodules.

Carbon influences the fluidity of the molten iron and the shrinkage characteristics of the cast metal, both of which affect casting design. Carbon also influences the size and number of graphite particles that are formed on solidification. The size and number of graphite particles is also influenced by inoculation procedures.

Silicon is a powerful graphitizing agent. Within the normal composition limits, increasing amounts of silicon promote structures that have progressively greater amounts of ferrite; furthermore, silicon contributes to the solution strengthening of ferrite. Increasing the amount of ferrite increases ductility and slightly increases yield strength, but concurrently reduces tensile strength and Brinell hardness.

Among the alloying elements commonly used to improve the mechanical properties of ductile iron, manganese acts as a pearlite stabilizer and increases strength, but reduces ductility. Nickel is frequently used to increase strength by promoting formation of fine pearlite. Nickel is also used to increase hardenability, especially for surface-hardening applications. Copper has been used as a pearlite stabilizer, and as such, increases strength. Molybdenum can be added to stabilize the structure at elevated temperature, thus promoting better retention of strength at temperatures up to about 650 °C (1200 °F) in unalloyed or low-alloy ductile irons.

**Effect of Graphite Shape.** Conversion of graphite from flakes to nodules, which is caused by addition of magnesium (or magnesium and cerium) to the molten iron, results in a fivefold to sevenfold increase in the strength of the cast metal. Shapes that are intermediate between a true nodular form and a flake form (such as, respectively, ASTM types I and VII, as established by ASTM A 247) yield mechanical properties that are inferior to those of ductile iron with a true nodular graphite but that are still better than the properties of gray iron of similar composition.

**Effect of Section Size.** Cooling rate is the variable chiefly affected by section size. The cooling rate, in turn, affects both the size of the graphite nodules and the microstructure of the matrix. The heavier the section, the more slowly it cools, and therefore, the larger the graphite nodules that can form on solidification. When ductile iron is cast in sections greater than about 65 mm ( $2\frac{1}{2}$  in.), there is the possibility that degenerative graphite shapes (vermicular, crab, etc.) will be produced. Careful control of residual and/or the presence of small amounts of cerium are usually effective in combating this problem.

The structure of the matrix is essentially determined by the cooling rate through the eutectoid temperature range, although the specific effects of cooling rate are modified by the presence of alloying elements, as discussed previously in the section on effect of composition. Slow cooling rates prevalent in heavy sections promote transformation of ferrite. For a given silicon content, a decrease in section size and an increase in cooling rate tends to promote pearlite formation, along with an increase in strength and hardness and a decrease in ductility. Bainitic or martensitic structures are not often found in as-cast ductile iron, although it is possible for such structures to occur in very thin sections; these structures are normally obtained by heat treatment. Bainite and martensite are the main constituents in high-strength, heat-treated ductile irons such as grade 120-90-2.

**Tensile properties** of one heat of ductile iron heat treated to strength levels approximately equivalent to four standard ductile irons are given in Table 5. These values are not necessarily the average property values that can be expected for metal produced to the indicated grades. Within each grade, strength and ductility vary somewhat with hardness, as shown in Fig. 4. In some instances, the ranges of expected strength and ductility overlap those for the next higher or lower grade.

**Table 5 Average mechanical properties of ductile irons heat treated to various strength levels**

Note: Determined for a single heat of ductile iron, heat treated to approximate standard grades. Properties were obtained using test bars machined from 25 mm (1 in.) keel blocks.

(a) 0.2% offset.

(b) 0.0375% offset.

(c) Calculated from tensile modulus and Poisson's ratio in tension

**Fig. 4** Tensile properties of ductile iron versus hardness. Mechanical properties were determined on specimens taken from a 25 mm (1 in.) keel block.

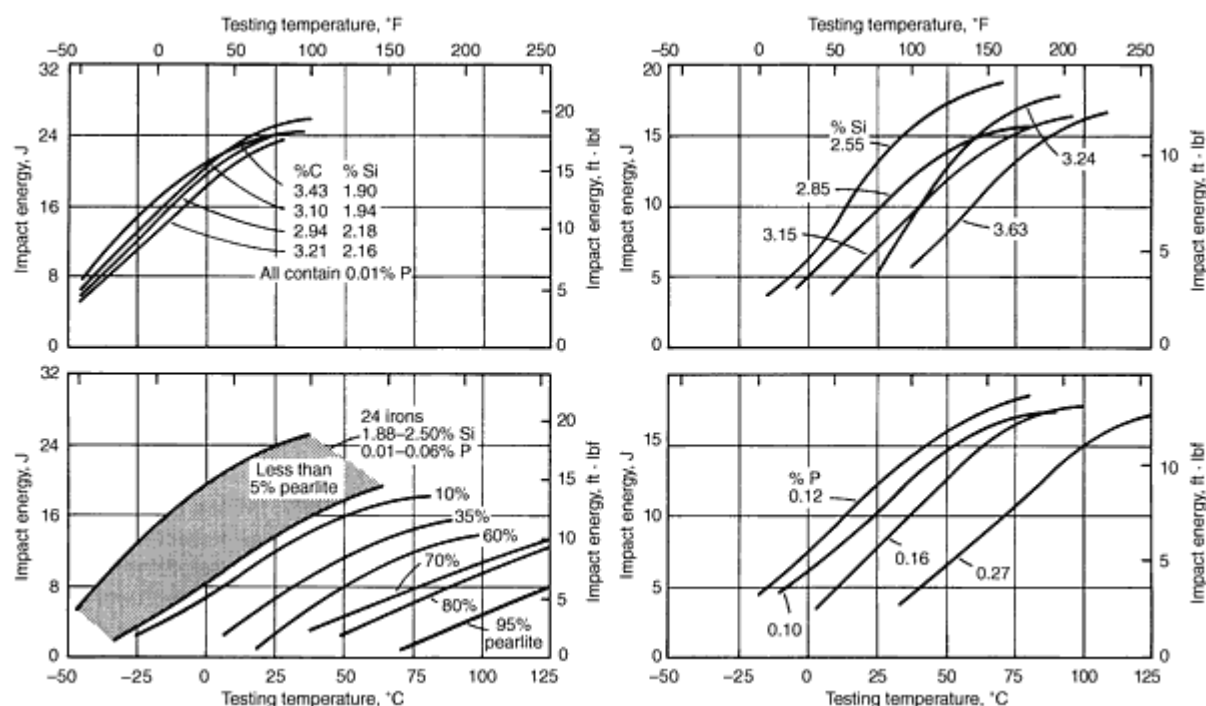

As shown in Table 5, the modulus of elasticity in tension range from 164 to 169 GPa ( $23.8$  to  $24.5 \times 10^6$  psi) and does not vary greatly with grade. The values of tensile modulus shown in Table 5 were determined using standard 12.83 mm diameter (0.505 in. diameter) tensile bars equipped with strain gages affixed to the reduced section.

**Compressive Properties.** The 0.2% offset yield strength of ductile iron in compression generally is reported as 1.0 to 1.2 times the 0.2% offset yield strength in tension. The compressive properties shown in exit Table 5 were determined using specimens from the same single heat of ductile iron described previously above under "Tensile Properties."

**Torsional Properties.** Very few data are available on the ultimate shear strength of ductile iron because it is very difficult to obtain accurate shear data on materials that exhibit some ductility. It is generally agreed that the ultimate shear strength of ductile cast iron is about 0.9 to 1.0 times the ultimate tensile strength and 0.0375% offset yield strength in torsion for a single heat of ductile iron heat treated to strength levels approximately equivalent to four standard ductile irons.

**Damping Capacity.** The average damping capacity of ductile iron in the hardness range of 156 to 241 HB is about 6.6 times that of 1018 steel and about 0.12 times that of class 30 gray iron.

**Impact Properties.** Figure 5 shows data from a comprehensive study of impact properties of ductile iron. These data show that increasing pearlite decreases impact energy and that increasing phosphorus and/or silicone decreases impact energy. The transition temperature is significantly affected by phosphorus and/or silicon content, but is little affected by other elements present within the normal variations in composition.

**Fig. 5** Effect of composition and microstructure on Charpy V-notch impact behavior of ductile iron

**Fracture Toughness.** Certain low-strength grades of ductile iron do not fracture in a brittle manner when tested under nominal plane-strain conditions in a standard fracture toughness test. The behavior is contrary to the basic tenets of fracture mechanics and has been attributed to localized deformation in the ferrite envelope surrounding each graphite nodule. In the low-strength ductile irons, plane-strain conditions are established only at temperatures low enough to embrittle the ferrite. Otherwise, an increase in the size of the fracture toughness test specimens does not provide the degree of mechanical constraint necessary to obtain a valid measurement of  $K_{Ic}$ .

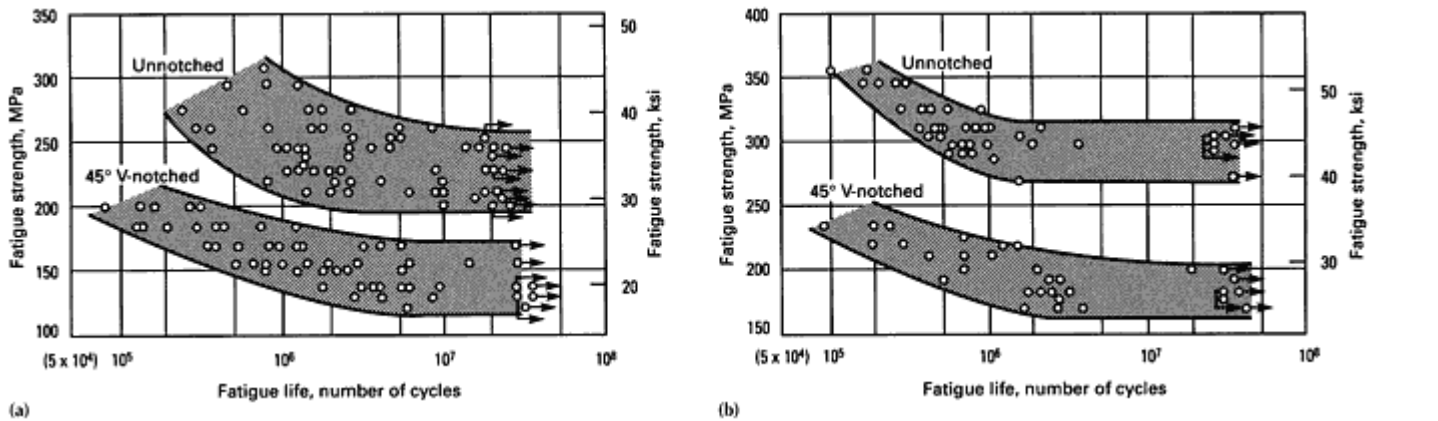

Table 6 gives selected values of fracture toughness. These values were determined using compact tension specimens 21 mm (0.83 in.) in width. All tests were completed in accordance with ASTM E 399. Table 6 gives data for ductile iron with a nodule shape approximately corresponding to 50% ASTM type I.

Table 6 Fracture toughness of ductile iron

(a) Estimated

**Fatigue Strength.** Figure 6 shows fatigue-strength curves for ferritic and pearlitic ductile iron in both the notched and unnotched conditions. The tests were made on Wohler-type fatigue machines with polished specimens 10.6 mm (0.417 in.) in diameter.

Grade	Tensile strength		Unnotched				Notched				Stress concentration factor
			Endurance limit		Endurance ratio	Endurance limit		Endurance ratio			
	MPa	ksi	MPa	ksi		MPa	ksi				

<b>60-40-18</b>	480	70	205	30	0.43	125	18	0.26	1.67
<b>80-55-06</b>	680	99	275	40	0.40	165	24	0.24	1.67

**Fig. 6** Fatigue strength versus fatigue life for ductile iron in both the unnotched and 45° Charpy V-notched condition. (a) Ferritic (60-40-18 annealed). (b) Pearlitic (80-55-06 as-cast)

The endurance limit for a given grade of ductile iron depends on surface conditions. Endurance ratio is defined as endurance limit divided by tensile strength. Because the endurance ratio of ductile iron declines as tensile strength increases, regardless of matrix structure, there may be little value in specifying a higher-strength ductile iron for a structure that is prone to fatigue failure; redesigning the structure to reduce stresses may prove to be a better solution.

### Elevated-Temperature Properties

Ductile irons exhibit several properties that enable them to perform successfully in numerous elevated-temperature applications. Unalloyed grades retain their strength to moderate temperatures and exhibit significantly better resistance to dimensional growth and oxidation than unalloyed gray iron. High-alloy ductile irons (Ni-Resists) provide outstanding resistance to deformation, growth, and oxidation at high temperatures.

# Compacted Graphite Iron

### Introduction

COMPACTED GRAPHITE (CG) IRONS are the newest member of the cast iron family. Compacted graphite irons have inadvertently been produced in the past as a result of insufficient magnesium or cerium levels in melts intended to produce spheroidal graphite iron; however, it has only been since 1965 that CG iron has occupied its place in the cast iron family as a material with distinct properties requiring distinct manufacturing technologies.

### Graphite Morphology

The shape of compacted graphite is rather complex. An acceptable CG iron is an iron in which there is no flake graphite in the structure and for which the amount of spheroidal graphite is less than 20%; that is, 80% of all graphite is compacted (vermicular) (ASTM A 247, Type IV). Figure 1 shows typical CG iron microstructures. It can be seen that although the two-dimensional appearance of compacted graphite is that of flakes with a length-to thickness ratio of 2 to 10 (Fig. 1a), the three-dimensional scanning electron microscopy (SEM) structure (Fig. 1b) shows that graphite does not appear in flakes but rather in clusters interconnected with the eutectic cell.

**Fig. 1** Typical microstructures of CG irons. (a) Optical micrograph. Etched with nital. (b) SEM micrograph

showing true shape of graphite in CG iron. Full deep etch. 395×

This graphite morphology allows better use of the matrix, yielding higher strength and ductility than gray irons containing flake graphite. Similarities between the solidification patterns of flake and compacted graphite iron explain the good castability of the compacted graphite iron compared to that of ductile iron. In addition, the interconnected graphite provides better thermal conductivity and damping capacity than spheroidal graphite.

## Chemical Composition

**Carbon Equivalent.** The characteristic properties of CG irons have been demonstrated over a rather wide range of carbon equivalent, CE, values, extending from hypoeutectic (CE = 3.7) to hypoeutectic (CE = 4.7), with carbon contents of 3.1 to 4.0% and silicon in amounts of 1.7 to 3.0%. At constant silicon levels, a lower CE slightly increases the chilling tendency and results in lower nodularity. At constant CE, higher silicon increases nodularity. Figure 2 shows the optimum carbon and silicon content.

Fig. 2 Optimum range for carbon and silicon contents for CG iron

The optimum CE must be selected as a function of section size. For a given section size, too high a CE will result in graphite flotation, as in the case of spheroidal graphite cast iron, while too low a CE may result in increasing chilling tendency. For wall thicknesses ranging from 10 to 40 mm (0.4 to 1.6 in.), eutectic composition (CE = 4.3) is recommended in order to obtain optimum casting properties.

**Manganese and Phosphorus Contents.** The manganese content of CG iron can vary between 0.9 and 0.6%, depending on whether a ferritic or pearlitic structure is desired. The phosphorus content should be less than 0.06% to obtain maximum ductility from the matrix.

**Sulfur Content.** Although CG iron has been produced from base irons having sulfur contents as high as 0.07 to 0.12%, it is probably more economical to desulfurize the iron to a level of 0.01 to 0.025% before liquid treatment. The higher the sulfur content, the more alloy is required for melt treatment. Also, the risk of missing the composition window for CG iron is increased, because the residual treatment elements must be balanced with the residual sulfur. Typical residual sulfur levels after treatment are 0.01 to 0.02%.

**Melt Treatment Elements.** The change in graphite morphology from the flake graphite in the base iron to the compacted graphite in the final iron is achieved by liquid treatment with different iron elements. Those elements may include one or more of the following: magnesium, rare earths (cerium, lanthanum, praseodymium, etc.), calcium,

titanium, and aluminum. The amount and combination to be used are a function of the method of liquid treatment (level of minor elements), base and sulfur, and section thickness.

**Alloying elements**, such as copper, tin, molybdenum, and even aluminum, can be used to change the as-cast matrix of CG iron from ferrite to pearlite. Typical ranges are 0.48 to 0.9% Cu, 0.033 to 0.13% Sn, and 0.5 to 1% Mo.

## Properties and Applications

**Properties.** In general, the property values of CG irons (both mechanical and physical) fall between those of gray irons and ductile irons. Compared to gray irons, CG irons have certain advantages:

- Higher tensile strength at the same carbon equivalent, which reduces the need for expensive alloying elements such as nickel, chromium, copper and molybdenum
- Higher ratio of tensile strength to hardness
- Much higher ductility and toughness, which result in a higher safety margin against fracture
- Lower oxidation and growth at high temperatures
- Less section sensitivity for heavy sections

Compared to ductile irons, the advantages of CG irons are:

- Lower coefficient of thermal expansion
- Higher thermal conductivity
- Better resistance to thermal shock
- Higher damping capacity
- Better castability, leading to higher casting yield and the capability of pouring more intricate castings
- Improved machinability

Table 1 compares selected properties of gray, ductile, and CG irons. A listing of tensile properties of various CG irons produced by different melt treatment methods is given in Table 2. Table 3 lists property requirements of CG irons per ASTM A 842.

**Table 1 Comparison of properties of cerium-treated CG iron with flake graphite (FG) iron of the same chemical composition, high-strength pearlitic FG iron, and ferritic spheroidal graphite (SG) iron in the as-cast condition**

<b>450<sup>(d)</sup></b>	450	65.3	315	45.7	1.0	207-269	4.2-3.7

- (a) Grades are specified according to the minimum tensile strength requirement given in MPa.
- (b) Brinell impression diameter (BID) is the diameter (in mm) of the impression of a 10 mm diameter ball at a load of 3000 kgf.
- (c) The 250 grade is a ferritic grade. Heat treatment to attain required mechanical properties and microstructure is the option of the manufacturer.
- (d) The 450 grade is a pearlitic grade usually produced without heat treatment with addition of certain alloys to promote pearlite as a major part of the matrix.

**Applications.** Compacted graphite iron can be substituted for gray iron in all cases in which the strength of gray iron has become insufficient, but in which a change to SC iron is undesirable because of the less favorable casting properties of the SG iron. Examples include bed plates for large diesel engines, crankcases, gearbox housing, turbocharger housing, connecting forks, bearing brackets, pulleys for truck servodrives, sprocket wheels, and eccentric gears.

Because the thermal conductivity of CG iron is higher than that of ductile iron, CG iron is preferred for castings operating at elevated temperature and/or under thermal fatigue conditions. Applications include ingot molds, crankcases, cylinder heads, exhaust manifolds, and brake disks.

# Malleable Iron

## Introduction

MALLEABLE IRON is a type of cast iron that has most of its carbon in the form of irregularly shaped graphite nodules instead of flakes, as in gray iron, or small graphite spherulites, as in ductile iron. Malleable iron is produced by first casting the iron as a white iron and then heat treating the white cast iron to convert the iron carbide into the irregularly shaped nodules of graphite. This form of graphite in malleable iron is called temper carbon because it is formed in the solid state during heat treatment. Figure 1 shows the microstructure of typical malleable cast iron.

**Fig. 1** Microstructure of a typical malleable cast iron showing graphite in the form of temper carbon. 4% picral etch. 250×

Malleable irons can be classified into three categories; ferritic malleable, pearlitic malleable, and martensitic malleable irons. There are two types of ferritic malleable iron, "blackheart," and "whiteheart." Only the blackheart type is produced in the United States. This material has a matrix of ferrite with interspersed nodules of temper carbon. "Cupola malleable iron" is a blackheart malleable iron produced by cupola melting and used for pipe fittings and similar thin-section castings. Because of its low strength and ductility, cupola malleable iron usually is not specified for structural applications. Pearlitic malleable iron is designed to have combined carbon in the matrix, resulting in higher strength and hardness than are available in ferritic malleable iron. Martensitic malleable iron is produced by quenching and tempering pearlitic malleable iron.

Malleable iron, like ductile iron, possesses considerable ductility and toughness because of its combination of nodular graphite and a low-carbon metallic matrix. Consequently, malleable iron and ductile iron are suitable for some of the same applications requiring good ductility and toughness and the choice between them is based on economy rather than properties. However, because ductile iron castings have similar properties to malleable iron castings, and do not require the long and expensive heat treatment, malleable iron production has fallen to very low levels, and only a few thin section castings are made this way today. Because solidification of white iron throughout a section is essential in the production of malleable iron, ductile iron also has a clear advantage when the section is too thick to permit solidification as white iron. Malleable iron castings are produced in section thicknesses ranging from about 1.5 to 100 mm ( $\frac{1}{16}$  to 4 in.) and in weight from less than 30 g (1 oz) to 180 kg (400 lb) or more.

## Metallurgical Control

The desired formation of temper carbon in malleable irons has two basic requirements: graphite should not form during the solidification of white cast iron, and graphite must be readily formed during the annealing heat treatment. These metallurgical requirements influence the useful compositions of malleable irons and the melting, solidification, and annealing procedures. Metallurgical control is based on the following criteria:

- Produce solidified white iron throughout the section thickness.
- Anneal on an established time-temperature cycle set to minimum values in the interest of economy.
- Produce the desired graphite distribution (nodule count) upon annealing.

Changes in melting practice or composition that would satisfy the first requirement listed above are generally opposed to satisfaction of the second and third requirement, while attempts to improve annealability beyond a certain point may result in an unacceptable tendency for the as-cast iron to be mottled instead of white.

**Composition.** Because of the two metallurgical requirements described above, malleable irons involve a limited range of chemical composition and the restricted use of alloys. The chemical composition of malleable iron generally conforms to the range given in Table 1.

**Table 1 Typical compositions for malleable iron**

Element	Composition, %	
	Ferritic	Pearlitic
<b>Total carbon</b>	2.2-2.9	2.0-2.9
<b>Silicon</b>	0.9-1.9	0.9-1.9
<b>Manganese</b>	0.2-0.6	0.2-1.3
<b>Sulfur</b>	0.02-0.2	0.05-0.2
<b>Phosphorus</b>	0.02-0.2	0.02-0.2

The common elements in malleable iron are generally controlled within about  $\pm 0.05$  to  $\pm 0.15\%$ . A limiting minimum carbon content is required in the interest of mechanical quality and annealability, because decreasing carbon content reduces the fluidity of the molten iron, increases shrinkage during solidification, and reduces annealability. A limiting maximum carbon content is imposed by the requirement that the casting be white as cast. The range in silicon content is limited to ensure proper annealing during a short-cycle, high-production annealing process and to avoid the formation of primary graphite (known as mottle) during solidification of the white iron. Manganese and sulfur contents are balanced to ensure that all sulfur is combined with manganese and that only a safe, minimum quantity of excess manganese is present in the iron. An excess of either sulfur or manganese will retard annealing in the second stage and therefore increase annealing costs.

In addition to the common elements listed in Table 1, malleable irons also contain some minor elements that are added as ladle additions. These include boron ( $<0.004\%$ ) and aluminum ( $0.005\%$ ), which promote graphitization during annealing, and bismuth ( $0.01\%$ ) and tellurium ( $<0.004\%$ ), which retard mottling.

**Heat treatment** is a two-stage process. In the first stage, the carbon is precipitated, and in the second stage the structure of the steel matrix is obtained. The first stage treatment is carried out at temperatures of  $900$  to  $970\text{ }^{\circ}\text{C}$  ( $1650$  to  $1780\text{ }^{\circ}\text{F}$ ) for 3 to 6 h, depending on the section size and composition. During this period iron carbide transforms to graphite. Higher temperatures can be used and will shorten the annealing time and increase nodule count; however, as the annealing temperature increases, the chance of casting distortion on cooling also increases. The number of graphite nodules produced depend on the carbon and silicon content, and generally should be between  $80$  and  $150\text{ mm}^2$  at  $100\times$  magnification for optimum properties.

To produce ferritic malleable iron, in which the matrix is ferritic, the castings are cooled to  $740$  to  $760\text{ }^{\circ}\text{C}$  ( $1650$  to  $1780\text{ }^{\circ}\text{F}$ ), a process that takes from 1 to 6 h, depending on the casting configuration. The castings are then cooled at the rate of  $3$  to  $11\text{ }^{\circ}\text{C}$  ( $5$  to  $20\text{ }^{\circ}\text{F}$ ) per h. As the castings cool, the carbon in the matrix diffuses to the temper carbon nodules, leaving a ferritic matrix.

In the production of pearlitic malleable, the first stage graphitization step is the same as that used for ferritic iron. However, at the end of the first stage, the castings are slowly cooled to around  $870\text{ }^{\circ}\text{C}$  ( $1600\text{ }^{\circ}\text{F}$ ) and rapidly cooled in air (which is blasted at the castings) or oil and then tempered (held for a period of time at a lower temperature) between  $590$  to  $725\text{ }^{\circ}\text{C}$  ( $100$  to  $1340\text{ }^{\circ}\text{F}$ ) according to specifications.

**Microstructure/Property Relationships.** The mechanical properties of malleable iron are dominated by matrix microstructure, so the mechanical properties may relate quite well to the relative hardness levels of different matrix microstructures. This general effect of microstructure on malleable irons is similar to that of many other steels and irons. The softer ferritic matrix provides maximum ductility with lower strength, while increasing the amount of pearlite

increases hardness and strength but decreases ductility. Martensite provides further increases in hardness and strength but with additional decreases in ductility.

## Ferritic Malleable Iron

Because ferritic malleable iron consists of only ferrite and temper carbon, the properties of ferritic malleable castings depend on the quantity, size, shape, and distribution of temper carbon and on the composition of the ferrite. Fully annealed ferritic malleable iron castings generally contain 2.00 to 2.70% graphite carbon by weight, which is equivalent to approximately 6 to 8% by volume. Because the graphite carbon contributes nothing to the strength of the castings, those with the lesser amount of graphite are somewhat stronger and more ductile than those containing the greater amount (assuming equal size and distribution of graphite particles). Elements such as silicon and manganese in solid solution in the ferritic matrix contribute to the strength and reduce the elongation of the ferrite. Therefore, by varying base metal composition, it is possible to obtain slightly different strength levels in a fully annealed ferritic product.

**Table 2 Specifications and applications related to malleable iron castings**

Specification No.	Class or grade <sup>(a)</sup>	ASTM metric equivalent class <sup>(b)</sup>	Microstructure	Typical applications

	M8501 <sup>(d)</sup>	724	105	586	85	269-302	1

Microstructure and typical applications are given in Table 2.

- (a) Minimum in 50 mm (2 in.).
- (b) Annealed.
- (c) Air-quenched and tempered.
- (d) Liquid-quenched and tempered

**The mechanical properties** that are most important for design purposes are tensile strength, yield strength, modulus of elasticity, fatigue strength, and impact strength. Hardness can be considered an approximate indicator that the ferritizing anneal was complete. The hardness of ferritic malleable iron almost always ranges from 110 to 156 HB and is influenced by the total carbon and silicon contents. Table 3 lists typical properties of unmachined test bars of ferritic malleable iron.

## Pearlitic and Martensitic Malleable Iron

Pearlitic and martensitic-pearlitic malleable irons can be produced with a wide variety of mechanical properties, depending on heat treatment, alloying, and melting practices. The lower-strength pearlitic malleable irons are often produced by air cooling the casting after the first-stage anneal, while the higher-strength (pearlitic-martensitic) malleable irons are made by liquid quenching after the first-stage anneal.

**Specifications.** Some specifications for pearlitic and martensitic malleable iron are based on grade designations that require certain minimum tensile, yield, and elongation values, with advisory Brinell hardnesses (see Tables 2 and 3). The hardnesses are termed "advisory" because the hardness ranges corresponding to the various grades overlap so much that hardness alone cannot ensure that a given casting meets the specification for a specific grade (see, e.g., ASTM A 220). Other specifications (e.g., ASTM A 602 and SAE J158) are based on required hardness ranges and microstructures, and tensile data are considered advisory.

**The mechanical properties** of pearlitic and martensitic malleable iron vary in a substantially linear relationship with Brinell hardness. In the low-hardness ranges, below about 207 HB, the properties of air-quenched and tempered pearlitic malleable are essentially the same as properties of oil-quenched and tempered martensitic malleable. This is because attaining the low hardnesses requires considerable coarsening of the matrix carbides and partial second-stage graphitization. Either an air-quenched pearlitic structure or an oil-quenched martensitic structure can be coarsened and decarburized to meet this hardness requirement.

At higher hardnesses, oil-quenched and tempered malleable iron has higher yield strength and elongation than air-quenched and tempered malleable iron because of greater uniformity of matrix structure and finer distribution of carbide particles. Oil-quenched and tempered pearlitic malleable irons produced commercially to hardnesses as high as 321 HB (see Table 3), while the maximum hardness for high-production air-quenched and tempered pearlitic malleable iron is about 255 HB. The lower maximum hardness is applied to the air-quenched material because:

- Hardness upon air quenching normally does not exceed 321 HB and may be as low as 269 HB; therefore, attempts to temper to a hardness range above 255 HB produce nonuniform hardness and make the process control limits excessive.
- Very little structural alteration occurs during the tempering heat treatment to a higher hardness, and the resulting structure is more difficult to machine than an oil-quenched and tempered structure at the same hardness.
- There is only a slight improvement in other mechanical properties with increased hardness above 255 HB.

Because of these considerations, applications for air-quenched and tempered pearlitic malleable iron are usually those requiring moderate strength levels, with the higher-strength applications need the oil-quenched and tempered material.

# Alloy Cast Irons

## Introduction

ALLOY CAST IRONS are considered to be those casting alloys based on the Fe-C-Si system that contain one or more alloying elements intentionally added to enhance one or more useful properties. The addition of a small amount of a substance (e.g., ferrosilicon, cerium, or magnesium) that is used to control the size, shape, and/or distribution of graphite particles is termed inoculation rather than alloying. The quantities of material used for inoculation neither change the basic composition of the solidified iron nor alter the properties of individual constituents. Alloying elements, including silicon when it exceeds about 3%, are usually added to increase the strength, hardness, hardenability, or corrosion resistance of the basic iron, and they are often added in quantities sufficient to affect the occurrence, properties, or distribution of constituents in the microstructure.

In gray and ductile irons, small amounts of alloying elements such as chromium, molybdenum, or nickel are used primarily to achieve high strength or to ensure the attainment of a specified minimum strength in heavy sections. Otherwise, alloying elements are used almost exclusively to enhance resistance to abrasive wear or chemical corrosion or to extend service at elevated temperatures.

## Types of Alloy Cast Irons

Alloy cast irons can be broadly classified as either graphite-free, high-alloy cast irons (white irons) or graphitic high-alloy cast irons (graphite-containing ductile or gray irons). Table 1 lists approximate ranges of alloy content for various types of alloy cast irons, which can be further classified as abrasion-resistant cast irons, corrosion-resistant cast irons, or heat-resistant cast irons. Individual alloys within each type are made to compositions in which the actual ranges of one or more of the alloying elements span only a portion of the listed ranges. The listed ranges serve only to identify the types of alloys used in specific kinds of applications.

Table 1 Ranges of alloy content for various types of alloy cast irons

(a) Where a single value is given rather than a range, that value is a maximum limit.

(b) Total carbon.

(c) CP, coarse pearlite; M, martensite; A, austenite; F, ferrite.

(d) Can be produced from a malleable iron-base composition.

(e) Copper can replace all or part of the nickel.

(f) Such as Duriron, Durichlor 51, Superchlor (ASTM A 518).

(g) Such as Ni-Resist austenitic iron (ASTM A 436).

(h) Such as Ni-Resist austenitic ductile iron (ASTM A 439).

(i) Such as Silal.

(j) Such as Nicrosilal

**White cast irons**, so named because of their characteristically white fracture surfaces, do not have any graphite in the microstructure. Instead, the carbon is present in the form of carbides, chiefly of the types  $\text{Fe}_3\text{C}$  and  $\text{Cr}_7\text{C}_3$ . Often, complex carbides are also present, such as  $(\text{Fe,Cr})_3\text{C}$  from additions of 3 to 5% Ni and 1.5 to 2.5% Cr,  $(\text{Cr,Fe})_7\text{C}_3$  from additions of 11 to 35% Cr, or those containing other carbide-forming elements.

White cast irons are usually very hard, which is the single property most responsible for their excellent resistance to abrasive wear. White iron can be produced either throughout the section (chiefly by adjusting the composition) or only partly inward from the surface (chiefly by casting against a chill). The latter iron is sometimes referred to as chilled iron to distinguish it from iron that is white throughout.

Chilled iron castings are produced by casting the molten metal against a metal or graphite chill resulting in a surface virtually free from graphitic carbon. In the production of chilled iron, the composition is selected so that only the surfaces cast against the chill will be free from graphitic carbon (Fig. 1). The more slowly cooled portions of the casting will be gray or mottled iron. The depth and hardness of the chilled portion can be controlled by adjusting the composition of the metal, the extent of inoculation, and the pouring temperature.

**Fig. 1** Fracture surface of as-cast chilled iron. White, mottled, and gray portions are shown at full size, from top to bottom.

White iron is cast iron that is virtually free from graphitic carbon. The composition is chosen so that, for the desired section size, graphite does not form as the casting solidifies. The hardness of white iron castings can be controlled by adjustment of the composition.

The main difference between microstructure of chilled iron and white iron is that chilled iron is fine grained and exhibits directionality perpendicular to the chilled face, while white iron is ordinarily coarse grained, randomly oriented, and white throughout, even in relatively heavy sections. This difference reflects the composition difference between the two types of abrasion-resistant iron. Chilled iron is directional only because the casting, made of a composition that is ordinarily gray, has been cooled through the eutectic temperature so rapidly at one or more faces that the iron solidified white, growing inward from the chilled face. White iron, on the other hand, has a composition so low in CE or so high in alloy content that gray iron cannot be produced even at the relatively low rates of cooling that exist in the center of the heaviest section of the casting.

**Corrosion-resistant irons** derive their resistance to chemical attack chiefly from their high alloy content. Depending on which of three alloying elements dominates the composition (silicon up to 15%, chromium up to 28%, or nickel up to 35%) a corrosion-resistant iron can be ferritic, pearlitic, martensitic, or austenitic in its microstructure. Depending on composition, cooling rate, and inoculation practice, a corrosion-resistant iron can be white, gray, or nodular in both form and distribution of carbon.

**Heat-resistant irons** combine resistance to high-temperature oxidation and scaling with resistance to softening or microstructural degradation. Resistance to scaling depends chiefly on high alloy content, and resistance to softening depends on the initial microstructure plus the stability of the carbon-containing phase. Heat-resistant irons are usually ferritic or austenitic as-cast; carbon exists predominantly as graphite, either in flake or nodular form, which subdivides heat-resistant irons into either gray or ductile irons. There are also ferritic and austenitic white iron grades, although they are less frequently used and have no ASTM designations.

## Effects of Alloying Elements

In most cast irons, it is the interaction between alloying elements (including carbon and silicon) that has the greatest effect on properties. This influence is exerted largely by effects on the amount and shape of graphitic carbon present in the casting. For example, depth of chill or the tendency of the iron to be white as cast depends greatly on the carbon equivalent and the balance between carbon and silicon in the composition; addition of other elements can only modify the basic tendency established by the carbon-silicon relationship.

In general, only small amounts of alloying elements are needed to improve depth of chill, hardness, and strength. Typical effects on depth of chill are given in Fig. 2 for the alloying elements commonly used in low to moderately alloyed cast irons. High-alloy contents are needed for the most significant improvements in corrosion resistance or elevated-temperature properties.

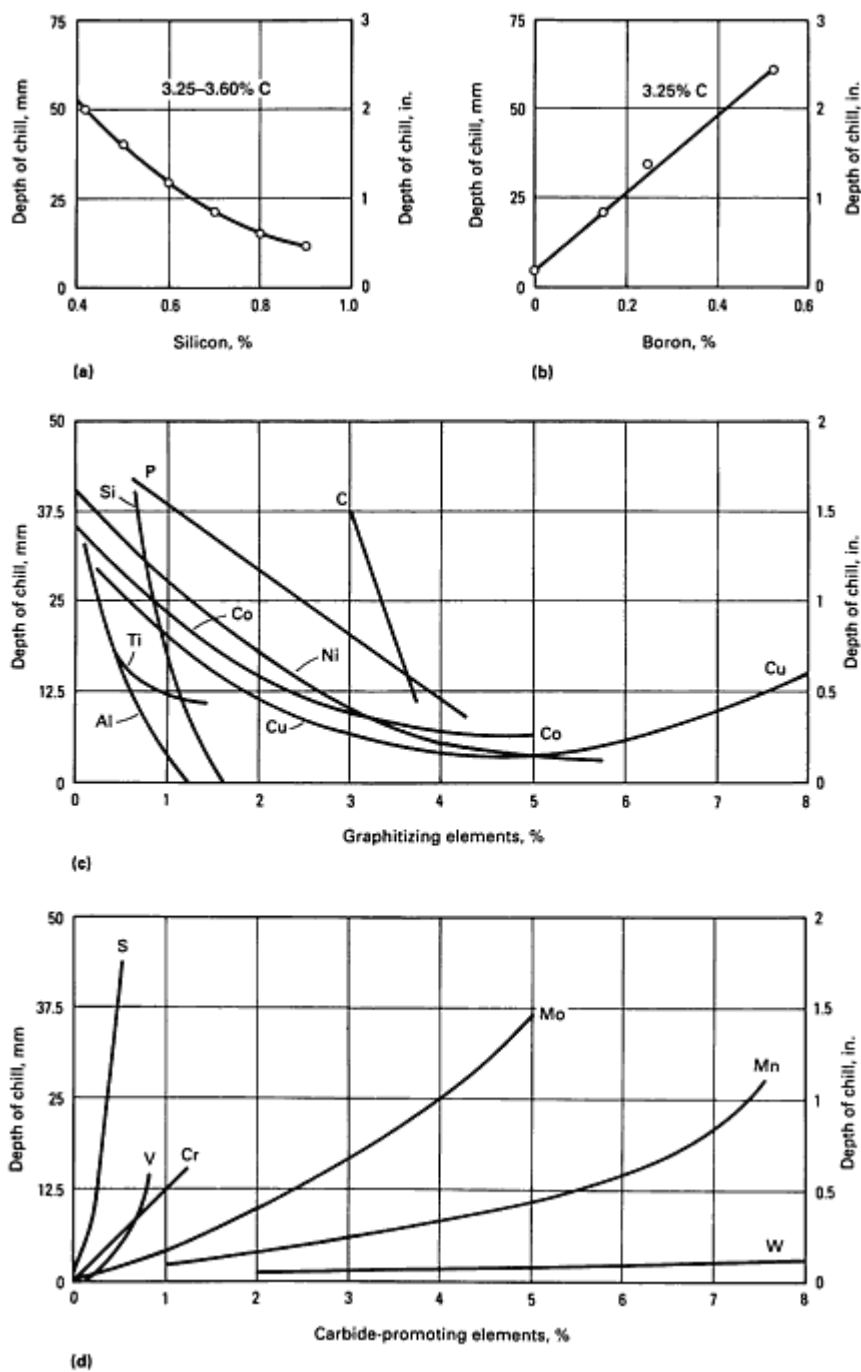

Fig. 2 Typical effects of alloying elements on depth of chill

**Carbon.** In chilled irons, the depth of chill decreases and the hardness of the chilled zone increases, with increasing carbon content (Fig. 2c). Carbon also increases the hardness of white irons.

**Silicon** is present in all cast irons. In alloy cast irons, as in other types, silicon is the chief factor that determines the carbon content of the eutectic. Increasing the silicon content lowers the carbon content of the eutectic and also promotes the formation of graphite on solidification. Thus, the silicon content is the principal factor controlling the depth of the chill in unalloyed or low-chromium chilled and white irons. Figure 2(a) summarizes this effect for relatively high-carbon irons.

Silicon additions of 4.5 to 8% improve high-temperature properties by raising the eutectoid transformation and by reducing the rates of scaling and growth. Additions of 14 to 17% Si (often accompanied by addition of about 5% Cr and

1% Mo) yield cast iron that is very resistant to corrosive acids, although resistance varies somewhat with acid concentration.

High-silicon irons are difficult to cast and are virtually unmachinable. High-silicon irons have particularly low resistance to mechanical and thermal shock at room temperature or moderately elevated temperature. However, above approximately 250 °C (500 °F), the shock resistance exceeds that of ordinary gray iron.

**Manganese and sulfur** should be considered together for their effects on gray or white iron. Alone, either manganese or sulfur increases the depth of chill, but when one element is present, addition of the other element decreases the depth of chill until the residual concentration is neutralized by the formation of manganese sulfide. Generally, sulfur is the residual element, and excess manganese can be used to increase chill depth and hardness, as shown in Fig. 2(d). Because it promotes formation of finer and harder pearlite, manganese is often used to decrease or prevent mottling in heavy-section castings.

Manganese, in excess of the amount needed to scavenge sulfur, mildly suppresses pearlite formation. It is also a relatively strong austenite stabilizer and normally is kept below  $\sim 0.7\%$  in martensitic white irons. In some pearlitic or ferritic alloy cast irons, up to  $\sim 1.5\%$  Mn can be used to help ensure that specified strength levels are obtained.

**Phosphorus** is a mild graphitizer in unalloyed irons; it mildly reduces chill depth in chilled irons (Fig. 2c). In alloyed irons, the effects of phosphorus are somewhat obscure. There is some evidence that it reduces the toughness of martensitic white irons.

**Chromium** has three major uses in cast irons: to form carbides, to impart corrosion resistance, and to stabilize the structure for high-temperature applications. Small amounts of chromium are added routinely to stabilize pearlite in gray iron, to control chill depth in chilled iron, or to ensure a graphite-free structure in white iron containing  $<1\%$  silicon. At such low percentages, usually no greater than 2 to 3%, chromium has little or no effect on hardenability, chiefly because most of the chromium is tied up in carbides. However, chromium does influence the fineness and hardness of pearlite and also tends to increase the amount of hardness of the eutectic carbides.

When the chromium content of cast iron is greater than  $\sim 10\%$ , eutectic carbides of the  $M_7C_3$  type are formed, rather than the  $M_3C$  type that predominates at lower chromium contents. More significantly, however, the higher chromium content causes a change in solidification pattern to a structure in which the  $M_7C_3$  carbides are surrounded by a matrix of austenite or its transformation products. At lower chromium contents, the  $M_3C$  carbide forms the matrix. Because of the solidification characteristics, hypoeutectic irons containing  $M_7C_3$  carbides normally are stronger and tougher than irons containing  $M_3C$  carbides.

The relatively good abrasion resistance, toughness, and corrosion resistance found in high-chromium white irons have led to the development of a series of commercial martensitic or austenitic white irons containing 12 to 18% chromium. Because much of the chromium in these irons is present in combined form as carbides, chromium is much less effective than molybdenum, nickel, manganese, or copper in suppressing the eutectoid transformation to pearlite and thus has a lesser effect on hardenability than it has in steels. Martensitic white irons usually contain one or more of the elements molybdenum, nickel, manganese, and copper to give the required hardenability. These elements ensure that martensite will form on cooling from above the upper transformation temperature either while the casting is cooling in the mold or during subsequent heat treatment.

**Nickel** is almost entirely distributed in the austenite phase or its transformation products. Nickel tends to promote graphite formation, and in white and chilled irons, this effect usually is balanced by the addition of about one part chromium for every three parts nickel in the composition.

One of the Ni-Hard family of commercial alloy white irons (Type IV Ni Hard, also known as Class I Type D, Ni-HiCr in ASTM A 532) contains 1.0 to 2.2% Si, 5 to 7% Ni, and 7 to 11% Cr. In the as-cast condition, it has a structure of  $M_7C_3$  eutectic carbides in a martensitic matrix. If retained austenite is present, the martensite content and hardness of the alloy can be increased by refrigeration treatment or by reaustenitizing and air cooling. Ni-Hard IV often is specified for pumps and other equipment used for handling abrasive slurries because of its combination of relatively good strength, toughness, and resistance to abrasion.

Nickel additions of  $>12\%$  are needed for optimum resistance to corrosion or heat. High-nickel gray or ductile irons usually contain 1 to 6% chromium, and can contain as much as 10% copper. These elements act in conjunction with the

nickel to promote resistance to corrosion and scaling, especially at elevated temperatures. All types of cast iron with nickel contain >18% are fully austenitic.

**Copper** in moderate amounts can be used to suppress pearlite formation in both low- and high-chromium martensitic white irons. It has a relatively mild effect compared with that of nickel, and, because of the limited solubility of copper in austenite, copper additions probably should be limited to  $\sim 2.5\%$ . This limitation means that copper cannot completely replace nickel in Ni-Hard-type irons.

Copper is used in amounts of  $\sim 3$  to 10% in some high-nickel gray and ductile irons that are specified for corrosion or high-temperature service. Here, copper enhances corrosion resistance, particularly resistance to oxidation or scaling.

**Molybdenum** in chilled and white iron compositions is distributed between the eutectic carbides and the matrix. In graphitic irons, the functions are to promote deep hardening and to improve corrosion resistance and high-temperature strength.

In chilled iron compositions, molybdenum additions mildly increase depth of chill (they are about one-third as effective as chromium; see Fig. 2d). The primary purpose of small additions (0.25 to 0.75%) of molybdenum to chilled iron is to improve the resistance of the chilled face to spalling, pitting, chipping, and heat checking. Molybdenum hardens and toughens the pearlitic matrix.

Where a martensitic white iron is desired for superior abrasion resistance, additions of 0.5 to 3.0% molybdenum effectively suppress formation of pearlite and other high-temperature transformation products when used in combination with copper, chromium, nickel, or both chromium and nickel.

**Vanadium** is a potent carbide stabilizer and increases depth of chill. The magnitude of the increase of depth of chill depends on the amount of vanadium and the composition of the iron, as well as on section size and conditions of castings. The powerful chilling effect of vanadium in thin sections can be balanced by additions of nickel or copper, or by a large increase in carbon or silicon, or both. In addition to carbide-stabilizing influence, vanadium in amounts of 0.10 to 0.50% refines the structure of the chill and minimizes coarse columnar grain structure.

Because of its strong carbide-forming tendency, vanadium is rarely used in gray or ductile irons for corrosion or elevated-temperature service.

## Abrasion-Resistant Cast Irons

High-alloy white irons are used for abrasion-resistant applications in crushing, grinding, and materials handling. They usually contain substantial amounts of chromium, to stabilize the carbide, and to form chromium carbides, which are harder than iron carbide. Maximum hardness is found with a fully martensitic matrix. These irons fall into three categories:

- Nickel-chromium irons containing 3 to 5% Ni and 1 to 4% Cr, known by the trade name Ni-Hard. These are relatively low cost irons used primarily in mining operations as ball mill liners and grinding balls. They may also be used in slurry pumps and crusher segments. If moderate impact resistance is needed, the low-carbon version of the iron is used.
- Chromium-molybdenum irons, containing 11 to 23% Cr and up to 3% Mo, and some nickel and copper. These alloys provide the best combination of toughness and abrasion resistance of all white irons and are used in hard rock mining equipment, slurry pumps, coal grinding mills, and brick molds.
- High-chromium irons, containing 25 to 28% Cr and additions of molybdenum or nickel up to 1.5%. The high-chromium contents provide not only high hardness, but also corrosion resistance, and these irons are used in pumps for handling fly ash and in chloride-containing environments.

Hardness also increases as the carbon content increases, and silicon increases the temperature at which martensite (a very hard matrix structure produced by rapid quenching) forms, making heat treatment for martensitic alloy white irons easier. However, as higher carbon and silicon contents tend to promote graphite formation during solidification, they must be used in conjunction with alloying elements such as chromium to stabilize the carbide.

ASTM specification A 532 covers white iron grades used for abrasion-resistant applications. Table 2 lists the composition requirements for these alloys. Depending on the heat treatment carried out, hardness values ranging from 41 to 59 HRC can be achieved. Figure 3 shows typical microstructures encountered with these alloys.

Table 2 Compositions of abrasion-resistant white irons per ASTM A 532

Class	Type	Designation	Composition, wt%

## Corrosion-Resistant Cast Irons

The corrosion resistance of gray cast iron is enhanced by the addition of appreciable amounts of nickel, chromium, and copper, singly or in combination, or silicon in excess of about 3%. Table 1 gives chemical composition ranges for some of the more widely used corrosion-resistant cast irons.

Up to 3% silicon is normally present in all cast irons; in larger percentages, silicon is considered an alloying element. It promotes the formation of a strongly protective surface film under oxidizing conditions such as exposure to oxidizing acids. Relatively small amounts of molybdenum and/or chromium can be added in combination with high silicon. The addition of nickel to gray iron improves resistance to reducing acids and provides a high resistance to caustic alkalis. Chromium assists in forming a protective oxide that resists oxidizing acids, although it is of little benefit under reducing conditions. Copper has a smaller beneficial effect on resistance to sulfuric acid.

**High-silicon irons** are the most universally corrosion-resistant alloys available at moderate cost. They are widely used for handling corrosive media common in chemical plants, even when abrasive conditions also are encountered. When the silicon content is  $\geq 14.2\%$  these irons exhibit a very high resistance to boiling sulfuric acid.

The 14.5% Si iron is less resistant to the corrosive action of hydrochloric acid, but this resistance can be improved by additions of chromium and molybdenum and can be further enhanced by increasing the silicon content to 17%. The chromium-bearing silicon irons are very useful in contact with solutions containing copper salts, "free" wet chlorine, or other strongly oxidizing contaminants.

High-silicon irons, which are covered by ASTM specification A 518, have poor mechanical properties and particularly low thermal and mechanical shock resistance. These alloys are typically very hard and brittle with a tensile strength of about 110 MPa (16 ksi) and a hardness of 480 to 520 HB. They are difficult to cast and are virtually unmachinable.

**High-chromium irons** containing from 40 to 35% Cr give good service with oxidizing acids, particularly nitric, but are not resistant to reducing acids. These irons are also reliable for use in weak acids under oxidizing conditions, in numerous salt solutions, in organic acid solutions, and in marine or industrial atmospheres.

## Heat-Resistant Cast Irons

Heat-resistant cast irons are basically alloys of iron, carbon, and silicon having high-temperature properties markedly improved by the addition of certain alloying elements, singly or in combination, principally chromium, nickel, molybdenum, aluminum, and silicon  $>3\%$ . Silicon and chromium increase resistance to heavy scaling by forming a light surface oxide that is impervious to oxidizing atmospheres. Both elements reduce the toughness at elevated temperatures. Molybdenum also increases high-temperature strength. Aluminum additions reduce both growth and scaling but adversely affect mechanical properties at room temperature. Table 1 gives chemical composition ranges of some of the more widely used heat-resistant irons (both gray and ductile types) suitable for elevated-temperature service.

**Growth** is the permanent increase in volume that occurs in some cast irons after prolonged exposure to elevated temperature or after repeated cyclic heating and cooling. It is produced by the expansion that accompanies graphitization, expansion, and contraction at the transformation temperature and internal oxidation of the iron. Gases can penetrate the surface of hot cast iron at the graphite flakes and oxidize the graphite as well as the iron and silicon. The occurrence of fine cracks, or "crazing," may accompany repeated heating and cooling through the transformation temperature range because of thermal and transformational stresses.

Silicon contents of less than  $\sim 3.5\%$  increase the rate of growth by promoting graphitization but silicon contents of  $\geq 4\%$  retard growth.

The carbide-stabilizing alloying elements, particularly chromium, effectively reduce growth in gray irons  $\geq 450^\circ\text{C}$  ( $850^\circ\text{F}$ ). Growth is not a problem at  $<400^\circ\text{C}$  ( $750^\circ\text{F}$ ), except in the presence of superheated steam, where it can occur in coarse-grain irons at  $310^\circ\text{C}$  ( $600^\circ\text{F}$ ). Even small amounts of chromium, molybdenum, and vanadium produce marked reductions in growth at the higher temperatures.

**Scaling.** In addition to the internal oxidation that contributes to growth, a surface scale forms on unalloyed gray iron after exposure at a sufficiently high temperature.

Silicon, chromium, and aluminum increase the scaling resistance of cast iron by forming a light surface oxide that is impervious to oxidizing atmospheres. Unfortunately, these elements tend to reduce toughness and thermal shock resistance. The presence of nickel improves the scaling resistance of most alloys containing chromium and, more importantly, increases their toughness and strength at elevated temperatures. Carbon has a somewhat damaging effect at 700 °C (1300 °F) as a result of the mechanism of decarburization and the evolution of carbon monoxide and carbon dioxide. When these gases are evolved at the metal surface, the formation of protective oxide layers is hindered, and cracks and blisters can develop in the scale.

Figure 4 indicates the temperatures at which various silicon-chromium irons can be used with only slight or insignificant scaling in sulfur-free oxidizing atmospheres. Greater scaling rates can be tolerated in some applications, so that higher useful temperatures are often possible.

**Fig. 4** Relation of silicon and chromium contents to the scaling resistance of silicon-chromium irons. Temperatures indicated at which various irons can be used with very little or insignificant scaling in sulfur-free oxidizing atmospheres

**High-Nickel Irons.** The austenitic cast irons containing 18 to 36% Ni, up to 7% Cu, and 1.75 to 4% Cr are used for both heat-resistant and corrosion-resistant applications. Known as Ni-Resist, this type of iron exhibits good resistance to high-temperature scaling and growth up to 815 °C (1500 °F) in most oxidizing atmospheres and good performance in steam service up to 530 °C (990 °F) can handle sour gases and liquids up to 400 °C (750 °F). The maximum use temperature is 540 °C (1000 °F) if appreciable sulfur is present in the atmosphere. Austenitic cast irons can be employed at temperatures as high as 950 °C (1740 °F). Austenitic irons have the advantage of considerably greater toughness and thermal shock resistance than the other heat-resistant alloy irons, although their strength is rather low.

High-nickel ductile irons are considerably stronger and tougher than the comparable gray irons. Tensile strengths of 400 to 470 MPa (58 to 68 ksi), yield strengths of 200 to 275 MPa (30 to 40 ksi), and elongations of 10 to 40% may be realized in high-nickel ductile irons. Tables 3 and 4 list compositions and properties, respectively, of austenitic ductile irons.

**Table 3** Compositions of nodular-graphite (ductile) austenitic cast irons per ASTM A 439

**High-Silicon Irons.** Graphitic irons alloyed with 4 to 6% Si provide good service and low cost in many elevated-temperature applications. These irons, whether gray or ductile, provide good oxidation resistance and stable ferritic matrix structures that will not go through a phase change at temperatures up to 900 °C (1650 °F).

Although quite brittle at room temperature, the high-silicon gray irons are reasonably tough at temperatures above 260 °C (500 °F). The ductile iron versions of these alloys have higher strength and ductility and are used for more rigorous service. Substantial improvements in yield and tensile strengths can be achieved in high-silicon ductile irons by alloying with molybdenum ( $\leq 2.5\%$  Mo).

**High-Aluminum Irons.** Alloy cast irons containing 6 to 7% Al, 18 to 25% Al, or 12 to 25% Cr plus 4 to 16% Al are reported to have considerably better resistance to scaling than several other alloy irons, including the high-silicon type. These high-aluminum irons have been used infrequently commercially because of their brittleness and poor castability.

# Pressed-and-Sintered Ferrous Powder Metallurgy Parts

## Introduction

IRON POWDERS are the most widely used powder metallurgy (P/M) material for structural parts. Nearly 90% of all iron and iron-base (ferrous) powder produced is used in P/M part applications, and the automotive industry is the leading powder user. Other important application areas include business machines, lawn and garden equipment, power tools, lock hardware, and appliances.

The single largest use of iron powders for nonstructural applications is coated and tubular electrodes for arc welding. Other nonstructural areas include pharmaceuticals and food enrichment (Americans consume about two million lb of iron powder annually in iron-enriched cereals and bread). Iron powder is also used as a carrier for toner in electrostatic copying machines.

This article will review low- to medium-density iron and low-alloy steel parts produced by pressing-and-sintering technology (a subsequent article in this Section reviews high-density ferrous parts produced by powder forging and injection molding). Manufacturing processes for pressed-and-sintered P/M parts consist of (1) powder production, cold compaction, and sintering, or (2) powder production, warm compaction, and sintering. By cold pressing and sintering only, parts are produced to density levels of about 6.4 to 7.1 g/cm<sup>3</sup>, which is about 80 to 90% of theoretical density (the theoretical density of iron or low-carbon steel is about 7.87 g/cm<sup>3</sup>). Warm compaction can increase density levels to 7.2 g/cm<sup>3</sup> to slightly more than 7.4 g/cm<sup>3</sup> (about 95% of theoretical density). High-temperature sintering also produces higher densities. Secondary processes, such as infiltration or double-pressing/double-sintering, can be used to increase densities to levels just below what are achievable with high-density processes. As shown in Fig. 1, however, higher costs are associated with secondary processing or high-density processing. As will be described below, higher densities correlate with improved mechanical properties.

## Powder Production

There are a number of commercial processes available for production of ferrous powders. Among these, the most important are direct reduction of oxides and atomization of liquid metal. Iron powders are also produced by carbonyl vapor metallurgy processing (carbonyl iron) and electrolysis (electrolytic iron).

### Direct Reduction of Oxides

There are two commercially available processes for direct reduction of oxides: reduction with carbon (Hoeganaes process) and reduction with hydrogen (Pyron process). Generally, reduced iron powders are used for low- or medium-stress applications.

**In the Hoeganaes process**, sponge iron is produced by direct reduction of magnetite (Fe<sub>3</sub>O<sub>4</sub>) ore. Magnetite ore is dried in a rotary dryer and ground and cleaned with a magnetic separator. Cleaned ore is then charged into silicon carbide

tubes with a crushed lime and coke mixture and heated at 1260 °C (2300 °F) for 24 to 40 hours in a tunnel kiln. Iron ore is reduced by carbon monoxide gas generated from the coke.

After removal from the kiln, the caked 25 mm (1 in.) diam sponge iron lumps undergo a series of grinding, screening, and magnetic separation steps to produce a powder of the desired particle size distribution. The cleaned powder is then charged into a strip belt furnace and annealed at about 870 °C (1600 °F) in an atmosphere of dissociated ammonia in order to reduce the carbon and oxygen levels. At the same time, strain hardening introduced during grinding is relieved. As shown in Fig. 2, the resultant powder has an irregular shape and is highly porous.

Fig. 2 Scanning electron micrograph of carbon-reduced iron ore shown at 180×

**In the Pyron process**, iron powder is produced by reducing selected iron oxides under a hydrogen atmosphere. In this process, mill scale is ground, magnetically separated, and screened. The mill scale is then preheated in air in order to convert all the oxides into hematite ( $\text{Fe}_2\text{O}_3$ ), because hematite reduces more readily than magnetite ( $\text{Fe}_3\text{O}_4$ ). The oxides are then reduced in a belt furnace under a hydrogen atmosphere at approximately 980 °C (1800 °F). The reduced iron is then ground, screened, and blended to specifications. No annealing step is necessary with the Pyron process.

Pyron iron powder has fine porosity and a spongelike microstructure (Fig. 3). The pores in the interior structure of Pyron iron powder particles are considerably finer than those in Hoeganaes sponge iron powder particles because in the latter the long-term reducing treatment at higher temperature coarsens the pores.

Fig. 3 Scanning electron micrograph of hydrogen-reduced mill scale shown at 750×

### Atomization of Liquid Metal

Another major commercial process for production of ferrous powders is atomization of liquid metal by either water or inert gas. Generally, gas atomization is employed for highly alloyed materials (e.g., superalloys and tool steels) and will not be described further here. Both iron-carbon and some prealloyed powders are produced by water atomization. They are used for higher-stress, higher-performance applications.

For the production of iron powder by water atomization of low-carbon iron, molten carbon steel (typically 0.1% C) is poured, either directly or by means of a runner, into a tundish (Fig. 4), which is essentially a reservoir that supplies a uniform and controlled flow of molten metal to the tundish nozzle. The nozzle, which is located at the base of the tundish,

controls the shape and size of the metal stream and directs it through an atomizing nozzle system in which the metal stream is disintegrated into fine droplets by the high-velocity atomizing medium. The liquid metal droplets cool and solidify (quench) as they settle to the bottom of the water-filled atomizing tank.

**Fig. 4** Schematic of the water atomization process

After magnetic separation, dewatering, and drying, the powder is heated in a belt furnace to about 800 to 1000 °C (1470 to 1830 °F). Furnace atmosphere is hydrogen or dissociated ammonia. During this process, the oxygen content is lowered to less than 0.2%, and the carbon content is reduced to about 0.01%. At the same time, the powder softens through annealing. Subsequent hammer milling of the sinter cake restores the original as-atomized particle size distribution, with only moderate work hardening of the resultant powder. Sieving and blending follow standard practices.

More iron powder (including prealloyed steel powder) is produced by this process than by any other process. The high compressibility and high purity of this powder are the primary reasons for its wide usage. High compressibility, or high pressed-and-sintered density, is desirable in the many applications that require superior mechanical properties. High purity is essential in powder forging and other full-dense processes, where the presence of even small amounts of oxides is detrimental to dynamic properties. Figure 5 shows the irregular shape of a water-atomized steel powder. The particle shape shown is typical of this class of powder.

**Fig. 5** Scanning electron micrograph of water-atomized iron particles exhibiting a fair degree of irregularity or roughness on the surface (note particle indicated by arrows). 190×

Iron powder may also be produced by water atomizing a high-carbon-content feedstock. In one process, a high-carbon (approximately 3.5% C) steel melt is water atomized to a granular "shot," which is then ball milled to powder size. The ground shot, which contains carbon, is mixed with ground mill scale (iron oxide) that contains oxygen. The carbon and oxygen are chemically combined in a belt furnace at sintering temperatures to form carbon monoxide gas (reducing atmosphere), thus leaving a pure iron cake. The cake is disintegrated to powder size and further refined.

Another process, which utilizes high-carbon pig iron (3.3 to 3.8% C) as the starting feedstock, combines water atomization and partial oxidation of the granulated hot metal. The coarsely granulated iron is then ball milled into powder, which subsequently undergoes a decarburization/annealing step. The reduced-iron cake is further refined by crushing, milling, and blending.

## Carbonyl and Electrolytic Iron

**Carbonyl iron powders** are produced via the thermal decomposition of iron pentacarbonyl,  $\text{Fe}(\text{CO})_5$ . High-purity iron powders produced using carbonyl technology are typically spherical (Fig. 6) and have particle sizes that range from 2 to 20  $\mu\text{m}$  making them suitable for injection-molded parts (conventional powders for cold-die compaction range from 50 to 150  $\mu\text{m}$ ). Their high surface area and fine particle size allow the material to sinter to near full density with large associated shrinkages.

**Fig. 6** Scanning electron micrograph of carbonyl iron powder. 3000×

**Electrolytic iron powder** is produced by electrodeposition of iron from chloride or sulfate baths (electrolytes) onto a stainless steel cathode. A brittle iron deposit is subsequently stripped from the cathode and pulverized in ball mills. The resulting particles are irregularly shaped (flaky) with a fairly rough surface (Fig. 7). The high purity of electrolytic iron makes it suitable for soft magnetic parts, toner carriers in photocopying machines, and enrichment of food products.

**Fig. 7** Scanning electron micrograph of electrolytic iron powder. Note the flaky shape characteristic of these powders. 190×

## Compaction and Sintering

**Mixing or Blending.** Powders are mixed and blended before consolidation. Both lubricant and graphite are added to the ferrous powder. The lubricant--for example, synthetic wax or stearic acid--not only minimizes die friction and wear, but also reduces interparticle friction, allowing the particles to pack more closely and resulting in higher density for the lower range of molding pressures. The amount of lubricant added depends on many factors, including composition of the metal powder, type of tooling, compacted density, and complexity of the part. Amounts generally vary from 0.5 to 1.5 wt%.

The graphite provides carbon for reduction of oxides and the final carbon level of the sintered part. Small percentages of alloying additives, such as nickel or copper, if required to increase strength, are also introduced during final mixing.

Powder manufacturers also provide bonded mixes in which  $\frac{1}{8}\%$  of a polymer attaches the additives to the iron powder. This prevents segregation, increases flow rate, and decreases dimensional variation among parts (see the discussion below on "Warm Compaction" ).

**Cold Compaction.** Compacting powder serves several important functions: The powder is consolidated into the desired shape--a compact that must be strong enough to withstand subsequent handling; compacting controls the amount and type

of porosity of the finished product; and compacting is largely responsible for the final dimensions of the part, subject to dimensional changes during sintering.

Of the numerous compacting methods, closed-die pressure compacting at room temperature is the method that is most commonly used in the production of ferrous P/M parts. Most conventional P/M parts are pressed at pressures ranging from about 415 to 700 MPa (30 to 50 tsi). The pressure exerted depends largely on the required density/strength of the part.

Compaction may also be carried out by cold isostatic pressing. Typically, pressures ranging from 310 to 415 MPa (45 to 60 ksi) are required. Generally, cold isostatic pressing of ferrous P/M parts has rather limited use because of its low production speed. This process is more commonly employed for difficult-to-process materials or for producing highly complex shapes.

Compacting consolidates and densifies the loose powder into a shape called a "green compact." With conventional pressing techniques, the compact has the size and shape of the finished product when ejected from the die. It has sufficient strength (termed green strength) for in-process handling and transport to the sintering furnace.

**Warm compaction** allows the production of higher-density ferrous P/M parts via a single compaction process. The process utilizes heated tooling and powder during the compaction step. The powder and tooling are typically heated between 130 and 150 °C (260 and 300 °F). In order for the powder premix to perform at these temperatures, a proprietary lubricant system has been developed that provides lower die ejection forces than conventional lubricants. This lubricant system also incorporates a polymeric binder system to limit segregation and provide enhanced flow characteristics of the powder premix. By utilizing warm compaction technology, the green density of the consolidated part can be increased from 0.10 to 0.25 g/cm<sup>3</sup> over traditionally processed (single-pressed/single-sintered) materials. The green strength is typically increased between 50 and 100%. Table 1 compares the green properties of warm-compacted and cold-compacted P/M parts. This increase in green strength provides advantages such as a reduction in green chipping and cracking due to part handling prior to sintering and makes possible the crack-free compaction of complex multiple-level parts. Additionally, the higher green strength provides an opportunity to machine the P/M part in the green state. This capability is critical in the use of high-performance alloy systems that achieve high hardness in the as-sintered state.

**Table 1 Effect of processing on the green properties of ferrous compacts**

Base material	Processing technique	Compaction pressure		Green density, g/cm <sup>3</sup>	Green strength		Peak die ejection force	
		MPa	tsi		MPa	psi	Mpa	tsi

- (a) Ancorsteel 85HP is a prealloyed steel powder containing 2.0% Ni, 0.85% Mo, 0.4% graphite, and 0.6% lubricant.
- (b) Distaloy 4800A is a diffusion-alloyed steel powder containing 4% Ni, 1.5% Cu, 0.50% Mo, 0.5% graphite, and 0.6% lubricant.

As shown in Fig. 1, warm compaction also enables P/M fabricators to single press and single sinter P/M parts to densities as high as approximately  $7.4 \text{ g/cm}^3$ , which is considerably higher than cold-compacted-and-sintered P/M parts. Traditional methods to increase density and improve mechanical properties, which include double-pressing/double-sintering, copper infiltration, powder forging, or high-temperature sintering, all involve higher costs when compared to single-press/single-sinter warm compaction.

Warm compaction, although applicable to all ferrous material systems, produces the greatest benefits when coupled with high-performance compositions such as diffusion-alloyed steels (described further below) or molybdenum-prealloyed steels. Achieving densities in excess of  $7.25 \text{ g/cm}^3$  using these compositions results in mechanical properties that are comparable to steel forgings and ductile iron castings.

**Sintering** is one of the most complex phenomena in P/M processing. For powder metallurgy, sintering may be generally defined as the process wherein powder particles develop metallurgical bonding and densify under the influence of heat. During sintering of ferrous P/M parts, in particular, the following reactions take place:

- Metallurgical bonds are developed from the mechanical interlocks between powder metal particles in the compact.
- Metal oxides in the powder compact are reduced by reaction with the carbon from the blended graphite powders.
- The desired final carbon level of the P/M compact is obtained by diffusion of carbon from graphite powder.
- Densification of P/M compacts can be achieved during sintering. The degree of densification depends on the sintering parameters and the alloy(s) involved. Generally, higher sintering temperatures and longer sintering times promote greater densification of sintered parts.

The equipment and techniques used in sintering are diversified; there must be a means of heating the parts in a suitable protective atmosphere and a means of controlling the process variables. Heating and cooling rates, time and temperature of sintering, and composition of the atmosphere are the most critical variables. The dimensions of the finished parts are affected by the sintering conditions, as well as by the compacting process and the properties of the powder itself. In the sintering of ferrous metals, the atmosphere serves a dual purpose: it both protects the metal from oxidation and helps to control the carbon content of the parts, especially the carbon content at the surface. Commercial ferrous powders, including prealloyed steel powders, generally contain very little carbon. The carbon content of the finished part is

regulated by the amount of graphite mixed into the powder and the carbon potential of the sintering atmosphere. Particularly in alloy steels, the rate of cooling from the sintering temperature can determine which microconstituents are formed as a result of austenite decomposition, but the rate of cooling generally is slow enough to produce ferritic or pearlitic microstructures.

Most ferrous parts are sintered in mesh belt conveyor furnaces at 1105 to 1120 °C (2020 to 2050 °F). Common furnace atmospheres employed include dissociated ammonia (75 vol% H<sub>2</sub>, 25 vol% N<sub>2</sub>), endothermic gas (40 vol% N<sub>2</sub>, 40 vol% H<sub>2</sub>, 20 vol% CO with small amounts of water, carbon dioxide, and methane), and nitrogen-base atmospheres (e.g., nitrogen and 10% dissociated ammonia). Vacuum is used for some high-temperature sintering applications. The parts pass through a delubrication zone at 760 to 870 °C (1400 to 1600 °F) and then spend about 15 to 25 min at the high-heat temperature. These furnaces produce 90 to 360 kg/h (200 to 800 lb/h) of parts. They have been improved by the addition of preheat zones that heat rapidly using gas flames to provide an oxidizing environment, which prevents blistering and sooting of parts. Other furnaces have forced atmosphere gas recirculating coolers at the discharge end. These can give finer pearlite spacing or can even form some martensite or bainite, for increased strength.

For higher temperatures and improved toughness, parts are now being sintered in large-scale walking beam furnaces at 1230 to 1315 °C (2250 to 2400 °F). Yield can be up to 900 kg/h (2000 lb/h), with good dimensional control and decreased spread in mechanical properties, as well as increases in the mean properties.

**Secondary Operations.** In many applications, a P/M part that is made by compacting (either cold or warm) and sintering meets every performance requirement. In other instances, however, the functional requirements (mechanical properties, surface finish/or dimensional tolerances) for a part exceed the capabilities of compacted-and-sintered parts, and one or more secondary operations are required. Some of the common secondary operations are:

- Re-pressing: To increase density as well as strength and ductility; may or may not be accompanied by resintering. Also commonly referred to as double pressing
- Sizing: To tighten dimensional tolerances, usually in the radial direction, relative to the direction of compacting pressure
- Coining: To obtain a definite surface configuration (not to be confused with re-pressing or sizing)
- Machining: To obtain shapes that cannot be compacted, such as by tapping holes or cutting undercut grooves
- Infiltration: To increase strength and decrease porosity
- Heat treating: To increase hardness and strength
- Joining: By sinter bonding, staking, brazing, infiltrating, or welding
- Finishing: Includes deburring, polishing, impregnating, and plating

When the application of a P/M part requires high levels of strength, toughness, or hardness, the mechanical properties can be improved or modified by infiltration, heat treatment, or a secondary mechanical forming operation such as cold (room-temperature) re-pressing. The effect of these secondary processes on P/M mechanical properties is discussed below.

## Designation of Ferrous P/M Materials

Powder metallurgy materials are customarily designated by the specifications or standards to which they are made. Comparable standards are published by:

- Metal Powder Industries Federation (MPIF): MPIF Standard 35, Materials Standards for P/M Structural Parts
- ASTM: ASTM B 783, "Standard Specification for Materials for Ferrous Powder Metallurgy Structural Parts"
- International Organization for Standardization (ISO): ISO 5755-2, "Sintered Metal Materials--Specifications Part 2, Sintered Iron and Sintered Steel Containing One or Both of the Elements Carbon and Copper, Used in Structural Parts"; and ISO 5755-3, "Sintered Metal Materials--Specifications Part 3, Sintered Alloyed and Stainless Steels Used for Structural Parts"

Tables 2 and 3 list composition and property requirements, respectively, for ferrous P/M parts/materials per MPIF Standard 35. More detailed information on the material groups described below can be found in this document.

- (a) Unnotched Charpy test.
- (b) Apparent hardness measures a combination of matrix hardness plus the effect of porosity. Where applicable, the matrix (converted) hardness is also given in parentheses.
- (c) Fatigue limit for  $10^7$  cycles from reverse-bending tests (R.R. Moore testing machines).
- (d) The suffix number represents the minimum yield strength (in ksi) for the material in the as-sintered condition.
- (e) The suffix number for the heat treated (HT) or sinter-hardened conditions represents the minimum yield strength (in ksi). Tempering temperature for most heat treated materials is 175 °C (350 °F); nickel steels are tempered at 260 °C (500 °F).
- (f) Yield strength and ultimate tensile strength are approximately the same for heat treated materials.

**Ferrous Materials Produced from Elemental Powders.** The MPIF designations for ferrous P/M materials manufactured from elemental iron powders include a prefix of one or more letters (the first of which is F to indicate an iron-base material), four numerals, and a suffix. The second letter in the prefix, which may be C for copper or N for nickel, identifies the principal alloying element (if one is specified); the percentage of that element is indicated by the first two digits. The third and fourth digits indicate the amount of carbon in the compacted-and-sintered part; the code designation 00 indicates less than 0.3%, 05 indicates 0.3 to 0.6%, and 08 indicates 0.6 to 0.9%. The suffix is used to indicate the minimum 0.2% yield strength of the as-sintered parts and the minimum ultimate tensile strength of heat treated materials in units of  $10^3$  psi (6.894 MPa). The letters HT indicate heat treated. Ferrous materials produced from elemental powders include the iron and carbon steel, iron-copper and copper steels, and iron-nickel and nickel steels listed in Tables 2 and 3.

**Ferrous Materials Produced From Prealloyed Powders.** In the case of prealloyed P/M low-alloy steels, the four-digit series described above is replaced with a designation derived from the American Iron and Steel Institute (AISI) coding system. An example would be FL-4605-100HT, where the prefix FL indicates an prealloyed low-alloy ferrous material and the four digits (4605) indicate a nickel-molybdenum low-alloy steel.

When a prealloyed P/M steel powder is modified with elemental additions, a three or four digit alpha-numeric designator is used. For example, FLN-4205 indicates a prealloyed steel powder (FL) with an elemental nickel (N) addition. Compositions and properties of prealloyed low-alloy P/M steels are given in Tables 2 and 3.

**Sinter-hardened materials** are also produced from prealloyed low-alloy steel powders containing nickel, molybdenum, and manganese as the major alloying elements. They may also contain elemental additions of copper and/or nickel. Due to their compositions, these materials may be quench hardened during the cooling cycle following sintering, thereby eliminating a subsequent heat treating step (i.e., cost savings). Compositions and properties of sinter-hardened P/M steels are given in Tables 2 and 3. They are generally used in applications where high strength and wear resistance are required.

**Diffusion-alloyed materials** are powders in which the alloying elements of molybdenum, nickel, and copper are added as finely divided elements or oxides to the iron powder. They are then co-reduced with the iron powders at an annealing step, resulting in firm attachment and partial diffusion of the elements to the iron. This partial alloying increases hardenability compared to elemental mixtures, and yet these powders exhibit good compressibility. Diffusion bonding of the alloying elements also reduces the tendency toward powder segregation. Compositions and properties of diffusion-alloyed steels, which are indicated by the prefix FD in MPIF Standard 35, are listed in Tables 2 and 3. As mentioned previously, these materials are also amenable to the warm compaction process. Table 4 compares the properties of diffusion-alloyed steels manufactured by warm compaction and sintering, cold compaction and sintering, and double-pressing/double-sintering (both by cold and warm consolidation methods). These data indicate the superior properties exhibited by the warm compaction process.

(a) SP/SS, single-pressing/single-sintering; DP/DS, double-pressing/double-sintering.

(b) Ancorsteel 85HP is a prealloyed steel powder containing 2.0% Ni, 0.85% Mo, 0.4% graphite, and 0.6% lubricant. Compacts were sintered at 1260 °C (2300 °F).

(c) Distaloy 4800A is a diffusion-alloyed steel powder containing 4.0% Ni, 1.5% Cu, 0.50% Mo, 0.5% graphite, and 0.6% lubricant. Compacts were sintered at 1120 °C (2050 °F).

**Copper-Infiltrated Irons and Steels.** Infiltration of ferrous P/M compacts with copper (10 to 20% Cu) increases their strength, hardness, fatigue resistance, and impact energy. As shown in Fig. 1, densities on the order of  $\leq 7.5 \text{ g/cm}^3$  are readily achieved. This figure also shows one of the disadvantages of copper infiltration--its higher cost. Compositions and properties of infiltrated irons and steels, which are indicated by the prefix FX in MPIF Standard 35, are listed in Tables 2 and 3. Additional information can be found below (see the discussion "Properties of Ferrous P/M Materials" ).

## Properties of Ferrous P/M Materials

The mechanical and physical properties of compacted-and-sintered ferrous P/M materials depend on many factors. Some factors, such as microstructure, chemical composition, and heat treatment, affect the properties of P/M materials just as they affect the properties of wrought or cast steels. However, these factors themselves are affected by conditions unique to the P/M process, such as type of iron powder, whether alloying additions are prealloyed or admixed, type and amount of lubricant added to the powder, variations in the compacting process, and sintering conditions. For example, prealloyed powders generally produce stronger and tougher parts than do powders mixed from elemental metal powders, assuming that the same compacted density is obtained with each powder. The variations in the P/M process, such as compacting pressure and sintering temperature, also affect the properties of P/M materials.

**Effect of Porosity/Density.** The most obvious distinction between the microstructures of wrought and P/M materials is the porosity often found in P/M materials. This porosity originates as the spaces between powder particles and persists to some extent through sintering and subsequent secondary operations. The microstructure in Fig. 8 shows an example of a pore in a P/M material.

**Fig. 8** Atomized iron powder with 0.3% graphite added to yield 0.1 to 0.2% combined carbon ( $6.7 \text{ g/cm}^3$ ). Pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at  $1120^\circ\text{C}$  ( $2050^\circ\text{F}$ ) in dissociated ammonia. White regions are ferrite. Arrows E surround a colony of eutectoid (pearlite). Arrow P points to a pore. 2% nital. 545 $\times$

Powder metallurgy materials are specified in terms of the guaranteed minimum 0.2% tensile yield strength for as-sintered materials, and the minimum ultimate tensile strength for heat treated materials (refer to Table 3). Nonetheless, for a specific base iron powder and degree of sintering, mechanical properties do increase with density. Under the guaranteed minimum property system, the design engineer selects the needed strength properties and chemistry, and the parts fabricator chooses the density, base iron, sintering, and heat treatment to provide the properties. Table 3 shows all the guaranteed minimum tensile properties and related typical properties, including density, for the P/M materials that have been standardized by the MPIF. Table 4 shows the effects of various processing routes on the properties of ferrous P/M parts.

The effects of density on the mechanical properties of heat treated 2% Ni steel, FN-0208, are given in Fig. 9. The effects of density on the mechanical properties of sintered pure iron, F-0000, are shown in Fig. 10.

The apparent hardness of P/M material is measured with the regular Rockwell hardness tester. The HRC, HRB, and HRF scales measure the resistance to indentation (Table 3). They average the true hardness of the matrix material and the porosity and show lower readings than the corresponding material at full density. They are effective for quality control when applied to a specified region of the part, and an average of five readings is taken. Table 5 shows some typical Rockwell hardnesses and the precision that may be expected.

**Table 5 Precision of Rockwell apparent hardness readings on P/M parts**

All laboratories tested identical coupons. If similar but different coupons were to be compared, variability would be increased, and larger differences between respective readings would be expected.

MPIF material designation	Density, g/cm <sup>3</sup>	Number of laboratories	Average apparent hardness	Repeatability <sup>(a)</sup> (95% confidence limits)		Reproducibility <sup>(a)</sup> (95% confidence limits)

(b) HRB scale with 1.6 mm ( $\frac{1}{16}$  in.) diam carbide ball indenters.

The abrasion or wear resistance of heat treated materials is measured by the 100 g Knoop microhardness. Through the use of a microscope, these hardness measurements, made on the solid regions between the pores, show the intrinsic hardness of the steel matrix. The Knoop microhardness may be directly converted to HRC readings using the method described in MPIF Standard 51, Determination of Microhardness of Powder Metallurgy Materials. The precision or reproducibility between laboratories of the measurement of microhardness on a 4650 heat treated P/M steel is 3 HRC points when the laboratories take the average of six readings and use the conversion method noted above. Comparison of Knoop 100 g readings has a reproducibility between laboratories of 48 points, when the average of six readings are compared between laboratories.

In the range of densities normally encountered, the fatigue strength of a ferrous P/M material is approximately 25 to 40% of its tensile strength, regardless of composition. Typical fatigue strength values are given in Table 3. The effect of porosity on elastic modulus, a property that is generally considered independent of variations in structure, is given in Fig. 11 and in Table 3.

Fig. 11 Effect of density on the elastic modulus of sintered irons and steels after sintering to various densities

**Effect of Composition.** Alloying elements are added to ferrous P/M materials for the same reasons they are added to wrought or cast steels: primarily to improve strength and hardenability. The alloying elements most commonly used in ferrous P/M materials are carbon, copper, nickel, and molybdenum. The alloying elements are chosen for easy reduction in hydrogen. The amounts of alloying additions are important to the properties of the material, but so are the forms and sources of the alloying elements, particularly, whether they are added as elemental powders or as prealloyed powders. Elemental additions allow better compressibilities, but prealloying gives greater depth of hardening.

Carbon is the most important alloying element in P/M alloys because it strengthens iron and enables it to be heat treated. The effect of carbon content on the ultimate tensile strength of sintered iron is shown in Fig. 12. This strengthening effect can be traced to an increase in the amount of pearlite in the microstructure. As-sintered hypereutectoid P/M steels may have very low strength because proeutectoid cementite forms at austenite grain boundaries. The brittle cementite between the pores can fracture under relatively low levels of macroscopic stress. Combined carbon contents exceeding 0.8% are not recommended.

**Fig. 12** Tensile properties of as-sintered iron-carbon alloys at  $6.7 \text{ g/cm}^3$  as a function of carbon content

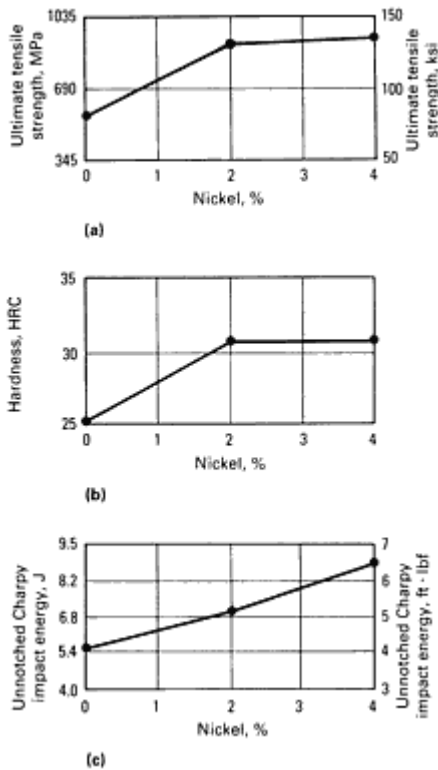

Iron and prealloyed steel powders are usually made with very low carbon content to maximize their compressibilities; carbon is added to these powders as admixed graphite. The carbon content of the sintered compact is also affected by the composition of the sintering atmosphere. The amount of graphite that is retained in the sintered compact as combined carbon depends on the sintering atmosphere and temperature, the source and type of both the graphite and the metal powder, and the amount and types of oxides in the metal powder. The correct graphite addition is determined empirically for each lot of iron powder.

Copper increases the strength of ferrous P/M materials, as shown in Fig. 13, primarily through solid-solution strengthening. Copper is also thought to accelerate the sintering and homogenizing processes, particularly if elemental copper or a copper-rich master alloy exists in the liquid state during the early stages of sintering. Copper causes atomized iron-base compacts to expand during sintering; thus, additions of copper can be used to compensate for shrinkage in iron-carbon or Fe-C-Ni alloys. Sponge iron blends with elemental copper do not expand.

**Fig. 13** Effect of copper and carbon content on the tensile strength of ferrous P/M materials

Nickel strengthens ferrous P/M alloys by solid-solution strengthening and increases their hardenability. The effect of nickel content on the mechanical properties of P/M nickel steels is given in Fig. 14. The presence of nickel increases shrinkage during sintering; additions of copper help maintain dimensions during sintering. The heterogeneous microstructure with nickel-rich islands (see Fig. 15) decreases notch sensitivity and raises tensile strength and impact resistance of the heat treated materials. The copper helps dissolve nickel in iron and increases hardenability.

**Fig. 14** Effect of nickel on the mechanical properties of heat treated P/M steels ( $7.0 \text{ g/cm}^3$ ). (a) Ultimate tensile strength. (b) Hardness. (c) Impact toughness

Arrow M, martensite or bainite at nickel-rich boundary. Arrows marked L, diffusion layer between nickel and pearlite. This is not unalloyed ferrite. Arrow F, ferrite. 4% nital etched

Molybdenum and nickel are the elements most frequently added to iron powders to improve hardenability. The amounts of these elements are relatively small, as in the MPIF designations FL-4605 and FL-4205. These two commonly used prealloyed powders correspond in composition to 46xx and 42xx wrought steels except that they have a higher molybdenum content and a lower manganese content.

Some prealloyed steels (sinter-hardening steels) with extra molybdenum and manganese, when blended with 2% Cu and eutectoid carbon, have enough hardenability to air harden during normal belt furnace sintering. After sintering, parts are tempered 1 h at  $175^\circ\text{C}$  ( $350^\circ\text{F}$ ).

Phosphorus can reduce the temperature used for sintering. It forms a liquid phase, giving rapid pore rounding, strengthening, and toughening when used in amounts of 0.45 to 0.80% P. It also reduces the hysteresis losses in magnetic core applications. The hot shortness that phosphorus causes in wrought steels is generally not a problem in P/M materials.

Sulfur may be added to ferrous P/M materials to improve machinability. The amounts of sulfur used in P/M materials exceed those used in wrought steels; however, sulfur contents as high as 1.0% appear to have little effect on the

mechanical properties of as-sintered compacts. Sulfur may be prealloyed to form MnS in situ, added as elemental sulfur to sponge iron, or added as manganese sulfide powder. The prealloyed form can decrease drill times by a factor of two.

Alloying elements having oxides that are stable in typical sintering atmospheres are used sparingly, if at all, in low-alloy ferrous P/M materials. Manganese and chromium are sometimes used in very small amounts; vanadium and titanium are rarely used.

**Effect of Infiltration.** The infiltration of ferrous P/M materials is a common processing technique. Infiltrants, usually copper-base alloys, are placed in contact with the green compact, and the two are sintered together at a temperature above the melting point of the infiltrant. Capillary action draws the infiltrant into the ferrous compact, where it can promote the sintering of iron particles. In an alternative technique, the ferrous compact is sintered and then infiltrated in a second step.

As indicated in Fig. 16 and Table 3, infiltration increases the strength, hardness, fatigue strength, and impact energy of ferrous P/M products compared to the iron-carbon matrix. Infiltration increases the density of the part (Fig. 1) and decreases variations in density. Porosity can be partly or completely eliminated by infiltration. As the infiltrant runs in under capillary action, it fills the higher-density fine-pore regions first. Recent proprietary techniques have increased unnotched impact toughness to more than 200 J (150 ft · lbf). Some of the disadvantages of infiltration are its high cost (Fig. 1), the likelihood of growth of the part during infiltration, and the possibility of erosion of the surface of the compact by the infiltrant.

**Fig. 16** Effect of infiltration on transverse rupture strength of iron-carbon alloys sintered to a density of 6.4 g/cm<sup>3</sup>. Combined carbon in the alloys was about 80% of the amount of graphite added to the iron powder. The amount of copper infiltrant was adjusted to fill various fractions of void space.

**Effect of Heat Treatment.** Ferrous P/M materials may be heat treated in the same manner as wrought or cast steels of comparable compositions. The porosity in P/M materials can cause complications, such as apparent loss of hardenability, greater depth of carburization or decarburization, and possible entrapment of quenchants. The effect of porosity on hardenability, which is exaggerated in measurements of apparent hardness, is shown in Fig. 17. The reduction in hardenability was caused by the reduced thermal conductivity of the porous sintered compact. The effect of porosity on depth of carbon is shown in Fig. 18. The porosity of the sintered compact enables the carbonitriding gas to penetrate well below the surface, hardening the compact to a greater depth. The use of vacuum carburizing for 2 to 10 min, followed by quenching, can form a definite case on low-carbon parts with a density as low as 6.8 g/cm<sup>3</sup>.

**Fig. 17** Effect of porosity on hardenability. Compacts of F-0008 powder were pressed and sintered to various densities, then austenitized and end quenched. Apparent hardness traverses reflect both depth of hardening and density of compacts. Horizontal bars represent approximate distance over which the average amount of martensite in the microstructure exceeded 50%. Hardenability band for 1080 wrought steel, which has a higher manganese content, is included for comparison.

**Fig. 18** Effect of porosity on carbonitriding. Compacts of F-0000 powder were pressed and sintered to various densities, then carbonitrided. Hardness traverses reflect both depth of carbonitrided case and density of compacts. Hardness traverse for a carbonitrided specimen of wrought 1018 steel is included for comparison.

The effect of various tempering temperatures on the properties of FN-0205 nickel steel is shown in Fig. 19. Tensile strength data for a wrought steel of comparable composition is also given in this figure to illustrate the deleterious effect of porosity on the strength of P/M materials.

**Fig. 19** Effect of tempering temperature on the mechanical properties of hardened-and-tempered FN-0205 sintered nickel steel. Specimens were hardened by quenching from 870 °C (1600 °F) and tempering at various temperatures. Tensile data for wrought 4640 steel is included for comparison.

Steam treating is a heat treatment sometimes applied to ferrous P/M materials. A typical treatment might be 2 h in superheated steam at 540 to 600 °C (1000 to 1100 °F). In such a treatment, a layer of black iron oxide ( $\text{Fe}_3\text{O}_4$ ) is formed on the surfaces of the sintered part, including the surfaces of pores that are connected to the surface. The process increases the density, hardness, compressive strength, and resistance to wear and corrosion of the part. The effect of steam treating on the density and hardness of several ferrous P/M materials is given in Table 6. Steam treating can reduce the tensile strength, elongation, and impact strength below the as-sintered values (Table 7). The ductility of steam-treated P/M steels is significantly reduced because of the internal stresses created by the formation of the iron oxide. Care must be taken when treating high-carbon P/M steels because these internal stresses can initiate microcracking and cause severe loss of ductility. Many cases have been reported in which parts were accidentally dropped on the floor after being steam treated, and the parts subsequently shattered like glass. The best recommendation for preventing such an incident is to specify a 0.5% C (max) content on materials that are to be steam treated.

**Table 6** Effect of steam treating on the density and hardness of ferrous P/M materials

**Effect of Re-Pressing.** As a secondary mechanical forming operation performed at room temperature, re-pressing (or double pressing) is done primarily to increase density, which increases mechanical and physical properties and hardness. When re-pressing is performed primarily to increase dimensional accuracy rather than density, it is termed sizing. When re-pressing is intended to change the contour of the surface in contact with the punches, it is termed coining. For example, a sintered blank could be coined so that the surface is indented with small slots or letters and numbers.

The amount of material deformation achieved with re-pressing is greater than in sizing because the forces used are greater than the sizing forces. The reduction in height of a ferrous part generally ranges from 3 to 5%. As with sizing, part tolerance after re-pressing depends on material type and part size.

Re-pressing generally refers to the application of high pressures on a sintered part at room temperature, while powder forging refers to processes in which a P/M preformed part is kept at an elevated temperature during the application of high pressure. At room temperature and at pressures as high as or higher than the compacting pressure, re-pressing increases the strength of a sintered P/M part by decreasing its porosity and by cold working the metal. The part is considerably strengthened, but at the expense of ductility. Resintering after re-pressing increases the ductility and toughness of the part without diminishing its strength. Table 4 lists the property benefits obtained by using re-pressing and resintering. As shown in Fig. 1, however, the disadvantage of re-pressed and resintered parts lies in their relatively high cost. Those materials that are difficult to re-press after sintering usually can be re-pressed if the sintering is done at a low temperature at which alloying cannot take place; this low-temperature sintering is called presintering. For iron alloys, presintering is done at 845 °C (1550 °F).

The effect of re-pressing on the density of ferrous P/M materials is shown in Fig. 20. The density that is achieved by re-pressing depends on the density of the sintered or presintered compact, the re-pressing pressure and lubricant, and whether the powder used was prealloyed or mixed from elemental powders.

**Fig. 20** The effect of re-pressing on density of P/M compacts. Alloy steel powders (4640 composition) were compacted at various pressures, then sintered, re-pressed, and resintered. For each specimen, the final density is indicated by the intersection between the curve that indicates the re-pressing pressure and the grid line that indicates the green compacting pressure. ## Introduction

FERROUS PARTS of near and full theoretical density can be produced by a variety of thermomechanical methods. These methods involve various amounts of heat and mechanical work to aid densification of the powder mass. For production of low-alloy steel parts, powder forging and injection molding have received the most attention. Both of these powder process technologies are formulated specifically to yield a product as close to full density as possible. This contrasts significantly with the conventionally processed products where attainment of full density is not the primary goal.

## Powder Forging

Powder forging involves fabrication of a preform by conventional press-and-sinter processing, followed by hot forging of the preform, which is quite porous, into a final shape with substantial densification. Forging is generally performed in one blow in confined dies to eliminate flash formation and achieve net shapes. Thus, parts containing through holes and complex configurations can be manufactured with little or no material loss due to trimming, hole punching, machining, or grinding. Powder forging is used to obtain higher density in P/M parts for high-stress applications, where pores must be minimized or completely eliminated.

There are two basic forms of powder forging:

- Hot upsetting, in which the preform experiences a significant amount of lateral material flow
- Hot re-pressing, in which material flow during densification is mainly in the direction of pressing; sometimes referred to as hot restriking, or hot coining

These two deformation modes and the stress conditions they impose on pores are illustrated in Fig. 1.

**Fig. 1** Forging modes and stress conditions on pores for (a) re-pressing and (b) upsetting

In hot upset powder forging, the extensive unconstrained lateral flow of material results in a stress state around the pores that is a combination of normal and shear stresses. A spherical pore becomes flattened and elongated in the direction of lateral flow. The sliding motion due to shear stresses breaks up any residual interparticle oxide films and leads to strong metallurgical bonding across collapsed pore interfaces. This enhances dynamic properties such as fracture toughness and fatigue strength.

The stress state during hot re-press powder forging consists of a small difference between vertical and horizontal stresses, which results in very little material movement in the horizontal direction and thus limited lateral flow. As densification proceeds, the stress state approaches a pure hydrostatic condition. A typical pore simply flattens, and the opposite sides of the pore are brought together under pressure. Hot re-press forging requires higher forging pressures than does hot upset forging for comparable densification. The decreased interparticle movement compared with upsetting reduces the tendency to break up any residual interparticle oxide films and may result in lower ductility and toughness.

While powder forged parts are primarily used in automotive applications where they compete with cast and wrought products, parts have also been developed for military and off-road equipment. Typical automotive applications include connecting rods and components for automatic transmissions.

## Material Considerations

The initial production steps of powder forging (preforming and sintering) are identical to those of the conventional press and sinter P/M process. Certain defined physical characteristics and properties are required in the powders used in these

processes. In P/M parts, surface finish is related to the particle size distribution of the powder. In powder forging, however, the surface finish is directly related to the finish of the forging tools.

Typical pressing grades are -80 mesh with a median particle size of about 75  $\mu\text{m}$ . The apparent density and flow are important for maintaining fast and accurate die filling. The chemistry affects the final alloy produced, as well as the compressibility.

Green strength and compressibility are more critical in conventionally processed P/M parts than they are in powder forging applications. Although there is a need to maintain edge integrity in powder forging preforms, there are rarely thin, delicate sections that require high green strength. Because powder forging preforms do not require high densities (typically 6.2 to 6.8  $\text{g/cm}^3$ ), the compressibility obtainable with prealloyed powders is sufficient. However, carbon is not prealloyed because it has an extremely detrimental effect on compressibility.

The two principal requirements for powder forged materials are a capability to develop an appropriate hardenability that will guarantee strength and to maximize fatigue performance by the control of microstructural features such as inclusions.

**Hardenability.** Nickel and molybdenum have the advantage that their oxides are reduced at conventional sintering temperatures. Alloy design is therefore a compromise, and the majority of atomized prealloyed powders in commercial use are nickel/molybdenum-base, with manganese present in limited quantities. The compositions of three commercial P/M steels are:

Alloy	Composition <sup>(a)</sup> , wt%		
	Mn	Ni	Mo
<b>P/F-4600</b>	0.10-0.25	1.75-1.90	0.50-0.60
<b>P/F-4200</b>	0.25-0.35	0.40-0.50	0.35-0.65

(a) All compositions contain balance of iron.

The higher cost of nickel and molybdenum, along with the higher cost of powder, compared with conventional wrought materials, is often offset by the higher material utilization inherent in the powder forging process.

More recently, powder forged parts have been produced from iron powders (0.10 to 0.25% Mn) with copper and/or graphite additions for parts that do not require the heat treating response or high-strength properties achieved through the use of the low-alloy steels.

**Inclusion Assessment.** Because the properties of material powder forged to near full density are strongly influenced by the composition, size distribution, and location of nonmetallic inclusions, a method has been developed for assessing the inclusion content of powders intended for powder forging applications. Samples of powders intended for forging applications are re-press powder forged under closely controlled laboratory conditions. The resulting compacts are sectioned and prepared for metallographic examination. The inclusion assessment technique involves the use of automatic image analysis equipment. The compact used for inclusion assessment may also be used to measure the amount of unalloyed iron powder particles present.

## Process Considerations

The development of a viable powder forging system requires the consideration of many process parameters. The mechanical, metallurgical, and economic outcomes depend to a large extent on operating conditions, such as temperature, pressure, flow/feed rates, atmospheres, and lubrication systems. Equally important consideration must be given to the types of processing equipment, such as presses, furnaces, dies, and robotics, and to secondary operations, in order to obtain the process conditions that are most efficient. This efficiency is maintained by optimizing the process line layout.

**Preforming.** Preforms are manufactured from admixtures of metal powders, lubricants, and graphite. Compaction is predominantly accomplished in conventional P/M presses that use closed dies.

The control of weight distribution within preforms is essential to produce full density and thus maximize performance in the critical regions of the forged component. Excessive weight in any region of the preform may cause overload stresses that could lead to tool breakage at forging.

Successful preform designs have been developed by an iterative trial-and-error procedure, using prior experience to determine the initial shape. More recently, computer-aided design (CAD) has been used for preform design.

Preform design is intimately related to the design and dimensions of the forging tooling, the type of forging press, and the forging process parameters. Among the variables to be considered for the preforming tools are:

- Temperature, that is, preform temperature, die temperature, and, when applicable, core rod temperature
- Ejection temperature of the forged part
- Lubrication conditions, that is, influence on compaction/ejection forces and tooling temperatures
- Transfer time and handling of the preform from the preheat furnace to the forging die cavity

Correct preform design not only entails having the right amount of material in the various regions of the preform, but also is concerned with material flow between the regions and prevention of potential fractures and defects.

**Sintering and Reheating.** Preforms may be forged directly from the sintering furnace; sintered, reheated, and forged; or sintered after the forging process. The basic requirements for sintering in a ferrous powder forging system are:

- Lubricant removal
- Oxide reduction
- Carbon diffusion
- Development of particle contacts
- Heat for hot densification

Oxide reduction and carbon diffusion are the most important aspects of the sintering operations. For most ferrous powder forging alloys, sintering takes place at about 1120 °C (2050 °F) in a protective reducing atmosphere with a carbon potential to prevent decarburization. Typical P/M sintering has been performed at 1120 °C (2050 °F) for 20 to 30 min. Increases in temperature reduce the time required for sintering by improving oxide reduction and increasing carbon diffusion. Chromium-manganese steels have been limited in their use because of the higher temperatures required to reduce their oxides and the greater care needed to prevent reoxidation.

Any of the furnaces used for sintering P/M parts, such as vacuum, pusher, belt, rotary hearth, walking beam, roller hearth, and batch/box, may be used for sintering or reheating powder forged preforms. The sintered preforms may be forged directly from the sintering furnace; stabilized at lower temperatures and forged; or cooled to room temperature, reheated,

and forged. All cooling, temperature stabilization, and reheating must occur under protective atmosphere to prevent oxidation.

Induction furnaces are often used to reheat axisymmetric preforms to the forging temperature because of the short time required to heat the material. Difficulties may be encountered in obtaining uniform heating throughout asymmetric shapes because of the variation in section thickness.

**The Forging Process.** Powder forging involves removing heated preforms from a furnace, usually by robotic manipulators, and locating them in the die cavity for forging at high pressures (690 to 965 MPa, or 100 to 140 ksi). Preforms may be graphite coated to prevent oxidation during reheating and transfer to the forging die. Lubrication of the die and punches is usually accomplished by spraying a water-graphite suspension into the cavity.

The forging presses commonly used in conventional forging, including hammers, high-energy-rate forming machines, mechanical presses, hydraulic presses, and screw presses, have been evaluated for use in powder forging. The essential characteristics that differentiate presses are contact time, stroke velocity, available energy and load, stiffness, and guide accuracy.

**Metal Flow in Powder Forging.** Draft angles, which facilitate forging and ejection in conventional forging, are eliminated in powder forged parts. This means that greater ejection forces--on the order of 15 to 20% of press capacity as a minimum--are required for the powder forging of simple shapes. However, the elimination of draft angles permits P/M parts to be forged closer to net shape.

**Tool Design.** In order to produce sound forged components, the forging tooling must be designed to take into account:

- Preform temperature
- Die temperature
- Forging pressure
- The elastic strain of the die
- The elastic/plastic strain of the forging
- The temperature of the part upon ejection
- The elastic strain of the forging upon ejection
- The contraction of the forging during cooling
- Tool wear

Specified part dimensional tolerances can only be met when the above parameters have been taken into account. However, there is still some flexibility in the control of forged part dimensions even after die dimensions have been selected. Higher preform ejection temperatures result in greater shrinkage during cooling. Increases in die temperature expand the die cavity and thus increase the size of the forged part. Therefore, if the forgings are undersize for a given set of forging conditions, a lower preform preheat temperature and/or a higher die preheat temperature can be used to produce larger parts. On the other hand, if the forged parts are oversize, the preform preheat temperature could be raised and/or the die temperature lowered to bring the parts to the desired size.

**Secondary Operations.** In general, the secondary operations applied to conventional components such as plating and peening may be applied to powder forged components. The most commonly used secondary operations involve deburring, heat treating, and machining.

The powder forged components may require deburring or machining to remove limited amounts of flash formed between the punches and the die. This operation is considerably less extensive than that required for wrought forgings.

The heat treatment of P/M products is the same as that required for conventionally processed materials of similar composition. The most common heat treating practices involve treatments such as carburizing, quench-and-temper cycles, or continuous-cooling transformations.

The amount of machining required for powder forged components is generally less than the amount required for conventional forgings because of their improved dimensional tolerances. Standard machining operations may be used to

achieve final dimensions and surface finish. One of the main economic benefits of powder forging is the reduced amount of machining required, as illustrated in Fig. 2.

**Fig. 2** Comparison of material use for a conventionally forged reverse idler gear (top) and the equivalent powder forged part (bottom). Material yield in conventional forging is 31%; that for powder forging is 86%. 1 lb = 453.6 g

In general, pore-free powder forged materials machine as readily as conventional forgings processed to achieve identical composition, structure, and hardness. Difficulties are encountered, however, if powder forged components are machined with the same cutting speeds, feed rates, and tool types as conventional components. These differences in machinability have been related to inclusion types and microporosity. Improved machinability can be accomplished by the addition of solid lubricants such as manganese sulfide.

However, the presence of microporosity and low-density noncritical areas in powder forged components leads to reduced machinability. The machinability behavior for these areas is similar to that of conventional P/M materials. The overall machinability of a powder forged component may be said to depend on the amount, type, size, shape, and dispersion of inclusions and/or porosity, as well as on the alloy and heat treated structure.

## Mechanical Properties

Wrought steel bar stock undergoes extensive deformation during cogging and rolling of the original ingot. This creates inclusion stringers and leads to planes of weakness, which affect the ductile failure of the material. The mechanical properties of wrought steels vary considerably with the direction test pieces are cut from the wrought billet. Powder forged materials, on the other hand, undergo relatively little material deformation, and their mechanical properties have been shown to be relatively isotropic.

The mechanical properties of powder forged materials are usually intermediate to the transverse and longitudinal properties of wrought steels. The rotating-bending fatigue properties of powder forged materials have also been shown to fall between the longitudinal and transverse properties of wrought steel of the same tensile strength.

While the performance of machined laboratory test pieces follows the intermediate trend described above, in the case of actual components powder forged parts have been shown to have superior fatigue resistance. This has generally been attributed not only to the relative mechanical property isotropy of powder forgings, but also to their better surface finish and finer grain size.

The data presented below represent results obtained on machined standard laboratory test pieces. Data are reported for four primary materials. The first two material systems are based on prealloyed powders (P/F-4600 and P/F-4200). The third material, based on Fe-Cu-C, was used by Toyota in 1981 to make powder forged connecting rods; Ford Motor Company introduced powder forged rods with a similar chemistry in 1986. Mechanical property data are therefore presented for copper and graphite powders mixed with an iron powder base to produce materials that generally contain 2% Cu.

**Heat Treatments.** There were three heat treatments used in developing the properties of the prealloyed powder forged materials: case carburizing, blank carburizing, and through-hardening (quenching and tempering).

Case carburizing was applied to materials with a nominal core carbon content of 0.20 to 0.25%. Blank carburizing is intended to produce a microstructure similar to that found in the core of case carburized samples. At the 0.20 to 0.25% C level, this results in a core hardness of 45 to 55 HRC.

Quenching and tempering was applied to achieve through-hardened microstructures over a range of forged carbon contents. A low-temperature temper or stress relief at 175 °C (350 °F) resulted in core hardnesses in the range of 55 to 65 HRC for materials with carbon contents of 0.4% and above. In addition, higher-temperature tempers were designed to achieve core hardnesses of 45 to 55 HRC and 25 to 30 HRC in these higher-carbon samples.

**Hardenability.** Jominy hardenability curves are presented in Fig. 3 for the P/F-4600, P/F-4200, and Fe-Cu-C alloys. Testing was carried out according to ASTM A 255. Specimens were machined from upset forged billets that had been sintered at 1120 °C (2050 °F) in dissociated ammonia.

**Fig. 3** Jominy hardenability curves for (a) P/F-4600, (b) P/F-4200, and (c) Fe-Cu-C materials at various forged carbon levels. Vickers hardness was determined at a 30 kgf load.

**Tensile, Impact, and Fatigue Properties.** Tensile properties were determined on test pieces with a gage length of 25 mm (1 in.) and a gage diameter of 6.35 mm (0.25 in.). Testing was carried out according to ASTM E 8 using a crosshead speed of 0.5 mm/min (0.02 in./min). Room-temperature impact testing was carried out on standard Charpy V-notch specimens according to ASTM E 23. Rotating-bending fatigue (RBF) testing was performed using single-load, cantilever, rotating fatigue testers. The tensile, impact, and fatigue data for the various materials are summarized in Tables 1, 2, and 3.

**Table 1** Mechanical property and fatigue data for P/F-4600 materials

(a) Still-air cooled.

(b) Forced-air cooled

The Fe-Cu-C alloys were either still-air cooled or forced-air cooled from the austenitizing temperature of 845 °C (1550 °F). The austenitizing temperature influences core hardness. These Fe-Cu-C alloys are often used with manganese sulfide additions for enhanced machinability. The tensile, impact, and fatigue properties for a sample with a 0.35% manganese sulfide addition are compared with a material without sulfide additions in Table 4. Data from the samples with manganese sulfide and sulfurized powders are included for comparison. The manganese sulfide addition had little influence on tensile strength, whereas the sulfurization process degraded tensile properties.

**Table 4 Mechanical property and fatigue data for iron-copper-carbon alloys with sulfur additions**

Sintered at 1120 °C (2050 °F) in dissociated ammonia, reheated to 980 °C (1800 °F) in dissociated ammonia, and forged.

## Metal Injection Molding

**Processing Steps.** The metal injection molding (MIM) process combines the structural benefits of metallic materials with the shape complexity of plastic injection molding technology. A uniform mixture of powder and binders is prepared and injected into a mold. The MIM powders are typically spherical in shape and much finer in particle size than those used for conventional cold-die compaction (MIM powder, 10 to 20  $\mu\text{m}$ ; conventional die-compaction powders, 50 to 150  $\mu\text{m}$ ). The binders are formulated specially to provide the proper rheological properties during injection molding as well as ease of binder removal after the molding step. Once the part is ejected from the mold, the binder material is removed using either solvent extraction or thermal processes (or both). After the debinding step the part is then sintered to complete the process. Sintering temperatures are usually in excess of 1260 °C (2300 °F). Due to the large amount of binder in the MIM starting material (up to 40% by volume), the MIM part undergoes a large reduction in size (as much as 20% linear shrinkage) during sintering. Dimensional tolerances, therefore, are not as good as in conventional die compaction and a straightening or coinciding step is sometimes needed.

**Cost Considerations.** Due to the high cost of the raw materials (carbonyl iron and binder), the MIM process is more expensive than conventional press-and-sinter methods. However, the capital equipment (presses) for injection molding is more economical than that for large-scale P/M presses. Tool life is at least 300,000 pieces. These factors help offset the added short-term material cost.

**Compositions and Properties.** Table 6 lists the compositions of powders used for producing low-alloy steels. Both prealloyed powders and admixtures of iron powder and alloying elements such as nickel, molybdenum, and carbon are employed.

**Table 6 Chemical compositions of MIM low-alloy steels**

Material designation	Composition (min to max), wt %				
	Fe	Ni	Mo	C	Other
<b>MIM-4600</b>	94.90-98.50	1.5-2.5	0.0-0.5	0.0-0.1	0.0-2.0
<b>MIM-4650</b>	94.40-98.10	1.5-2.5	0.0-0.5	0.4-0.6	0.0-2.0

Depending on the fineness of the starting powder and the sintering temperature, densities of 93 to 98% of full density are obtained. Minimum and typical mechanical property values for 95 and 96% dense MIM low-alloy steels are given in Table 7. As these data indicate, ductility of MIM-processed parts is very high, with elongation values of 30% or higher.

**Table 7 Mechanical properties of MIM low-alloy steels**

Material designation/condition	Minimum values					Typical values							
	Ultimate tensile strength		0.2% yield strength		Elongation in 25 mm (1 in.), %	Ultimate tensile strength		0.2% yield strength		Elongation in 25 mm (1 in.), %	Density, g/cm <sup>3</sup>	Apparent hardness <sup>(a)</sup>	
	MPa	ksi	MPa	ksi		MPa	ksi	MPa	ksi

Source: MPIF Standard 35, Materials Standards for Metal Injection Molded Parts, 1993-1994 edition

(a) Where applicable, the matrix (converted) hardness is also given in parentheses.

Figure 4(a), a photomicrograph of an unetched specimen of low-carbon iron plus 2% Ni steel illustrates the typical pore structure of injection molded parts. With the very small powders used, the pores remain small and isolated, with no interconnected porosity. Figure 4(b) shows the same field in the etched condition, displaying the typical enlargement of pores obtained by etching. There is no evidence of the presence of the original metal particles in the ferritic structure.

Because the interconnected porosity is so low (or absent), parts do not have to be resin impregnated prior to plating and close control over case depths is possible in carburizing.

**Fig. 4** Small, well-distributed, rounded pores in a MIM-processed nickel steel (97% density). (a) Unetched. 100 $\times$ . (b) Etched with 10% ammonium persulfate. Shows ferrite with grain boundaries. 100 $\times$

# Tool Steels

## Introduction

A TOOL STEEL is any steel used to make tools for cutting, forming, or otherwise shaping a material into a part or component adapted to a definite use. The earliest tool steels were simple, plain carbon steels, but by 1868 and increasingly in the early 20th century, many complex, highly alloyed tool steels were developed. These tool steels contain, among other elements, relatively large amounts of tungsten, molybdenum, vanadium, manganese, and chromium, and they make it possible to meet increasingly severe service demands and to provide greater dimensional control and freedom from cracking during heat treatment. Many alloy tool steels are also used for machinery components and structural applications in which particularly stringent requirements must be met, such as high-temperature springs, ultrahigh-strength fasteners, special-purpose valves, and bearings of various types for elevated-temperature service.

In service, most tools are subjected to extremely high loads that are applied rapidly. The tools must withstand these loads a great number of times without breaking and without undergoing excessive wear or deformation. In many applications, tool steels must provide this capability under conditions that produce high temperatures in the tool. No single tool material combines maximum wear resistance, toughness, and resistance to softening at elevated temperatures. Consequently, the selection of the proper tool material for a given application often requires a trade-off to achieve the optimal combination of properties.

Most tool steels are wrought products, but precision castings can be used to advantage in some applications. Powder metallurgy processing is also used in making tool steels. It provides, first, a more uniform carbide size and distribution in large sections and, second, special compositions that are difficult or impossible to produce by melting and casting and then mechanically working the cast product.

For typical wrought tool steels, raw materials (including scrap) are carefully selected not only for alloy content but also for qualities that ensure cleanliness and homogeneity in the finished product. Tool steels are generally melted in relatively small-tonnage electric arc furnaces to economically achieve composition tolerances, cleanliness, and precise control of melting conditions. Special ladle refining and secondary remelting processes such as electroslag remelting and vacuum arc remelting have been introduced to satisfy particularly stringent demands regarding tool steel quality and performance. The medium to high alloy contents of many tool steels require careful control of forging and rolling, which often results in a large amount of process scrap. Semifinished and finished bars are given rigorous in-process and final inspections. These inspections can be so extensive that both ends of each bar may be inspected for macrostructure (etch quality), cleanliness, hardness, grain size, annealed structure, and hardening ability. The inspections may also require that the entire bar be subjected to magnetic and ultrasonic inspections for surface and internal discontinuities. It is important that finished tool steel bars have minimal decarburization within carefully controlled limits, which requires that annealing be done by special procedures under closely controlled conditions.

Such precise production practices and stringent quality controls contribute to the high cost of tool steels, as do the expensive alloying elements they contain. Insistence on quality in the manufacture of these specialty steels is justified, however, because tool steel bars generally are made into complicated cutting and forming tools worth many times the cost of the steel itself. Although some standard constructional alloy steels resemble tool steels in composition, they are seldom used for expensive tooling because in general they are not manufactured to the same rigorous quality standards as are tool steels.

The performance of a tool in service depends on proper design of the tool, the accuracy with which the tool is made, selection of the property tool steel, and application of the proper heat treatment. A tool can perform successfully in service only when all four of these requirements have been met.

Classification and Characteristics

Table 1 gives composition limits for the wrought tool steels most commonly used. Each group of tool steels of similar composition and properties is identified by a capital letter; within each group, individual tool steel types are assigned code numbers.

(a) All steels except group W contain 0.25 max Cu, 0.03 max P, and 0.03 max S; group W contains 0.20 max Cu, 0.025 max P, and 0.025 max S. Where specified, sulfur may be increased to 0.06 to 0.15% to improve machinability of group A, D, H, M, and T steels.

- (b) Available in several carbon ranges.
- (c) Contains free graphite in the microstructure.
- (d) Optional.
- (e) Specified carbon ranges are designated by suffix numbers.

Tool steels are produced to various standards, including several ASTM specifications. The Steel Products Manual covering tool steels, which is published by the Iron and Steel Society, Inc. (Ref 1), contains much useful information that essentially represents the normal manufacturing practices of most tool steel producers. Frequently, more stringent chemical and/or metallurgical standards are invoked by the individual producers or consumers to achieve certain commercial goals. Where appropriate, standard specifications for tool steels, ASTM A600, A681, and A686, may be used as a basis for procurement. ASTM A600 sets forth standard requirements for tungsten and molybdenum high-speed steels; A681 is application to hot-work, cold-work, shock-resisting, special-purpose, and mold steels; and A686 covers water-hardening tool steels. In many instances, however, tool steels are purchased by tradename because the user has found that a particular tool steel from a certain producer gives better performance in a specific application than does a tool steel of the same AISI type classification purchased from another source.

## High-Speed Steels

High-speed steels are tool materials developed largely for use in high-speed cutting tool applications. There are two classifications of high-speed steels; molybdenum high-speed steels, also called group M, and tungsten high-speed steels, also called group T. Group M steels constitute more than 95% of all high-speed steel produced in the United States. A subgroup in the M group consists of intermediate high-speed steels.

Group M and group T high-speed steels are equivalent in performance. The main advantage of the group M steels is lower initial cost (approximately 40% lower than that of similar group T steels).

Molybdenum high-speed steels and tungsten high-speed steels are similar in many other respects, including hardening ability. Typical applications for both categories including cutting tools of all sorts, such as drills, reamers, end mills, milling cutters, taps, and hobs. Some grades are satisfactory for cold-work applications, such as cold-header die inserts, thread-rolling dies, punches, and blanking dies. Steels of the M40 series are used to make cutting tools for machining modern, very tough, high-strength steels. Additional information on the use of high-speed steels for cutting tools can be found in the Section "Machining" in this Handbook.

**Molybdenum high-speed steels** contain molybdenum, tungsten, chromium, vanadium, cobalt, and carbon as principal alloying elements. Group M steels have slightly greater toughness than group T steels at the same hardness. Otherwise, mechanical properties of the two groups are similar.

Increasing the carbon and vanadium contents of group M steels increases wear resistance. Increasing the cobalt content improves red (hot) hardness (that is, the capability of certain steels to resist softening at temperatures high enough to cause the steel to emit radiation in the red part of the visible spectrum), but it simultaneously lowers toughness. Type M2 and other grades in the M group have unusually high resistance to softening at elevated temperatures as a result of high alloy content (Fig. 1).

**Fig. 1** Variation of hardness with tempering temperature for four typical tool steels. Curves are for 1 h at temperature. Curve 1 illustrates low resistance to softening as tempering temperatures increases, such as exhibited by group W and group O steels. Curve 2 illustrates medium resistance to softening, such as exhibited by type S1 tool steel. Curves 3 and 4 illustrate high and very high resistance to softening, respectively, such as are exhibited by the secondary hardening tool steels A2 and M2.

Group M steels readily decarburize and can be damaged from overheating under adverse austenitizing environments, so they are more sensitive than group T steels to hardening conditions, particularly austenitizing temperature and atmosphere. This is especially true of high-molybdenum, low-tungsten compositions.

Group M high-speed steels are deep hardening. They must be austenitized at temperatures lower than those for hardening group T steels to avoid incipient melting. Group M high-speed steels can develop full hardness when quenched from temperatures of 1175 to 1230 °C (2150 to 2250 °F).

The maximum hardness that can be obtained in group M high-speed steels varies with composition. For those with lower carbon contents, that is, types M1, M2, M10 (low-carbon composition), M30, M33, M34, and M36, maximum hardness is usually 65 HRC. For higher carbon contents, including types M3, M4, and M7, maximum hardness is about 66 HRC. Maximum hardness of the higher-carbon, cobalt-containing steels, that is, types M41, M42, M43, M44, and M46, is 69 to 70 HRC. However, few industrial applications exist for steels of the M40 series at this maximum hardness. Usually, the heat treatment is adjusted to provide a hardness of 66 to 68 HRC.

**Tungsten high-speed steels** contain tungsten, chromium, vanadium, cobalt, and carbon as the principal alloying elements. Type T1 was developed partly as a result of the work of Taylor and White, who found in the early 1900s that certain steels with more than 14% W, about 4% Cr, and about 0.3% V exhibited red hardness. In its earliest form, type T1 contained about 0.68% C, 18% W, 4% Cr, and 0.3% V. By 1920, the vanadium content had been increased to about 1.0%. Over the years, the carbon content was gradually increased to its present level, for most steels, of approximately 0.75%.

Group T high-speed steels are characterized by high red hardness and wear resistance. They are so deep hardening that sections up to 75 mm (3 in.) in thickness or diameter can be hardened to 65 HRC or more by quenching in oil or molten salt. The high alloy and high carbon contents produce a large number of hard, wear-resistant carbides in the microstructure, particularly in types containing more than 1.5% V and more than 1.0% C. Type T15, which contains approximately 1.55% C, is the most wear-resistant steel of this group.

The combination of good wear resistance and high red hardness makes group T high-speed steels suitable for many high-performance cutting tool applications. Their toughness allows them to outperform cemented carbides in delicate tools and interrupted-cut applications. Group T high-speed steels are primarily used for cutting tools such as bits, drills, reamers, taps, broaches, milling cutters, and hobs. These steels are also used for making dies, punches, and high-load, high-temperature structural components such as aircraft bearings and pump parts.

Group T high-speed steels are all deep hardening when quenched from their recommended hardening temperature of 1205 to 1300 °C (2200 to 2375 °F). They are seldom used to make hardened tools with section sizes greater than 75 mm (3 in.).

Even very large cutting tools, such as drills 75 and 100 mm (3 and 4 in.) in diameter, have relatively small effective sections for hardening. Some large-diameter solid tools are made from group T high-speed steels, including broaches and cold extrusion punches as large as 100 to 125 mm (4 to 5 in.) in diameter.

The difference between surface hardness and center hardness varies with bar size. The section size and total mass of a given tool often have an effect on its response to a given hardening treatment that is equal to or greater than the effect of the grade of tool steel selected. For tools of extremely large diameter or heavy section, it is relatively common practice to use an accelerated oil quench to provide full hardness. This practice may yield values of Rockwell C hardness only one or two points higher than those obtainable through hot salt quenching or air cooling (which ordinarily produce full hardness in tools smaller than about 75 mm, or 3 in., in diameter) but at such high hardnesses that the increase in Rockwell hardness may prove quite significant.

The maximum hardness of tungsten high-speed steels varies with carbon content and, to a lesser degree, with alloy content. A hardness of at least 64.5 HRC can be developed in any high-speed steel. Those types that have high carbon contents and high carbides, such as T15, may be hardened to 67 HRC.

## Hot-Work Steels

Many manufacturing operations involve punching, shearing, or forming of metals at high temperatures. Hot-work steels (group H) have been developed to withstand the combinations of heat, pressure, and abrasion associated with such operations.

Group H tool steels usually have medium carbon contents (0.35 to 0.45%) and chromium, tungsten, molybdenum, and vanadium contents of 6 to 25%. These steels are divided into three subgroups: chromium hot-work steels (types H10 to H19), tungsten hot-work steels (types H21 to H26), and molybdenum hot-work steels (types H42 and H43).

**Chromium hot-work steels** (types H10 to H19) have good resistance to heat softening because of their medium chromium content and the addition of carbide-forming elements such as molybdenum, tungsten, and vanadium. The low carbon and low total alloy contents promote toughness at the normal working hardnesses of 40 to 55 HRC. Higher tungsten and molybdenum contents increase hot strength but slightly reduce toughness. Vanadium is added to increase resistance to washing (erosive wear) at high temperatures. An increase in silicone content improves oxidation resistance at temperatures up to 800 °C (1475 °F). The most widely used types in this group are H11, H12, H13, and, to a lesser extent, H19.

All of the chromium hot-work steels are deep hardening. The H11, H12, and H13 steels may be air hardened to full working hardness in section sizes up to 150 mm (6 in.); other group H steels may be air hardened in section sizes up to 305 mm (12 in.). The air-hardening qualities and balanced alloy contents of these steels result in low distortion during hardening. Chromium hot-work steels are especially well adapted to hot die work of all kinds, particularly dies for the extrusion of aluminum and magnesium, as well as die casting dies, forging dies, mandrels, and hot shears. Most of these steels have alloy and carbon contents low enough that tools made from them can be water cooled in service without cracking.

Tool steel H11 and modifications of this alloy are used to make certain highly stressed structural parts, particularly in aerospace technology. Material for such demanding applications is produced by vacuum arc remelting, which provides extremely low residual-gas content, excellent microcleanliness, and a high degree of structural homogeneity.

The chief advantage of H11 over conventional high-strength steels is its ability to resist softening during continued exposure to temperatures up to 540 °C (1000 °F) and at the same time provide moderate toughness and ductility at room-temperature tensile strengths of 1720 to 2070 MPa (250 to 300 ksi). In addition, because of its secondary hardening characteristic, H11 can be tempered at high temperatures, resulting in nearly complete relief of residual hardening stresses, which is necessary for maximum toughness at high strength levels. Other important advantages of H11, H12, and H13 steels for structural and hot-work applications include ease of forming and working, good weldability, relatively low coefficient of thermal expansion, acceptable thermal conductivity, and above-average resistance to oxidation and corrosion.

**Tungsten Hot-Work Steels.** The principal alloying elements of tungsten hot-work steels (types H21 to H26) are carbon, tungsten, chromium, and vanadium. The higher alloy contents of these steels make them more resistant to high-temperature softening and washing than H11 and H13 hot-work steels. However, high alloy content also makes them

more prone to brittleness at normal working hardnesses (45 to 55 HRC) and makes it difficult for them to be safely water cooled in service.

Although tungsten hot-work steels can be air hardened, they are usually quenched in oil or hot salt to minimize scaling. When air hardened, they exhibit low distortion. Tungsten hot-work steels require higher hardening temperatures than chromium hot-work steels, making the former more likely to scale when heated in an oxidizing atmosphere.

Although these steels have much greater toughness, in many characteristics they are similar to high-speed steels. In fact, type H26 is a low-carbon version of T1 high-speed steel. If tungsten hot-work steels are preheated to operating temperature before use, breakage can be minimized. These steels have been used to make mandrels and extrusion dies for high-temperature applications, such as the extrusion of brass, nickel alloys, and steel, and they are also suitable for use in hot-forging dies of rugged design.

**Molybdenum Hot-Work Steel.** There are only two active molybdenum hot-work steels: type H42 and type H43. These alloys contain molybdenum, chromium, vanadium, carbon, and varying amounts of tungsten. They are similar to tungsten hot-work steels, having almost identical characteristics and uses. Although their compositions resemble those of various molybdenum high-speed steels, they have a low carbon content and greater toughness. The principal advantage of types H42 and H43 over tungsten hot-work steels is their lower initial cost. They are more resistant to heat checking than are tungsten hot-work steels, but in common with all high-molybdenum steels, they require greater care in heat treatment, particularly with regard to decarburization and control of austenitizing temperature.

Proprietary Hot-Work Tool Steels

There are a number of proprietary low-alloy steel grades that are used for hot forging die holders and die blocks. As listed in Table 2, the principal alloying elements in these steels are nickel, molybdenum, and chromium, with vanadium and silicon in smaller additions. The total alloying content is generally small enough that adequate machinability is retained in prehardened die blocks of these grades. Characterized by high toughness and, in some instances, by good heat resistance, these steels have very good hardenability. As a trade-off to their good toughness, they are generally heat treated to relatively low hardnesses. Because of these low hardnesses, their wear resistance is only moderate. However, they are known to possess good resistance to shock loading (such as encountered in hammer forging), heat checking, and catastrophic failure.

Table 2 Nominal compositions of proprietary low-alloy hot-work tool steels

Steel <sup>(a)</sup>	Composition, wt%						
	C	Mn	Si	Cr	Ni	Mo	V
6G	0.55	0.80	0.25	1.00	...	0.45	0.10
6F2	0.55	0.75	0.25	1.00	1.00	0.30	0.10 <sup>(b)</sup>
6F3	0.55	0.60	0.85	1.00	1.80	0.75	0.10 <sup>(b)</sup>
6F4	0.20	0.70	0.25	...	3.00	3.35	...
6F5	0.55	1.00	1.00	0.50	2.70	0.50	0.10
6F6	0.50	...	1.50	1.50	...	0.20	...
6F7	0.40	0.35	...	1.50	4.25	0.75	...

<b>6H1</b>	0.55	...	...	4.00	...	0.45	0.85
<b>6H2</b>	0.55	0.40	1.10	5.00	1.50	1.50	1.00

(a) The designations of these steels represent a continuation of those used in the 1948 Metals Handbook, except that they were previously written in Roman numerals (VIF2, etc.). Neither AISI or SAE has assigned type numbers to these tool steels, compositions of which may vary slightly among various procedures.

(b) Optional alloying element

Because of the generally low tempering temperatures, these die steels are employed primarily in hammer operations where the contact times, during which heat transfer to the dies can occur, are short. Alternatively, they can be used in presses as die blocks with heat-resistant inserts made from the hot-work die steels (H grades). An exception to this general trend among the low-alloy tool steels is alloy 6F4 (see Table 2). Its large nickel and molybdenum contents impart high hardness and hardenability. Furthermore, it is generally underaged. Because of this, when it is used in presses or upsetters, heat transfer gives rise to age hardening and thus increased resistance to abrasive wear.

The origin of the "ASM" designations for the proprietary steels listed in Table 2 dates back to the 1948 edition of Metals Handbook. ASM International does not issue standards of any kind. However, because these steels were never given designations by AISI, SAE, or the Unified Numbering System (UNS), they are still often referred to by their ASM designations. In the 1948 Handbook, tool steels were grouped into six broad categories. The steels under discussion here were grouped under category VI (6), "Miscellaneous Tool Steels." The letters of the designation referred to the principal alloying elements. Thus, 6G is a chromium-molybdenum steel, while the 6F steels are nickel-chromium-molybdenum compositions. The difference between steels 6F2 through 6F7 is in the amounts of these principal alloying elements (see Table 2). The 6H grades in Table 2 are a continuation of those used in the 1948 Metals Handbook and are similar to the chromium hot-work tool steels described above.

## Cold-Work Steels

Cold-work tool steels, because they do not have the alloy content necessary to make them resistant to softening at elevated temperature, are restricted in application to those uses that do not involve prolonged or repeated heating above 205 to 260 °C (400 to 500 °F). There are three categories of cold-work steels; air-hardening steels (group A); high-carbon, high-chromium steels (group D); and oil-hardening steels (group O).

**Air-hardening, medium-alloy, cold-work steels** (group A) contain enough alloying elements to enable them to achieve full hardness in sections up to about 100 mm (4 in.) in diameter upon air cooling from the austenitizing temperature. (Type A6 through hardens in sections as large as a cube 175 mm, or 7 in., on a side.) Because they are air hardening, group A tool steels exhibit minimum distortion and the highest safety (least tendency to crack) in hardening. Manganese, chromium, and molybdenum are the principal alloying elements used to provide this deep hardening. Types A2, A3, A7, A8, and A9 contain a high percentage of chromium (5%), which provides moderate resistance to softening at elevated temperatures. (See curve 3 in Fig. 1 for a plot of hardness versus tempering temperature for type A2.)

Types A4, A6, and A10 are lower in chromium content (1%) and higher in manganese content (2%). They can be hardened from temperatures about 110 °C (200 °F) lower than those required for the high-chromium types, further reducing distortion and undesirable surface reactions during heat treatment.

To improve toughness, silicon is added to type A8, and both silicon and nickel are added to types A9 and A10. Because of the high carbon and silicon contents of type A10, graphite is formed in the microstructure. As a result, A10 has much better machinability in the annealed condition, and somewhat better resistance to galling and seizing in the fully hardened condition, than other group A tool steels.

Typical applications for group A tool steels include shear knives, punches, blanking and trimming dies, forming dies, and coining dies. The inherent dimensional stability of these steels makes them suitable for gages and precision measuring

tools. In addition, the extreme abrasion resistance of type A7 makes it suitable for brick molds, ceramic molds, and other highly abrasive applications.

The complex chromium or chromium-vanadium carbides in group A tool steels enhance the wear resistance provided by the martensitic matrix. Therefore, these steels perform well under abrasive conditions at less than full hardness. Although cooling in still air is adequate for producing full hardness in most tools, massive sections should be hardened by cooling in an air blast or by interrupted quenching in hot oil.

**High-carbon, high-chromium, cold-work steels** (group D) contain 1.50 to 2.35% C and 12% Cr. With the exception of type D3, they also contain 1% Mo. All group D tool steels except type D3 are air hardening and attain full hardness when cooled in still air. Type D3 is almost always quenched in oil (small parts can be austenitized in vacuum and then gas quenched). Therefore, tools made of D3 are more susceptible to distortion and are more likely to crack during hardening.

Group D steels have high resistance to softening at elevated temperatures. These steels also exhibit excellent resistance to wear, especially type D7, which has the highest carbon and vanadium contents. All group D steels, particularly the higher-carbon types D3, D4, and D7, contain massive amounts of carbides, which make them susceptible to edge brittleness.

Typical applications of group D steels include long-run dies for blanking, forming, thread rolling, and deep drawing; dies for cutting laminations; brick molds; gages; burnishing tools; rolls; and shear and slitter knives.

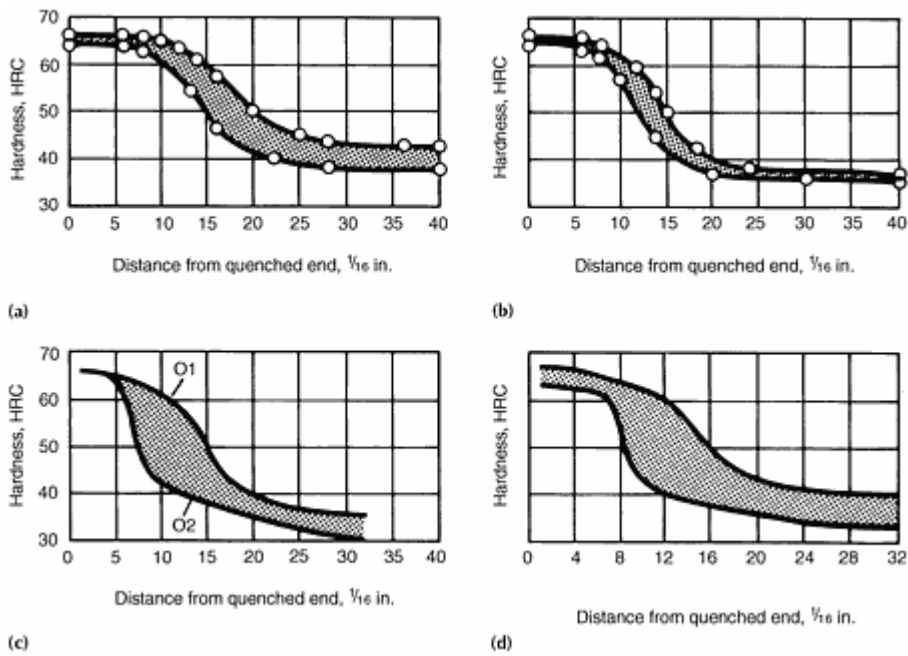

**Oil-hardening cold-work steels** (group O) have high carbon contents, plus enough other alloying elements that small to moderate sections can attain full hardness when quenched in oil from the austenitizing temperature. Group O tool steels vary in type of alloy, as well as in alloy content, even though they are similar in general characteristics and are used for similar applications. Type O1 contains manganese, chromium, and tungsten. Type O2 is alloyed primarily with manganese. Type O6 contains silicon, manganese, and molybdenum. It has a high total carbon content that includes free carbon, as well as sufficient combined carbon to enable the steel to achieve maximum as-quenched hardness. Type O7 contains manganese and chromium and has a tungsten content higher than that of type O1.

The most important service-related property of group O steels is high resistance to wear at normal temperatures, a result of high carbon content. On the other hand, group O steels have a low resistance to softening at elevated temperatures.

The ability of group O steels to harden fully upon relatively slow quenching yields lower distortion and greater safety (less tendency to crack) in hardening than is characteristic of the water-hardening tool steels. Tools made from these steels can be successfully repaired or renovated by welding if proper procedures are followed. In addition, graphite in the microstructure of type O6 greatly improves the machinability of annealed stock and helps reduce galling and seizing of fully hardened steel.

Group O steels are used extensively in dies and punches for blanking, trimming, drawing, flanging, and forming. Surface hardnesses of 56 to 62 HRC, obtained through oil quenching followed by tempering at 175 to 315 °C (350 to 600 °F), provide a suitable combination of mechanical properties for most dies made from type O1, O2, or O6. Type O7 has lower hardenability but better general wear resistance than any other group O tool steel, and it is more often used for tools requiring keen cutting edges. Oil-hardening tool steels are also used for machinery components (e.g., cams, bushings, and guides) and for gages, where good dimensional stability and wear resistance properties are needed.

The hardenability of group O steels can be measured effectively by the Jominy end-quench test. Hardenability bands for group O steels are shown in Fig. 2.

**Fig. 2** End-quench hardenability bands for group O steels. (a) O1, source A. (b) O2, source A. (c) O1 and O2, source B. (d) O6. Hardenability bands from source B represent the data from five heats each for O1 and O2 tool steels. Data from source A were determined only on the basis of average hardness, not as hardenability bands. Data for O6 is for a spheroidized prior structure. Steels O1 and O6 were quenched from 815 °C (1500 °F); O2, from 790 °C (1450 °F).

At normal hardening temperatures, group O steels retain greater amounts of undissolved carbides and thus do not harden as deeply as do steels that are lower in carbon but similar in alloy content. On the other hand, group O steels attain higher surface hardness. Raising the hardening temperature increases grain size, increases solution of alloying elements, and dissolves more of the excess carbide, thereby increasing hardenability. However, raising the hardening temperature can have an adverse effect on certain mechanical properties, most notably ductility toughness, and also can increase the likelihood of cracking during hardening.

## Shock-Resisting Steels

The principal alloying elements in shock-resisting steels, also called group S steels, are manganese, silicon, chromium, tungsten, and molybdenum, in various combinations. Carbon content is about 0.50% for all group S steels, which produces a combination of high strength, high toughness, and low to medium wear resistance. Group S steels are used primarily for chisels, rivet sets, punches, driver bits, and other applications requiring high toughness and resistance to shock loading. Types S1 and S7 are also used for hot punching and shearing, which require some heat resistance.

Group S steels vary in hardenability from shallow hardening (S2) to deep hardening (S7). In these steels of intermediate alloy content, hardenability is controlled to a greater extent by composition than by the incidental effects of grain size and melting practice, which are so important for group W steels. Group S steels require relatively high austenitizing temperatures to achieve optimal hardness; consequently, undissolved carbides are not a factor in the control of hardenability. Type S2 is normally water quenched; types S1, S5, and S6 are oil quenched; and type S7 is normally cooled in air, except that large sections are oil quenched.

Group S steels exhibit excellent toughness at high strength levels, so they are often considered for nontooling or structural applications.

## Low-Alloy Special-Purpose Steels

Low-alloy special-purpose steels, also called group L steels, contain small amounts of chromium, vanadium, nickel, and molybdenum. At one time, seven steels were listed in this group, but because of falling demand, only types L2 and L6

remain. Type L2 is available in several carbon contents, from 0.50 to 1.10%. Its principal alloying elements are chromium and vanadium, which make it an oil-hardening steel of fine grain size. Type L6 contains small amounts of chromium and molybdenum, as well as 1.50% Ni for increased toughness.

Although both L2 and L6 are considered oil-hardening steels, large sections of L2 are often quenched in water. A type L2 steel containing 0.50% C is capable of attaining about 57 HRC as oil quenched, but it will not through harden in sections of more than about 13 mm (0.5 in.) thickness. Type L6, which contains 0.70% C, has an as-quenched hardness of about 64 HRC. It can maintain a hardness above 60 HRC through sections of 75 mm (3 in.) thickness.

Group L steels are generally used for machine parts, such as arbors, cams, chucks, and collets, and for other special applications requiring good strength and toughness.

## **Mold Steels**

Mold steels, also called group P steels, contain chromium and nickel as principal alloying elements. Types P2 and P6 are carburizing steels produced to tool steel quality standards. They have very low hardness and low resistance to work hardening in the annealed condition. These factors make it possible to produce a mold impression by cold hubbing (hubbing is a technique for forming a mold cavity by forcing a hardness steel master hub, an exact replica of the article to be formed, into a softer die blank). After the impression is formed, the mold is carburized, hardened, and tempered to a surface hardness of about 58 HRC. Types P4 and P6 are deep hardening; with type P4, full hardness in the carburized case can be achieved by cooling in air.

Types P20 and P21 normally are supplied heat treated to 30 to 60 HRC, a condition in which they can be machined readily into large, intricate dies and molds. Because these steels are prehardened, no subsequent high-temperature heat treatment is required, and distortion and size changes are avoided. However, when used for plastic molds, type P20 is sometimes carburized and hardened after the impression has been machined. Type P21 is an aluminum-containing precipitation-hardening steel that is supplied prehardened to 32 to 36 HRC. This steel is preferred for critical-finish molds because of its excellent polishability.

All group P steels have low resistance to softening at elevated temperatures, with the exception of P4 and P21, which have medium resistance. Group P steels are used almost exclusively in low-temperature die casting dies and in molds for the injection or compression molding of plastics. Plastic molds often require massive steel blocks up to 762 mm (30 in.) thick and weighing as much as 9 metric tonnes (10 tons). Because these large die blocks must meet stringent requirements for soundness, cleanliness, and hardenability, electric furnace melting, vacuum degassing, and special deoxidation treatments have become standard practice in the production of group P tool steels. In addition, ingot casting and forging practices have been refined so that a high degree of homogeneity can be achieved.

## **Water-Hardening Steels**

Water-hardening steels, also called group W steels, contain carbon as the principal alloying element. Small amounts of chromium are added to most of the group W steels to increase hardenability and wear resistance, and small amounts of vanadium are added to maintain fine grain size and thus enhance toughness. Group W tool steels are made with various nominal carbon contents ( $\sim 0.60$  to 1.40%); the most popular grades contain approximately 1.00% C.

Group W tool steels are very shallow hardening and consequently develop a fully hardened zone that is relatively thin, even when quenched drastically. Sections more than about 13 mm ( $\frac{1}{2}$  in.) thick generally have a hard case over a strong, tough, and resilient core.

Group W steels have low resistance to softening at elevated temperatures. They are suitable for cold heading, striking, coining, and embossing tools; woodworking tools; hard metal-cutting tools, such as taps and reamers; wear-resistant machine tool components; and cutlery.

## **Properties of Tool Steels**

The basic properties of tool steels that determine their performance in service are hardness; resistance to wear, deformation, and breakage; toughness; and, in many instances, resistance to softening at elevated temperatures. It is difficult to obtain reliable correlations between the properties of tool steels as measured by laboratory tests and the performance of these steels in service or in fabrication, so these properties are often presented as general comparisons rather than as specific data. Property and fabrication characteristic comparisons are given in Table 3 and in Fig. 3 and 4.

Fig. 4 Relative abrasion resistance of tool steels

**Hardness** is the most commonly stipulated requirement of a tool steel and is used as an acceptance check of a heat-treated tool. Often the property or fabrication characteristics of tool steels can be measured by, or inferred from, the measurements of hardness. For example, high hardness improves strength and wear resistance but lowers toughness. As indicated in Table 3, the hardness of tool steel is most commonly measured and reported on the Rockwell C scale (HRC).

**Hot hardness**, the retention of high hardness at elevated temperature, is an important property for tool steels used for machining and hot metalworking applications. The ability of a tool steel to resist thermal softening is related to its ability to develop secondary hardening and to the amount of special phases, such as excess alloy carbides, in the microstructure. Useful information on the ability of tool steels to resist thermal softening at elevated temperatures can be obtained from tempering curves such as those shown in Fig. 1. Hardness testing at elevated temperatures (see Table 4) also can provide useful information.

(a) Small-diameter bars tested according to the recommended heat

treatment.

Figure 5 shows hot hardnesses of five hot-work die steels at various temperatures. All of these steels were heat treated to about the same initial hardness. Hardness measurements were made after holding the specimens at testing temperature for 30 min. Except for H12, all the die steels considered have about the same hot hardness at temperatures below about 315 °C (600 °F). The differences in hot hardness show up only at temperatures above 480 °C (900 °F).

**Fig. 5** Hot hardnesses of AISI hot-work tool steels. Measurements were made after holding at the test temperature for 30 min.

Figure 6 shows the resistance of some hot-work die steels to softening at elevated temperatures after 10 h of exposure. All of these steels have about the same initial hardness after heat treatment. For the die steels shown, there is not much variation in resistance to softening at temperatures below 540 °C (1000 °F). However, for longer periods of exposure at higher temperatures, high-alloy hot-work steels, such as H19, H21, and H10 modified, retain hardness better than do medium-alloy steels, such as H11.

**Fig. 6** Resistance of AISI hot-work tool steels to softening during 10 h elevated-temperature exposure as measured by room-temperature hardness. Unless otherwise specified by values in parentheses, initial hardness of all specimens was 49 HRC.

**Resistance to Abrasive Wear.** The high wear resistance of heat-treated tool steels is attributable to the hardness of the matrix phase, chiefly martensite, and the amount and type of carbides remaining undissolved in the matrix. The

amount and type of carbides present depend on the bulk carbon content and the quantity of carbide-forming elements (chromium, molybdenum, vanadium, and tungsten, for example) in the grade. Cementite is present in the carbon and low-alloy grades; more complex carbide types are found in the highly alloyed grades (Table 5). The hardness of carbides varies with their composition, from approximately 800 HV for cementite to approximately 1400 HV when other elements, such as chromium, are substituted for a portion of the iron.

**Table 5 Characteristics of alloy carbides found in tool steels**

Type of carbide	Lattice type	Remarks
$M_3C$	Orthorhombic	This is a carbide of the cementite ( $Fe_3C$ ) type, maybe Fe, Mn, Cr with a little W, Mo, V.
$M_7C_3$	Hexagonal	Mostly found in Cr alloy steels. Resistance to dissolution at higher temperatures. Hard and abrasion resistant. Found as a product of tempering high-speed steels.
$M_{23}C_6$	Face-centered cubic	Present in high-Cr steels and all high-speed steels. The Cr can be replaced with Fe to yield carbides with W and Mo.
$M_6C$	Face-centered cubic	Is a W- or Mo-rich carbide. May contain moderate amounts of Cr, V, Co. Present in all high-speed steels. Extremely abrasion resistant.
$M_2C$	Hexagonal	W- or Mo-rich carbide of the $W_2C$ type. Appears after temper. Can dissolve a considerable amount of Cr.
$MC$	Face-centered cubic	V-rich carbide. Resists dissolution. Small amount that does dissolve reprecipitates on secondary hardening.

Source: Ref 3

Figure 7 is a graphical comparison of the hardness of various alloy carbides relative to the hardness of martensite and cementite ( $Fe_3C$ ). As shown, the precipitated metal carbides such as MC and  $M_2C$  attain very high hardness, and they contribute significant wear resistance to tool steels that are alloyed to contain large volume fractions of carbides. For example, high-speed tool steels may contain as much as 30 vol% of carbides, consisting of a mixture of MC,  $M_{23}C_6$ , and  $M_6C$ .

**Fig. 7** Relative hardness of alloy carbides, cementite, and martensite in high-speed steels. Source: Ref 4

A detailed study of the dry abrasive wear of tool steels was conducted by Budinski (Ref 5). His assessment of the data showed very good correlation with a structural parameter, A, which equals the primary carbide size, multiplied by the volume fraction of carbides, multiplied by carbide hardness. The data are shown in Fig. 8. The implication of this finding is that the most abrasion-resistant tool steel has a large volume fraction of large, hard carbides.

**Fig. 8** Abrasion resistance of tool steels versus a structure parameter, A, that equals the primary carbide size, multiplied by the volume fracture of carbides, multiplied by carbide hardness. Source: Ref 5

Care must be used in committing these results to steelmaking practice. Most wear is metal to metal; therefore, abrasion is not the only mechanism involved. In addition, if large carbides are torn from the tool steel matrix, they will enhance tool steel wear by adding abrasive carbide particles to the wear debris. This effect can also occur if tool steels are overtempered.

**Resistance to Adhesive Wear.** Adhesive wear between tool steel and workpiece can result when direct contact occurs because of lubricant breakdown, high pressures, or process design. This type of wear is due to the cold welding of microscopic asperities between the tool and the workpiece. The environment also has an effect. Generally, adhesive wear becomes more severe as oxygen content decreases (for example, sliding in a vacuum), because no oxide layer can form.

Metallurgical factors that decrease the adhesive wear of tool steels include higher tool steel hardness at temperature (hot hardness), the built-in lubricity of graphite tool steels (types O6 and A10), small grain size (Ref 6), a large volume fraction of primary carbides (Ref 7), and small primary carbide size (Ref 6).

**Resistance to Deformation.** For all practical purposes, the resistance to elastic deformation (modulus of elasticity) of all tool steels in all conditions is about 210 GPa ( $30 \times 10^6$  psi) at room temperature. This decreases uniformly to about 185 GPa ( $27 \times 10^6$  psi) at 260 °C (500 °F) and to about 150 GPa ( $22 \times 10^6$  psi) at 540 °C (1000 °F).

**Toughness.** The amount of energy absorbed when a notched bar of fully hardened tool steel (except for certain grades) is broken in impact (Charpy V-notch test) is so small that it is very difficult to measure the differences in toughness that may make it possible to predict service performance. In addition, many tool steels have Charpy V-notch impact values of only a few joules. There is an error of  $\pm 1.5$  J associated with conventional Charpy V-notch testing, so some consider this mode of testing to be questionable. Charpy values for low-toughness steels should be measured on low-blow machines for reproducible results. Unnotched Izod values are the most commonly reported laboratory test values for fracture resistance and toughness of tool steels. However, excessive deformation of supporting fixtures makes it very difficult to obtain reproducible results. Torsion impact testing yields useful, reproducible data on the effects of variations on the composition and heat treatment of tool steels; however, it is difficult to correlate the results of such testing with service experience. Fatigue tests have been useful for research, but only in some instances have the results correlated well with field experience. Plane-strain fracture toughness tests that yield  $K_{Ic}$  values are also being used increasingly often. However, for most tool steel applications, the tooling is subject to a high strain rate, and fracture toughness may not be critical. (The normal failure mode for a tool steel in a typical application such as a highly stressed blanking die would be a

catastrophic failure, which would be better simulated by high strain rate testing including Charpy or Izod impact tests.) Results of Charpy, Izod, and fracture toughness tests are compared in Fig. 9.

**Fig. 9** Comparison of fracture toughness ( $K_{IC}$ ), longitudinal unnotched Izod, and longitudinal Charpy V-notch impact results for 89 mm (3.5 in.) square tool steel bars at working hardness. Source: Ref 8

In general, the ability of tool steels to withstand the rapid application of high loads without breaking increases with decreasing hardness. With hardness held constant, wide differences can be observed among tool steels of different compositions, or among steels of the same nominal composition made by different melting practices or heat treated according to different schedules.

## Effects of Surface Treatments on Properties

Most surface treatments are employed to increase surface hardness and/or wear resistance, minimize adhesion (reduce friction), or improve the corrosion resistance of the tool steel base.

**Carburizing.** The processes of case hardening and carburizing are of limited use in tool steel applications, because of the relatively high carbon contents of the tool steels. Carburizing can be accomplished in many ways and essentially

consists of heating the final machined tool into the austenite region in the presence of carbonaceous solids, liquids, or gases.

Low-carbon plastic mold steels (P type) are often carburized after hubbing or machining of the cavity in the mold. In this application, the tool steel is intentionally lean in carbon content to improve hubbing or machining and must be carburized in order to have sufficient surface hardness for the end use.

**Nitriding** is a frequently used surface treatment that increases surface hardness, adds to the corrosion resistance of the tool, and reduces friction. Basically, the process involves heating the finished tool in the presence of a nitrogen-containing liquid or gas and allowing nitrogen to diffuse into the tool. Gas nitriding is usually accomplished at a lower temperature (about 527 °C, or 980 °F) and longer time (10 to 90 h) than liquid nitriding, which occurs at temperatures ranging from 538 to 552 °C (1000 to 1025 °F) for 2 to 4 h. A nitrided depth that ranges from 13 to 76  $\mu\text{m}$  (0.005 to 0.003 in.) is desired.

Because of decreased wear and die pickup, cold-extrusion punches experience a two- to threefold improvement in life. Nitriding is often used whenever mold wash is a problem in the die casting of zinc or aluminum alloys. Galling of sheet metal working dies can be alleviated by nitriding these dies before use.

Steels that will be nitrided should contain one or more of the nitride-forming elements (chromium, vanadium, or aluminum) in order to prevent the easy spalling and chipping that results when iron nitride is formed. Commonly nitrided tool steels include H11, H12, H13, A2, O2, and the high-speed tool steels.

**Ion or plasma nitriding** has many of the same characteristics of liquid or gas nitriding. This process relies on nitrogen gas being ionized by glow discharge conditions between the tool (cathode) and the furnace wall or shield (anode). The primary advantages are the reductions in time and temperature, which save money and reduce the distortion and softening of prehardened tools. Usually, treatment times vary between 0.5 and 36 h.

**In the Toyota diffusion (TD) process**, metal dies to be treated are degreased, immersed in a carbide salt bath for a specific time period, quenched for core hardening, tempered, and washed in hot water for the removal of any residual salt. The borax salt bath contains compounds (usually ferroalloys) with carbide-forming elements such as vanadium, niobium, and chromium. The bath temperature is selected to conform to the hardening (austenitizing) temperature of the die steel. For example, the borax bath temperature should be between 1000 and 1050 °C (1830 and 1920 °F) for H13 die steel. Coating thicknesses range from 2 to 10  $\mu\text{m}$  (0.0001 to 0.0004 in.).

Tool steels that contain 0.3% C or more may be TD processed. This includes most cold- and hot-work steels, high-speed steels, and some martensitic stainless steels. Coatings employed include vanadium carbide (VC) and niobium carbide (NbC) for applications requiring high surface hardness (3000 HV or higher) and resistance to wear, seizure, and corrosion, and chromium carbide ( $\text{Cr}_7\text{C}_3$  and  $\text{Cr}_{23}\text{C}_6$ ) for applications requiring light wear resistance and high resistance to oxidation.

**Oxidation** is a well-established process used for high-speed steel-cutting tools. Increases in tool life of up to 100% are mostly due to a decrease in friction, because of the hard oxide coating and the ability of the porous oxide to entrap lubricant and draw it to the tool/workpiece interface (Ref 9). Steam oxidation of a finished tool is accomplished either by exposure to steam at a temperature of about 566 °C (1050 °F) or by treating in liquid sodium hydroxide and sodium nitrate salts at approximately 140 °C (285 °F) for periods of time ranging from 5 to 20 min. These treatments result in a black oxidized layer that is less than 5  $\mu\text{m}$  (0.0002 in.) thick and will not peel, chip, nor crack, even when the tool is bent or cut.

**Boriding.** In this process, boron atoms from a solid, liquid, gas, or plasma atmosphere surrounding the finished part are diffused into the surface creating a hard, wear-resistant iron boride layer. Metal-to-metal wear testing demonstrated a threefold improvement in wear resistance of borided O1 and O2 tool steels and over a twofold increase in A2 tool steel (Ref 10). Borided A2 tool steel showed twice the life of uncoated O2 tool steel in a deep-drawing operation in which low-carbon steel cups were manufactured (Ref 10). An H13 roller designed to flange milk cans was borided and produced three times as many cans before it wore out (Ref 11).

Boriding takes place at temperatures as low as 600 °C (1100 °F), but usual practice involves a period from 1 to 6 h at temperatures from 800 to 900 °C (1470 to 1650 °F) (Ref 10, 11). The resultant layer is between 13 and 130  $\mu\text{m}$  (0.0005 and 0.005 in.) and tends to be dull because of the microroughness of the surface. The high process temperature requires

that the boron treatment act as the austenitization step, or else the process must be followed by reaustenitization. This necessarily limits the process to applications where tolerances of about 25  $\mu\text{m}$  (0.001 in.) can be tolerated.

**Plating.** The most commonly practiced tool steel plating process is hard chromium plating. Plating thickness varies between 2 and 13  $\mu\text{m}$  (0.0001 and 0.0005 in.) and because it is very hard, it prolongs life by increasing abrasive wear resistance. More important than plating hardness is its very low friction coefficient, which effectively prevents adhesive wear.

However, hard chromium plating is not without problems. Tool steels may be hydrogen embrittled when plated, and the plating has a tendency to spall and flake. These wear debris can actually accelerate abrasive wear.

Electroless nickel plating has been used successfully as a replacement for chromium plating, both in routine production and for salvage plating operations on tool steel parts. Coating thicknesses for molds and dies range from 15 to 50  $\mu\text{m}$  (0.0006 to 0.002 in.). Typical applications include zinc die-casting dies, glass molds, plastic injection molds, and plastic extrusion dies.

Plating by this method is accomplished by means of chemical reduction, so it does not depend on any galvanic coupling between dissimilar metals, and there is no electrolysis involved. Therefore, there is no danger of hydrogen embrittlement.

**Chemical vapor deposition (CVD)**, a process conducted in a vacuum chamber, relies on a deposition from reacted gas onto the tool steel surface. Many different materials can be used as coatings. Chromium,  $\text{Al}_2\text{O}_3$ , TiC, CrC,  $\text{Fe}_4\text{N}$ , and TiN are commonly used, and other materials are being studied. This process utilizes high temperatures, usually above 800 °C (1472 °F), which means that tool steels must be tempered after the CVD coating is applied. The most popular wear-resistant coatings are TiC and TiN, which are used to coat high-speed, cold-work die and hot-work die tool steels. These coatings commonly range in thickness from 2.20  $\mu\text{m}$  (0.0001 to 0.001 in.). Using CVD coating with TiC and TiN, the primary mechanism of wear reduction is the extremely high hardness, which leads to excellent abrasion resistance, although some decrease in friction coefficient can often be realized.

Tool steels that can be successfully CVD coated include the AISI A, S, D, H, M, and T steel types. The lower-alloyed S type and all of the W and O types are either very difficult or impossible to properly coat, because of their low austenitization temperatures.

**Physical vapor deposition (PVD)**, which is also conducted in a vacuum chamber, can be accomplished in several different ways. The process relies on plasma-aided precipitation of either TiC or TiN onto tool steel at temperatures ranging from 200 to 550 °C (400 to 1025 °F) (Ref 12). This temperature range is much more suitable for the coating of high-speed tool steels than the temperature required for CVD.

Tool steel wear is reduced in about the same proportions (2 to 6 times less wear), whether the TiC or TiN is applied by CVD or PVD. TiN coatings on H13 pins reduced the friction coefficient in pin-on disk tests from 0.7 to less than 0.2 (Ref 13). Modified ASTM G65-10 abrasive wear testing of D3 steel showed that wear of the TiN-coated samples was between 4 and 23% of the uncoated samples, depending on their initial surface roughness (Ref 13). This result led Sundquist et al. to propose that increases in tool life that are due to TiN coating can only be expected when the surface roughness is less than the coating thickness (Ref 13).

**Ion implantation** is a process by which atoms of virtually any element can be injected into the near-surface region of any solid. The process involves forming a beam of charged ions of the desired element and then accelerating them at high energies toward the surface of the solid, which is held under high vacuum. The atoms penetrate into the solid to a depth of 0.25 to 25 nm (2.5 to 250 Å). This process differs from coating processes in that it does not produce a discrete coating; rather, it alters the chemical composition near the surface of the solid.

The number of applications involving the reduction of wear in stamping and punching tools probably exceeds all other uses if ion implantation for metals. The dominate cause of failure in high-speed tool steels used in metal stamping is adhesive wear. Ion implantation of nitrogen or titanium and carbon has provided the optimal treatment for such tools. For example, the life of punches and dies for manufacturing aluminum beverage cans has increased to 6 to 10 times that of untreated tooling. Similarly, punches for pressing powders into pellets have lasted twice as long after being treated. These applications range from forming pharmaceutical pills to more demanding service such as pressing ceramic pellets.

Ion implantation has also been used on a variety of low-temperature (to 200 °C, or 390 °F) cutting and slitting tools. Knife blades for cutting synthetic fibers have been implanted with titanium and carbon to improve wear resistance. Other applications include slitting blades for cutting rubber, hay baling cord cutters, plastic bandage cutter tools, corn-husking blades, paper slitters, and paper punches. Typical life improvements of 6 to 10 times have been reported for most of these applications (Ref 14). Other applications include ion implantation of injected molds for plastics and metal powders and extrusion and wire-drawing tools.

It should be noted that the ion implantation process is better suited to forming tools and dies than to cutting tools. This is attributable to the shallow implanted layer and the fact that a rise in temperature, such as may be expected in many cutting tools, causes diffusion of nitrogen into the specimen with the loss of the surface effect.

**Micropeening.** A proprietary surface treatment has been developed that uses controlled impaction of a small blasting media to develop rough texture and beneficial compressive stresses on the surface of dies and molds (Ref 15, 16, 17, 18). The rough texture increases the die lubricant retention characteristics, and the residual compressive stresses inhibit the initiation of fatigue microcracks due to the mechanical or thermal cycling of die surfaces during operation. This induced residual compressive strength has a subsurface penetration of 0.25 to 0.50 mm (0.010 to 0.020 in.) on dies that have not been nitrided and whose hardness is between 44 to 48 HRC. The impaction process also contributes a slight work hardening of the surface, which elevates the effective yield strength of the die as much as 25%.

Punch and die life increases of 6 to 10 times are claimed using this micropeening treatment. Drawing and forming dies have shown life improvements of 10 to 20 times in certain cases. Significant benefits can also be realized with cutting tools. In the field of die casting, micropeening has been used to increase the service life of new dies, close heat-checking cracks in used dies, and eliminates the deleterious effects of electrical discharge machining (EDM).

## Fabrication Characteristics

The properties that influence the ease of fabrication of tool steels include machinability; grindability; weldability; hardenability; and extent of distortion, safety (freedom from cracking), and tendency to decarburize during heat treatment.

**Machinability** of tool steels can be measured by the usual methods applied to constructional steels. Results are reported as percentages of the machinability of water-hardening tool steels (Table 6); 100% machinability in tool steels is equivalent to about 30% machinability in constructional steels, for which 100% machinability would be that of a free-machining constructional steel such as B1112. Improving the machinability of a tool steel by altering either the

composition or the preliminary heat treatment can be very important if a large amount of machining is required to form the tool and a large number of tools are to be made.

<b>M15</b>	25-30

(a) Equivalent to approximately 30% of the machinability of B1112.

(b) For hardness range 150 to 200 HB

**Grindability.** One measure of grindability is the ease with which the excess stock on heat-treated tool steel can be removed using standard grinding wheels. The grinding ratio (grindability index) is the volume of metal removed per volume of wheel wear. The higher the grindability index, the easier the metal is to grind (grinding ratios generally decrease as alloy and carbon contents increase). The index is valid only for specific sets of grinding conditions.

It should be noted that the grindability index does not indicate susceptibility to cracking during or after grinding, ability to produce the required surface (and subsurface) stress distribution, or ease of obtaining the required surface smoothness.

**Weldability.** The ability to construct, alter, or repair tools by welding without causing the material to crack may be an important factor in the selection of a tool material, especially if the tool is large. It is only rarely important in selecting materials for small tools. Weldability is largely a function of composition, but welding method and procedure also influence weld soundness. Generally, tool steels are more readily welded if they are deep hardening and are classified as having relatively high safety in hardening. In general, the lower-alloy tool steel grades have these characteristics.

**Hardenability** includes both the maximum hardness obtainable when the quenched steel is fully martensitic and the depth of hardening obtained by quenching in a specific manner. In this context, depth of hardening must be defined, generally as a specific value of hardness or a specific microstructural appearance. As a very general rule, maximum hardness of a tool steel increases with increasing carbon content; increasing the austenitic grain size and the amount of alloying elements reduces the cooling rate required to produce maximum hardness (increases the depth of hardening). The Jominy end-quench test, which is applied extensively to measure hardenability of construction steels, has limited application to tool steels. This test gives useful information only for oil-hardening grades. Air-hardening grades are so deep hardening that the standard Jominy test is not sufficient to evaluate hardenability.

An air-hardenability test has been developed that is based on the principles involved in the Jominy test, but which uses only still-air cooling and a 150 mm (6 in.) diameter end block to produce the very slow cooling rates of large sections. Such tests provide useful information for research but are of limited use for devising production heat treatments. By contrast, water-hardening grades of tool steel are so shallow hardening that the Jominy test is not sensitive enough. Special tests, such as the Shepherd penetration-fracture (P-F) test, are useful for research and for special applications of water-hardening tool steels.

In the Shepherd P-F test, a bar 19 mm ( $\frac{3}{4}$  in.) in diameter, in the normalized condition, is brine quenched from 790 °C (1450 °F) and fractured. The case depth (penetration, P) is measured in 0.4 mm ( $\frac{1}{64}$  in.) intervals, and the fracture grain size of the case (F) is determined by comparison with standard specimens. For example, a P-F value of 6 to 8 indicates a case depth of 2.4 mm ( $\frac{6}{64}$  in.) and a fracture grain size of 8. Fine-grained water-hardening tool steels are those with fracture grain sizes (F values) of 8 or more. Deep-hardening steels of this type have P values of 12 or more; medium-hardening steels, 9 to 11; and shallow-hardening steels, 6 to 8.

**Distortion and Safety in Hardening.** Minimal distortion in heat treating is important for tools that must remain within close size limits. In general, the amount of distortion and the tendency to crack increase as the severity of quenching increases.

**Resistance to decarburization** is an important factor in determining whether a protective atmosphere is required during heat treating. In a decarburizing atmosphere, the rate of decarburization increases rapidly with increasing austenitizing temperature, and, for a given austenitizing temperature, the depth of decarburization increases in direct proportion to holding time. Some types of tool steel decarburize much more rapidly than others under the same conditions of atmosphere, austenitizing temperature, and time.

## Machining Allowances

The standard machining allowance is the recommended total amount of stock that the user should remove from the as-supplied mill form to provide a surface free from imperfections that might adversely affect the response to heat treatment or the ability of tools to perform properly.

The decarburization resulting from oxidation at the exposed surfaces during the forging and rolling of the tool steel is a major factor in determining the amount of stock that should be removed. Although extra care is used in producing tool steels, scale, seams, and other surface imperfections that may be present must be removed.

In addition to the standard machining allowance, sufficient stock must be provided to permit the cleanup of any decarburization or distortion that may occur during final heat treatment. The amount varies with the type of tool steel, the type of heat treating equipment, and the size and shape of the tool.

Group W and group O tool steels are considered highly resistant to decarburization. Group M steels, cobalt-containing group T steels, group D steels, and types H42, A2, and S5 are rated poor for resisting decarburization.

Decarburization during final heat treatment is undesirable because it alters the composition of the surface layer, thereby changing the response to heat treatment of this layer and usually adversely affecting the properties resulting from heat treatment. Decarburization can be controlled or avoided by heat treating in a salt bath or in a controlled atmosphere or vacuum furnace. When heat treating is accomplished in vacuum, a vacuum of 13 to 27 Pa (100 to 200  $\mu\text{m}$  Hg) is satisfactory for most tools if the furnace is in good operating condition and has a very low leak rate. However, it is recommended that a vacuum of 7 to 13 Pa (50 to 100  $\mu\text{m}$  Hg) be used wherever possible.

If special heat-treating equipment is not available, appreciable decarburization can be avoided by wrapping the tool in stainless steel foil. Type 321 stainless steel foil can be used at austenitizing temperatures up to about 1010 °C (1850 °F). Type 309 or 310 foil is required at austenitizing temperatures from 1010 to 1205 °C (1850 to 2200 °F).

## P/M Tool Steels

Powder metallurgy (P/M) has become a major process for the manufacture of high-performance tool steels and tool steel products. The items now available include as-compacted or hot-worked billets and bars, semifinished parts, near-net shapes, and indexable cutting tool inserts. The P/M process has been used primarily for the production of advanced high-speed tool steels. However, it is now also being applied to the manufacture of improved cold-work and hot-work tool steels.

For most applications, the P/M tool steels offer distinct advantages over conventional tool steels. As a result of pronounced ingot segregation, conventional tool steels often contain a coarse, nonuniform microstructure accompanied by low transverse properties and problems with size control and hardness uniformity in heat treatment. Rapid solidification of the atomized powders used in P/M tool steels eliminates such segregation and produces a very fine microstructure with a uniform distribution of carbides and nonmetallic inclusions.

For high-speed tool steels, a number of important end-user properties have been improved by powder processing, notably machinability, grindability, dimensional control during heat treatment, and cutting performance under difficult conditions where high edge toughness is essential. Further, the alloying flexibility of the P/M process allows the production of new high-speed tool steels that cannot be made by conventional ingot processes because of segregation-related hot-workability problems.

## P/M Processing

Fully dense P/M tool steels are made either from hot isostatically pressed (HIP) gas-atomized tool steel powder or from cold compacted and vacuum sintered water-atomized tool steel powder. In both cases, the resulting billets have a fine, uniform carbide distribution with no segregation.

**Powder Production.** Tool steel powders are produced by induction melting of virgin raw materials and/or scrap. As mentioned above, gas or water atomization methods are used. Gas-atomized (with argon or nitrogen) tool steel powders have spherical particles (Fig. 10a) with high apparent densities (about 6 g/cm<sup>3</sup>). Oxygen content is less than 200 ppm. These powders are hot isostatically pressed into semifabricated shapes of full density. Complex shapes can also be made by cold isostatic pressing (CIP) followed by HIP. Water-atomized tool steel powders have irregularly shaped particles (Fig. 10b) and are suitable for conventional die compaction or CIP, followed by sintering to high or theoretical density.

**Fig. 10** Scanning electron micrographs of (a) nitrogen-atomized and (b) water-atomized high-speed tool steel powders

Water-atomized high-speed tool steel powders are annealed either in vacuum or hydrogen. Martensite and retained austenite are thereby transformed to a mixture of ferrite and spheroidal carbide. This renders the powder softer and more ductile and suitable for compaction.

**HIP of Tool Steels.** Since 1970, P/M high-speed tool steel powders have been consolidated to full density by HIP processing. In terms of tonnage, this processing route constitutes the vast majority of P/M high-speed tool steels produced worldwide.

Using the HIP method, the desired chemical composition is melted, and the molten stream is poured into an atomizing chamber where high-pressure gas jets disperse it into spheroidal droplets that are rapidly quenched to ambient temperature. Powder is removed from the atomizing chamber, dried, and screened to obtain the desired size fraction. It is then poured into cylindrical steel cans that are evacuated and sealed. The cans are subsequently heated to a specific temperature and hot isostatically compacted to achieve a fully dense product. Typical processing conditions are consolidated at 1100 °C (2000 °F) at 100 MPa (15 ksi) for 1 h. Compacts are further processed to the desired billet and bar sizes by conventional hot rolling and forging.

A distinguishing feature of P/M high-speed tool steels that have undergone HIP is the uniform distribution and small size of the primary carbides. The same is true of the sulfide inclusions in resulfurized grades. The size distributions of the primary carbides in P/M-produced and conventionally produced T15 have been measured, as shown in Fig. 11. Most of the carbides in gas atomized/HIPed P/M high-speed tool steels are less than about 3  $\mu\text{m}$ , while those in the conventional product cover the entire size range up to about 34  $\mu\text{m}$ , with a median size of 6  $\mu\text{m}$ . Microstructures of P/M and conventionally processed T15 are compared in Fig. 12.

Fig. 11 Primary carbide size distribution of T15 high-speed tool steel produced conventionally and by P/M processing

Fig. 12 Comparison of carbide size and distribution in P/M (left) and wrought (right) T15 steel

**Pressed-and-Sintered Tool Steels.** The use of conventional press-and-sinter technology offers the additional advantage of net shape or near-net shape capability. Current commercial fully dense sintering uses high green strength and compressible water-atomized tool steel powders that are compacted in rigid dies using either uniaxial pressing or in flexible rubber molds using CIP to make green tools and parts (generally, parts are pressed from 70 to 85% of theoretical density). These parts are then sintered in a microprocessor-controlled vacuum furnace near the solidus temperature of the alloy to virtually full density (at least 98% and frequently 99+% of theoretical). Sintering temperatures range from about 1240 to 1260 °C (2260 to 2300 °F). Due to the higher temperatures used in processing, the primary carbides tend to be larger in vacuum-sintered steels than in HIPed tool steels. However, they are still smaller than in conventional tool steels of similar composition.

P/M High-Speed Tool Steels

A large variety of P/M high-speed tool steels are available (Table 7). The P/M process has been applied primarily to standard high-speed tool steels (M2, M3, M4, M35, and so on) that are normally produced by conventional means but have significantly improved toughness and grindability when the P/M process is used. A number of P/M high-speed steels have been developed that cannot be made by conventional methods because of their high carbon, nitrogen, or alloy contents. For example, CPM Rex 76 is a cobalt-rich high-speed steel with exceptional hot hardness and wear resistance, along with greatly increased tool life in different cutting operations. Its high total alloy content (32.5%, compared to 27.8% for T15 and 25% for M42) renders this alloy unforgeable if produced by conventional methods.

(a) HCHS, high carbon, high sulfur; HS, high sulfur

**The machinability** as well as the grindability of high-speed steels are important factors that affect alloy selection and the cost of a finished tool. In general, the machinability of P/M high-speed tool steels in the annealed condition is comparable to or, in many cases, superior to that of conventional high-speed tool steels of similar composition.

An important advantage of the P/M process is that the machinability of P/M tool steels can be improved by increasing their sulfur contents to levels much higher than conventional, without sacrificing toughness or cutting performance. As indicated in Table 7, several P/M high-speed tool steels are available that contain as much as 0.30% S (see, for example, grades M2HCHS and M3HCHS). Depending on specific conditions, the highly resulfurized P/M tool steels can offer as much as a 30% improvement in machinability over P/M tool steels with lower sulfur levels or conventional high-speed tool steels of similar composition.

The machinability advantage of resulfurized P/M tool steels largely relates to the uniform distribution of the carbides and sulfides in their microstructures. The carbides and the sulfides in conventional steels are typically segregated in bands and are larger than those of the P/M steel. Because of the small size and uniform distribution of the sulfides, more sulfur (with a corresponding greater improvement in machinability) can be used in P/M tool steels than in conventional tool steels before hot workability or mechanical properties are degraded.

**The grindability** of P/M high-speed steels is also superior to that of conventional high-speed steel of the same composition because of the small size and uniform distribution of carbides in P/M steels, regardless of bar size. The relative grindability of several conventional and P/M high-speed tool steels is illustrated in Fig. 13. The grinding ratio is clearly superior for the P/M tool steels, particularly those with high sulfur contents. As expected, the grinding ratio generally decreases for both the conventional and P/M tool steels as their alloy and carbon contents increase.

Fig. 13 Comparison of the relative grindability of P/M and conventional high-speed tool steels

**Toughness, Hardness, and Wear Resistance.** The cutting performance of high-speed steels is primarily determined by their wear, their resistance to tempering at operating temperatures, and their toughness.

Wear resistance is generally a function of hardness and of the type, volume, and shape of the primary carbides present in the tool. In this respect, the higher hardness attainable with P/M high-speed tool steels, along with the greater amount of alloy carbides that can be included in these steels, constitutes a significant advantage over conventional high-speed steels.

Temper resistance, or hot hardness, is largely determined by the composition and growth of the secondary hardening carbides and is promoted by vanadium, molybdenum, and cobalt. These elements can be used in larger amounts in P/M high-speed steels than in conventional steels without degrading properties.

Toughness of the high-speed steels is determined by the state of tempering of the matrix and the spatial and size distribution of the primary carbides. Here again, the uniform distribution and small size of the carbides in P/M high-speed steels represents an important toughness advantage.

## P/M Cold- and Hot-Work Tool Steels

**P/M Cold-Work Tool Steels.** A number of improved, high-vanadium P/M tool steels designed for high-wear and cold-work applications are commercial available. The chemical compositions of six representative P/M cold-work grades are given in Table 7. As with P/M high-speed tool steels, the more uniform microstructure of the P/M cold-work steels yields better toughness (Fig. 14). This is very important in cold-work tooling, because it allows higher hardnesses to be used with associated improvements in yield strength and wear resistance. Further, substantial improvements in wear resistance have been realized by using higher vanadium contents in P/M cold-work tool steels than is practical in conventional cold-work tool steels.

**Fig. 14** Charpy C-notch impact properties of P/M and conventional tool steels at indicated hardness for cold-work applications

**P/M Hot-Work Tool Steels.** The absence of segregation in P/M tool steels makes them very attractive for hot-work tool and die applications, because a frequent cause of premature failure of large die casting dies is thermal fatigue attributed to segregation and nonhomogeneous microstructures. The compositions of three P/M hot-work tool steels now commercial available are given in Table 7. Two are P/M versions of standard H13 and H19 hot-work tool steels that have more uniform properties and equivalent or better toughness when made by P/M methods. The third is a high-vanadium modification of standard H19 with improved toughness and wear resistance.

## Precision-Cast Tool Steels

Precision casting of tools to nearly finished size offers important cost advantages through reductions in waste and machining. Casting is particularly advantageous when patternmaking costs can be distributed over a large number of tools.

Experience with cast forging and extrusion dies has shown that cast tools are more resistant to heat checking; minute cracks do occur, but they grow at much lower rates than in wrought material of the same grade and hardness. Slower propagation of thermal-fatigue cracks generally extends die life significantly. Mechanical testing of cast and wrought H13

indicates that yield and tensile strengths are virtually identical from room temperature to 600 °C (1100 °F), but that ductility is moderately lower in cast material. Hot hardness of cast H13 is higher than that of wrought H13 at temperatures above about 300 °C (about 600 °F); this hardness advantage increases with temperature and measures about eight points on the HRC scale at 650 °C (1200 °F).

Because cast dies exhibit uniform properties in all directions, no problem of directionality (anisotropy) exists. Dimensional control of castings is very consistent after an initial die is made and any necessary corrections are incorporated in the pattern. Reasonable finishing allowances are 0.25 to 0.38 mm (0.010 to 0.015 in.) on the impression faces, 0.8 to 1.6 mm ( $\frac{1}{32}$  to  $\frac{1}{16}$  in.) at the parting line of the mold, and 1.6 to 3.2 mm ( $\frac{1}{16}$  to  $\frac{1}{8}$  in.) on the back and outside surfaces. The hot-work tool steels most commonly cast include H12, H13, H21, and H25.

### Specialty Tool Steels

**Through-Hardening Stainless Steels.** Type 420 martensitic stainless steel (and modifications of this alloy) is commonly used for injection molds for all thermoplastic materials. It is particularly adaptable for molding vinyls or other corrosive plastics, or when the atmospheric or storage conditions are unusually severe, because it does not require chromium plating to resist these types of corrosive attack. Other stainless steels used for plastic molds include type 414, free-machining grade 420F, and Elmax, a high-hardness (58 to 60 HRC) wear-resistant P/M grade. Chemical compositions of these stainless steels are given in Table 8.

**Table 8 Chemical compositions of martensitic stainless steel plastic mold materials**

Alloy	Composition, wt%							
	C	Si	Mn	Cr	Ni	Mo	V	S
414	0.15	1.0	1.0	12.5	1.9	...	...	...
420 mod	0.38	0.9	0.5	13.6	...	...	0.3	...
420F mod	0.33	0.35	1.4	16.7	...	...	...	0.12
Elmax <sup>(a)</sup>	1.7	0.8	0.3	17.0	...	1.0	3.0	...

(a) P/M stainless steel produced by hot isostatic pressing of gas-atomized stainless steel powder

Type 440C martensitic stainless steel, both in wrought and P/M versions, is also used for some cold-work applications. CPM 440V is a high-vanadium, high-chromium tool steel for applications requiring both high wear resistance and good corrosion resistance. The composition of this material (Table 7) is essentially that of wrought type 440C to which about 5.75% V and increased carbon have been added to improve wear resistance.

**Maraging Steels.** Certain high-nickel maraging steels are being used for special noncutting tool applications; 18Ni(250) is the type most frequently used. However, for the most demanding applications, the higher-strength 18Ni(300) is often preferred. For applications requiring maximum abrasion resistance, any of the maraging steels can be nitrided.

Maraging steels achieve full hardness--nominally 500 HRC for 18Ni(250), 54 HRC for 18Ni(300), and 58 HRC for 18Ni(350)--by a simple aging treatment, usually 3 h at about 480 °C (900 °F). Because hardening does not depend on cooling rate, full hardness can be developed uniformly in massive sections, with almost no distortion. Decarburization is of no concern in these alloys because they do not contain carbon as an alloying element. If the long-time service temperature exceeds the aging temperature, maraging steels overage with a significant drop in hardness.

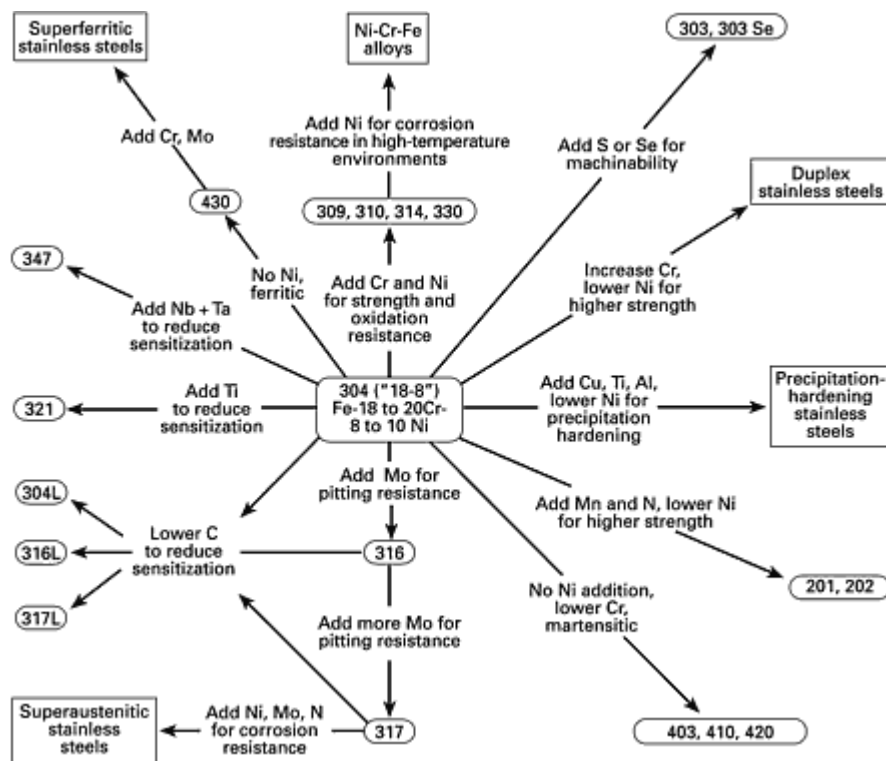

The 18Ni(250) grade is used for aluminum die-casting dies and cores, aluminum hot forging dies, dies for molding plastics, and various support tooling used in extrusion of aluminum. In die casting of aluminum, maraging steel dies can be used at higher hardness than is possible for dies made of H13 tool steel because maraging steel is not as prone to heat checking. Because the aging process results in very little size change, it is possible to machine the intricate impressions for plastic molding dies to final size prior to final hardening.

For molding extremely abrasive types of plastics, the higher surface hardness provided by 18Ni(300) maraging steel is desirable.

# Wrought Stainless Steels: Selection and Application

## Introduction

STAINLESS STEELS are iron-base alloys that contain a minimum of approximately 11% Cr, the amount needed to prevent the formation of rust in unpolluted atmospheres (hence the designation stainless). Few stainless steels contain more than 30% Cr or less than 50% Fe. They achieve their stainless characteristics through the formation of an invisible and adherent chromium-rich oxide surface film. This oxide forms and heals itself in the presence of oxygen. Other elements added to improve particular characteristics include nickel, molybdenum, copper, titanium, aluminum, silicon, niobium, nitrogen, sulfur, and selenium. Carbon is normally present in amounts ranging from less than 0.03% to over 1.0% in certain martensitic grades. Figure 1 provides a useful summary of some of the compositional and property linkages in the stainless steel family.

Stainless steels are used in a wide variety of applications. Most of the structural applications occur in the chemical and power engineering industries, which account for more than a third of the market for stainless steel products (see the following table). These applications include an extremely diversified range of uses, including nuclear reactor vessels, heat exchangers, oil industry tubulars, components for chemical processing and pulp and paper industries, furnace parts, and boilers used in fossil fuel electric power plants. The relative importance of the major fields of application for stainless steel products are as follows:

Application	Percentage
Industrial equipment	
<b>Chemical and power engineering</b>	34
<b>Food and beverage industry</b>	18
<b>Transportation</b>	9
<b>Architecture</b>	5
Consumer goods	
<b>Domestic appliances, household utensils</b>	28
<b>Small electrical and electronic appliances</b>	6

Some of these applications involve exposure to either elevated or cryogenic temperatures; austenitic stainless steels (see the following discussion) are well suited to either type of service.

## Designations for Stainless Steels

In the United States, wrought grades of stainless steels are generally designated by the American Iron and Steel Institute (AISI) numbering system, the Unified Numbering System (UNS), or the proprietary name of the alloy. In addition, designation systems have been established by most of the major industrial nations. Of the two institutional numbering systems used in the U.S., AISI is the older and more widely used. Most of the grades have a three-digit designation; the 200 and 300 series are generally austenitic stainless steels, whereas the 400 series are either ferritic or martensitic. Some of the grades have a one- or two-letter suffix that indicates a particular modification of the composition.

The UNS system includes a considerably greater number of stainless steels than AISI because it incorporates all of the more recently developed stainless steels. The UNS designation for a stainless steel consists of the letter S, followed by a five-digit number. For those alloys that have an AISI designation, the first three digits of the UNS designation usually correspond to an AISI number. When the last two digits are 00, the number designates a basic AISI grade. Modifications of the basic grades use two digits other than zeroes. For stainless steels that contain high nickel contents ( $\sim 25$  to 35% Ni), the UNS designation consists of the letter N followed by a five-digit number. Examples include N08020 (20Cb-3), N08024 (20Mo-4), N08026 (20Mo-6), N08366 (AL-6X), and N08367 (AL-6XN). Although classified as nickel-base alloys by the UNS system, the previously mentioned materials constitute the "superaustenitic" category of stainless steel shown in Fig. 1 and described in the following section "Classification of Stainless Steels."

# Classification of Stainless Steels

Stainless steels can be divided into five families. Four are based on the characteristic crystallographic structure/microstructure of the alloys in the family: martensitic, ferritic, austenitic, or duplex (austenitic plus ferritic). The fifth family, the precipitation-hardenable alloys, is based on the type of heat treatment used, rather than microstructure.

## Martensitic Stainless Steels

**Characteristics and Compositions.** Martensitic stainless steels are essentially Fe-Cr-C alloys that possess body-centered tetragonal (bct) crystal structure (martensitic) in the hardened condition. They are ferromagnetic, hardenable by heat treatments, and generally resistant to corrosion only in relatively mild environments. Chromium content is generally in the range of 10.5 to 18%, and carbon content can exceed 1.2%. The chromium and carbon contents are balanced to ensure a martensitic structure. Elements such as niobium, silicon, tungsten, and vanadium can be added to modify the tempering response after hardening. Small amounts of nickel can be added to improve corrosion resistance in some media and to improve toughness. Sulfur or selenium is added to some grades to improve machinability. Table 1 provides chemical compositions for standard (AISI) and nonstandard grades.

Table 1 Chemical compositions of martensitic stainless steels

UNS No.	Type/designation	Composition <sup>(a)</sup> , %							
		C	Mn	Si	Cr	Ni	P	S	Other

- (b) Optional.
- (c) German (DIN) specification

**Properties and Applications.** The most commonly used alloy within the martensitic stainless steel family is type 410, which contains approximately 12 wt% Cr and 0.1 wt% C to provide strength. The carbon level and, consequently, strength increase in the 420, 440A, 440B, and 440C alloy series. The latter three alloys, in particular, have an increased chromium level in order to maintain corrosion resistance. Molybdenum can be added to improve mechanical properties or corrosion resistance, as it is in type 422 stainless steel. Nickel can be added for the same reasons in types 414 and 431. When higher chromium levels are used to improve corrosion resistance, nickel also serves to maintain the desired microstructure and to prevent excessive free ferrite. The limitations on the alloy content required to maintain the desired fully martensitic structure restrict the obtainable corrosion resistance to moderate levels.

In the annealed condition, martensitic stainless steels have a tensile yield strength of approximately 275 MPa (40 ksi) and can be moderately hardened by cold working. However, martensitic alloys are typically heat treated by both hardening and tempering to yield strength levels up to 1900 MPa (275 ksi), depending primarily on carbon level. These alloys have good ductility and toughness properties, which decrease as strength increases. Depending on the heat treatment, hardness values range from approximately 150 HB (80 HRB) for materials in the annealed condition to levels greater than 600 HB (58 HRC) for fully hardened materials.

Martensitic stainless steels are specified when the application requires good tensile strength, creep, and fatigue strength properties, in combination with moderate corrosion resistance and heat resistance up to approximately 650 °C (1200 °F). In the United States, low- and medium-carbon martensitic steels (for example, type 410 and modified versions of this alloy) have been used primarily in steam turbines, jet engines, and gas turbines. In Europe, alloy HT9 (12Cr-1Mo-0.3V) has been widely used in elevated-temperature, pressure-containment applications, including steam piping and steam generator reheater and superheater tubing used in fossil fuel power plants. Type 420 and similar alloys are used in cutlery, valve parts, gears, shafts, and rollers. Other applications for higher carbon-level grades (type 440 grades) include cutlery, surgical and dental instruments, scissors, springs, valves, gears, shafts, cams, and ball bearings.

### Ferritic Stainless Steels

**Characteristics and Compositions.** Ferritic stainless steels are essentially iron-chromium alloys with body-centered cubic (bcc) crystal structures. Chromium content is usually in the range of 11 to 30%. Some grades may contain molybdenum, silicon, aluminum, titanium, and niobium to confer particular characteristics. Sulfur or selenium can be added to improve machinability. Table 2 lists compositions of ferritic stainless steels.

**Table 2 Chemical compositions of ferritic stainless steels**

(a) Single values are maximum unless otherwise indicated.

(b) Typical value

The ferritic alloys are ferromagnetic. They can have good ductility and formability, but high-temperature strengths are relatively poor compared to those of the austenitic grades. Toughness may be somewhat limited at low temperatures and in heavy sections. Unlike the martensitic stainless steels, the ferritic stainless steels cannot be strengthened by heat treatment. Also, because the strain-hardening rates of ferrite are relatively low and cold work significantly lowers ductility, the ferritic stainless steels are not often strengthened by cold work.

**Properties and Applications.** Typical annealed yield and tensile strengths for ferritic stainless steels are 35 to 55 ksi (240 to 380 MPa) and 60 to 85 ksi (415 to 585 MPa), respectively. Ductilities tend to range between 20 and 35%. Higher strengths, up to 75 ksi (515 MPa) for yield strength and 95 ksi (655 MPa) for tensile strength, are obtained in the more highly alloyed "superferritic" steels shown in Fig. 1.

Whereas the martensitic stainless steels offer only moderate corrosion resistance, that of the ferritic stainless steels can range from moderate for the low-to-medium, chromium-content alloys to outstanding for the superferritics such as type 444 and UNS No. S44627, S44635, S44660, S44700, and S44800. The low-chromium (11%) alloys, such as types 405 and 409, have fair corrosion and oxidation resistance and good fabricability at low cost. Type 409, the most widely used ferritic stainless steel, has gained wide acceptance for use in automotive exhaust systems. The intermediate-chromium (16 to 18%) alloys include type 430, which resists mild oxidizing acids and organic acids and is used in food-handling equipment, and type 434, which includes a molybdenum addition for improved corrosion resistance and is used for automotive trim. The high-chromium (19 to 30%) alloys, which include types 442 and 446 as well as the superferritics, are used for applications that require a high level of corrosion and oxidation resistance. By controlling interstitial element content via argon oxygen decarburization (AOD) processing, it is possible to produce grades with unusually high chromium and molybdenum (up to 4.5%) contents and very low carbon contents (as low as 0.01%). Such highly alloyed superferritics offer exceptional resistance to localized corrosion induced by exposure to aqueous chlorides. Localized corrosion, such as pitting, crevice corrosion, and stress-corrosion cracking (SCC) are problems that plague many austenitic stainless steels. Therefore, the superferritics are often used in heat exchangers and piping systems for chloride-bearing aqueous solutions and seawater.

## Austenitic Stainless Steels

**Characteristics and Compositions.** Austenitic stainless steels constitute the largest stainless family in terms of number of alloys and usage. Like the ferritic alloys, they cannot be hardened by heat treatment. However, their similarity ends there. The austenitic stainless steels are essentially nonmagnetic in the annealed condition and can be hardened only by cold working. They usually possess excellent cryogenic properties and good high-temperature strength and oxidation resistance. Chromium content generally varies from 16 to 26%; nickel content is less than or equal to approximately 35%; and manganese content is less than or equal to 15%. The 200 series steels contain nitrogen, 4 to 15% Mn, and lower nickel contents (up to 7% Ni). The 300 series steels contain larger amounts of nickel and up to 2% Mn. Molybdenum, copper, silicon, aluminum, titanium, and niobium can be added to confer certain characteristics, such as halide pitting resistance or oxidation resistance. Table 3 provides chemical compositions for standard (AISI) and nonstandard grades.

(a) Single values are maximum values unless otherwise indicated.

(b) Optional.

(c) Nominal compositions.

(d) UNS designation has not been specified; this designation appears in ASTM A 887 and merely indicates the form to be used.

**Properties and Applications.** The yield strengths of chromium-nickel austenitic stainless steels are rather modest and are comparable to those of mild steels. Typical minimum mechanical properties of annealed 300 series steels are yield strengths of 205 to 275 MPa (30 to 40 ksi), ultimate tensile strengths of 520 to 760 MPa (75 to 110 ksi), and elongations of 40 to 60%. Annealed 200 series alloys have higher yield strengths ranging from 345 to 480 MPa (50 to 70 ksi). Higher strengths are possible in cold-worked forms, especially in drawn wire, in which a tensile strength of 1200 MPa (175 ksi) or higher is possible. Figure 2 compares the work-hardening characteristics of 300 series and type 430 (ferritic) grades. The 200 series have work-hardening characteristics similar to types 301 and 302 in Fig. 2.

**Fig. 2** Typical effect of cold rolling on the tensile strength of selected stainless steels

Even the leanest austenitic stainless steels (e.g., types 302 and 304) offer general corrosion resistance in the atmosphere, in many aqueous media, in the presence of foods, and in oxidizing acids such as nitric acid. Types 321 and 347 are essentially type 304 with additions of either titanium or niobium, respectively, which stabilize carbides against sensitization (see the subsection "Thermally Induced Embrittlement"). The addition of molybdenum in types 316/316L (Fig. 1) provides pitting resistance in phosphoric and acetic acids and dilute chloride solutions, as well as corrosion resistance in sulfurous acid. An even higher molybdenum content, as in type 316L (3%), and even richer alloys further enhance pitting resistance. Nitrogen is added to enhance strength at room temperature and, especially, at cryogenic temperatures (e.g., type 304N). Nitrogen is also added to reduce the rate of chromium carbide precipitation and, therefore, the susceptibility to sensitization. It is also added to molybdenum-containing alloys to increase resistance to chloride-induced pitting and crevice corrosion. Higher amounts of chromium and/or nickel are used to enhance high-temperature oxidation resistance (e.g., types 309, 310, and 330). Copper and nickel can be added to improve resistance to reducing acids, such as sulfuric acid (type 320). Some of the more corrosion-resistant alloys, such as N08020 (20Cb-3) have nickel contents high enough (32 to 37%) to rate UNS classification as nickel-base alloys. Alloys containing nickel, molybdenum (~6%), and nitrogen (0.15 to 0.25%) are sometimes referred to as "superaustenitics," as shown in Fig. 1. These alloys were developed for improved resistance to chloride corrosion.

## Duplex Stainless Steels

**Characteristics and Compositions.** Duplex stainless steels are two-phase alloys based on the Fe-Cr-Ni system. These materials typically comprise approximately equal proportions of ferrite and austenite phases in their microstructure and are characterized by their low carbon contents (<0.03%) and additions of molybdenum, nitrogen, tungsten, and copper. Typical chromium and nickel contents are 20 to 30% and 5 to 8%, respectively. Table 4 gives compositions of duplex stainless steels. The specific advantages offered by duplex stainless steels over conventional 300 series stainless steels are strength (approximately twice that of austenitic stainless steels), improved toughness and ductility (compared to ferritic grades), and superior chloride SCC resistance and pitting resistance.

**Table 4 Chemical compositions of duplex stainless steels**

(a) Certain UNS numbers for duplex grades have been replaced. For example, S32950/39295 means that the original UNS No. (S32950) has been replaced by S39295.

(b) Not specified

**Properties and Applications.** Duplex stainless steels are capable of tensile yield strengths ranging from 550 to 690 MPa (80 to 100 ksi). The high yield strength offers designers the use of thin-wall material (which can lead to major reductions in weight) with adequate pressure-containing and load-bearing capacity. The high alloy content and the presence of a ferritic matrix render duplex stainless steels susceptible to embrittlement and loss of mechanical strength, particularly toughness, through prolonged exposure to elevated temperatures. For this reason, the upper temperature of application is generally less than 300 °C (570 °F).

As with all stainless steels, composition also plays a major role in the corrosion resistance of duplex stainless steels. Pitting corrosion resistance is most easily affected. To determine the extent of pitting corrosion resistance offered by the material, the pitting resistance equivalent (PRE) is commonly used. The PRE is calculated by adding the weight percentages of elements that affect pitting corrosion resistance--namely, chromium, molybdenum, and nitrogen--and then normalizing them with respect to the effect of 1% Cr. The most commonly used formula for pitting resistance equivalent is:

$$\text{PRE} = \% \text{Cr} + 3.3(\% \text{Mo}) + 16(\% \text{N}) \quad (\text{Eq 1})$$

As indicated in the following table, the PRE values for duplex stainless steels range from approximately 24 for grades containing no molybdenum to greater than 40 for the more highly alloyed (Fe-25Cr-7Ni-3.5Mo-0.25N-W-Cu) grades:

UNS number	PRE range
<b>S31200</b>	30.2-35.8
<b>S31260</b>	33.9-42.4
<b>S31500</b>	27.1-30.5
<b>S31803</b>	30.5-37.8
<b>S32304</b>	22.5-29.7
<b>S32550</b>	35.2-43.9
<b>S32750</b>	37.7-47.6
<b>S32760</b>	40(min)
<b>S32900</b>	26.3-34.6

Duplex stainless steels have found widespread use in a range of industries, particularly the oil and gas, petrochemical, and pulp and paper industries. They are commonly used in aqueous, chloride-containing environments and as replacements for austenitic stainless steels that have suffered from either chloride SCC or pitting during service.

### ***Precipitation-Hardening Stainless Steels***

**Characteristics and Compositions.** Precipitation-hardenable (PH) stainless steels are chromium-nickel grades that can be hardened by an aging treatment. These grades are classified as austenitic (e.g., A-286), semiaustenitic (e.g., 17-7PH), or martensitic (e.g., 17-4PH). The classification is determined by their solution-annealed microstructure. The semiaustenitic alloys are subsequently heat treated so that the austenite transforms to martensite. Cold work is sometimes used to facilitate the aging reaction. Various alloying elements, such as aluminum, titanium, niobium, or copper, are used to achieve aging. Table 5 lists compositions of PH stainless steels.

(a) Single values are maximum values unless otherwise indicated.

(b) Typical values

**Properties and Applications.** Like the hardenable 400 series martensitic stainless steels, PH alloys can attain high tensile yield strengths, up to 1700 MPa (250 ksi). Cold working prior to aging can result in even higher strengths. The PH grades generally have good ductility and toughness with moderate-to-good corrosion resistance. A better combination of strength and corrosion resistance is achieved than with the 400 series martensitic alloys. These improved properties are related to their higher chromium, nickel, and molybdenum contents, as well as their restricted carbon (0.040 max) levels. The low carbon content of the martensitic PH stainless steels is especially critical for toughness and good ductility. Because of their high strengths, most of the applications for PH stainless steels are in the aerospace and other high-technology industries.

### Physical and Mechanical Properties of Stainless Steels

**The physical properties** of stainless steels are quite different from those of commonly used nonferrous alloys such as aluminum and copper alloys. However, when comparing the various stainless families with carbon steels, many similarities in properties exist, although there are some key differences. Like carbon steels, the density of stainless steels is  $\sim 8.0 \text{ g/cm}^3$ , which is approximately three times greater than that of aluminum alloys ( $2.7 \text{ g/cm}^3$ ). Like carbon steels, stainless steels have a high modulus of elasticity (200 MPa, or 30 ksi) that is nearly twice that of copper alloys (115 MPa, or 17 ksi) and nearly three times that of aluminum alloys (70 MPa, or 10 ksi).

Differences among these materials are evident in thermal conductivity, thermal expansion, and electrical resistivity, as well. Figure 3 shows the large variation in thermal conductivity between various types of materials; 6061 aluminum alloy (Al-1Mg-0.6Si-0.3Cu-0.2Cr) has a very high thermal conductivity, followed by aluminum bronze (Cu-5Al), 1080 carbon steel, and then stainless steels. For stainless steels, alloying additions, especially nickel, copper, and chromium, greatly decrease thermal conductivity.

**Fig. 3 Comparison of thermal conductivity for carbon steel, copper alloy, aluminum, and stainless steels**

Thermal expansion (Fig. 4) is greatest for type 6061 aluminum alloy, followed by aluminum bronze and austenitic stainless alloys, and then ferritic and martensitic alloys. For austenitic stainless alloys, additions of nickel and copper can decrease thermal expansion. Stainless steels have high electrical resistivity (Fig. 5). Alloying additions tend to increase electrical resistivity. Therefore, the ferritic and martensitic stainless steels have lower electrical resistivity than the austenitic, duplex, and PH alloys, but higher electrical resistivity than 1080 carbon steel. Electrical resistivity of stainless steels is  $\sim 7.5$  times greater than aluminum bronze and nearly 20 times greater than type 6061 aluminum alloy.

Fig. 4 Comparison of thermal expansion for carbon steel, copper alloy, aluminum, and stainless steels

Fig. 5 Comparison of electrical resistivity for carbon steel, copper alloy, aluminum, and stainless steels

**Mechanical Properties.** Tables 6 and 7 list tensile properties and toughness for selected stainless alloys representing the five families. The grades listed under austenitic alloys have relatively low yield strength, compared with the heat-treatable alloys, but have the highest tensile ductility and toughness. The ferritic stainless steels (type 405 and 409) listed have tensile yield strengths similar to those of the austenitic grades but lower values for ultimate tensile strength, ductility, and toughness. The duplex stainless steels have twice the tensile yield strength of the austenitic and ferritic grades and approximately half the toughness. Again, their toughness is far superior to that of alloys that are heat treated and hardened.

Table 6 Minimum room-temperature mechanical properties for selected stainless steels

The martensitic alloys listed in Tables 6 and 7 have a large variation in strength, ductility, and toughness. In the annealed condition, their properties are similar to those of the ferritic alloys, with strength increasing and ductility decreasing with increasing carbon content. The higher carbon-containing alloys, type 420 and type 440C, are generally tempered at a low temperature (330 °C, or 625 °F max) to maximize their strength. Conversely, type 410 is tempered over a wide temperature range, from 260 to 650 °C (500 to 1200 °F).

The PH alloys, such as the martensitic grades S45500 and S17400, have higher annealed strength and lower ductility than the 400 series martensitic alloys and are aged at temperatures ranging from 480 to 620 °C (895 to 1150 °F). Their strength

is dependent on the hardener (titanium, niobium, and copper), the amount of hardener, and the aging temperatures used. Toughness is either similar or superior to the 400 series martensitic alloys at a given strength level.

## Factors in Selection

The selection of stainless steels can be based on corrosion resistance, fabrication characteristics, availability, mechanical properties in specific temperature ranges, and product cost. However, corrosion resistance and mechanical properties are usually the most important factors in selecting a grade for a given application.

Characteristics to be considered in selecting the proper type of stainless steel for a specific application include:

- Corrosion resistance
- Resistance to oxidation and sulfidation
- Strength and ductility at ambient and service temperatures
- Suitability for intended fabrication techniques
- Suitability for intended cleaning procedures
- Stability of properties in service
- Toughness
- Resistance to abrasion, erosion, galling, and seizing
- Surface finish and/or reflectivity
- Physical property characteristics, such as magnetic properties, thermal conductivity, and electrical resistivity
- Sharpness, or retention of cutting edge
- Rigidity
- Dimensional stability

**Corrosion resistance** is frequently the most important characteristic of a stainless steel but often is also the most difficult to assess for a specific application. General corrosion resistance to pure chemical solutions is comparatively easy to determine, but actual environments are usually much more complex.

General corrosion is often much less serious than localized forms such as SCC, crevice corrosion in tight spaces or under deposits, pitting attack, and intergranular attack in sensitized material such as weld heat-affected zones. Such localized corrosion can cause unexpected and sometimes catastrophic failure while most of the structure remains unaffected, and therefore it must be considered carefully in the design and selection of the proper grade of stainless steel. Corrosive attack can also be increased dramatically by seemingly minor impurities in the medium that may be difficult to anticipate but that can have major effects, even when present in only parts-per-million concentrations: heat transfer through the steel to or from the corrosive medium, contact with dissimilar metallic materials, stray electrical currents, and many other subtle factors. At elevated temperatures, attack can be accelerated significantly by seemingly minor changes in atmosphere that affect scaling, sulfidation, or carburization.

Despite these complications, a suitable steel can be selected for most applications on the basis of experience, perhaps with assistance from the steel producer. Laboratory corrosion data can be misleading in predicting service performance. Even actual service data have limitations, because similar corrosive media may differ substantially because of slight variations in some of the corrosion conditions listed previously. For difficult applications, extensive study of comparative data may be necessary, sometimes followed by pilot plant or in-service testing. Other important factors that must be considered when selecting a stainless steel for a corrosion application include:

- Chemical composition of the corrosive medium, including impurities
- Physical state of the medium: liquid, gaseous, solid, or combinations thereof
- Temperature
- Temperature variations
- Aeration of the medium

- Oxygen content of the medium
- Bacteria content of the medium
- Ionization of the medium
- Repeated formation and collapse of bubbles in the medium
- Relative motion of the medium with respect to the steel
- Chemical composition of the metal
- Nature and distribution of microstructural constituents
- Continuity of exposure of the metal to the medium
- Surface condition of the metal
- Stresses in the metal during exposure to the medium
- Contact of the metal with one or more dissimilar metallic materials
- Stray electrical currents
- Differences in electric potential
- Marine growth such as barnacles
- Sludge deposits on the metal
- Carbon deposits from heated organic compounds
- Dust on exposed surfaces
- Effects of welding, brazing, and soldering

More detailed information on selection of stainless steels for use in various corrosive environments can be found in the article "Corrosion of Wrought Stainless Steels" in this Section.

**Mechanical properties** at service temperature are obviously important, but satisfactory performance at other temperatures must also be considered. Thus, a product for arctic service must have suitable properties at subzero temperatures even though steady-state operating temperatures may be much higher; room-temperature properties after extended service at elevated temperature can be important for applications such as boilers and jet engines, which are intermittently shut down.

**Wear and Galling Resistance.** Stainless steels are characterized as having relatively poor wear and galling resistance, but they are often required for a particular application because of their corrosion resistance. Therefore, finding the most effective alloy to withstand wear and galling can be a difficult problem for design engineers. Lubricants and coatings are often used to reduce wear, although lubricant use is precluded in many applications, such as high-temperature environments, in which they can break down, or food and pharmaceutical processing equipment, which require sanitation. Additionally, a critical part, such as a valve in a power plant, must resist galling or seizing, because it can shut down or endanger the entire plant. Tables 8 and 9 present a comparison of wear compatibility and galling resistance of selected stainless steels.

**Table 8 Wear compatibility of dissimilar-mated stainless steels**

Alloy	Volume loss, mm <sup>3</sup>

**Fabrication and Cleaning.** Frequently a particular stainless steel is chosen for a fabrication characteristic such as machinability, formability, or weldability. Even a required or preferred cleaning procedure can dictate the selection of a specific type. For instance, a weldment that is to be cleaned in a medium such as nitric-hydrofluoric acid, which attacks sensitized stainless steel, should be produced from stabilized or low-carbon stainless steel even though sensitization may not affect performance under service conditions.

**Surface Finish.** Other characteristics in the stainless steel selection checklist are vital for some specialized applications but are of little concern for others. Among these characteristics, surface finish is important more often than any other except corrosion resistance. Stainless steels are sometimes selected because they are available in a variety of attractive finishes. Surface finish selection can be made on the basis of appearance, frictional characteristics, or sanitation. The effect of finish on sanitation sometimes is thought to be simpler than it actually is, and tests of several candidate finishes may be advisable. The selection of finish can in turn influence the selection of the alloy because of differences in availability or durability of the various finishes for different types.

## Product Forms

**Plate** is a flat-rolled or forged product more than 254 mm (10 in.) in width and at least 4.76 mm (0.1875 in.) in thickness. Stainless steel plate generally is produced in the annealed condition and is either blast cleaned or pickled. Blast cleaning generally is followed by further cleaning in appropriate acids to remove surface contaminants such as particles of steel picked up from the mill rolls.

**Sheet** is a flat-rolled product in coils or cut lengths at least 610 mm (24 in.) wide and less than 4.76 mm (0.1875 in.) thick. Stainless steel sheet is produced in nearly all types except the free-machining and certain martensitic grades.

**Strip** is a flat-rolled product, in coils or cut lengths, less than 610 mm (24 in.) wide and 0.13 to 4.76 mm (0.005 to 0.1875 in.) thick. Cold finished material 0.13 mm (0.005 in.) thick and less than 610 mm (24 in.) wide fits the definitions of both strip and foil and can be referred to using either term.

Cold rolled stainless steel strip is manufactured from hot rolled, annealed, and pickled strip (or from slit sheet) by rolling between polished rolls. Depending on desired thickness, various numbers of cold rolling passes through the mill are required for effecting the necessary reduction and for securing the desired surface characteristics and mechanical properties.

Hot rolled stainless steel strip is a semifinished product obtained by hot rolling slabs or billets and is produced for conversion to finished strip by cold rolling.

**Foil** is a flat-rolled product, in coil form, up to 0.13 mm (0.005 in.) thick and less than 610 mm (24 in.) wide. Foil is produced in slit widths with edge conditions corresponding to No. 3 (as-slit) and No. 5 (square edge produced by rolling or filing after slitting) edge conditions for strip.

**Bar** is a product supplied in straight lengths; it is either hot or cold finished and is available in various shapes, sizes, and surface finishes. This category includes small shapes, whose dimensions do not exceed 127 mm (5 in.), and hot-rolled flat stock at least 3.2 mm (0.125 in.) thick and up to 254 mm (10 in.) wide.

Hot finished bar commonly is produced by hot rolling, forging, or pressing ingots to blooms or billets of intermediate size, which are subsequently hot rolled, forged, or extruded to final dimensions. Whether rolling, forging, or extrusion is selected as the finishing method depends on several factors, including composition and final size.

Cold-finished bar is produced from hot-finished bar or rod by additional operations such as cold rolling or cold drawing, which result in the close control of dimensions, a smooth surface finish, and higher tensile and yield strengths. Sizes and shapes of cold-reduced stock classified as bar are essentially the same as for hot-finished bar, except that all cold-reduced flat stock less than 4.76 mm (0.1875 in.) thick and over 9.5 mm (0.375 in.) wide is classified as strip.

**Wire** is a coiled product derived by cold finishing hot rolled and annealed rod. Cold finishing imparts excellent dimensional accuracy, good surface smoothness, fine finish, and specific mechanical properties. Wire is produced in several tempers and finishes.

Wire is customarily referred to as round wire when the contour is completely cylindrical and as shape wire when the contour is other than cylindrical. Shape wire is cold finished either by drawing or by a combination of drawing and rolling.

**Special Wire Commodities.** There are many classes of stainless steel wire that have been developed for specific components or for particular applications. The unique properties of each of these individual wire commodities are developed by employing a particular combination of composition, steel quality, process heat treatment, and cold-drawing practice.

**Cold heading wire** is produced in any of the various types of stainless steel. In all instances, cold heading wire is subjected to special testing and inspection to ensure satisfactory performance in cold heading and cold forging operations.

Of the chromium-nickel group, types 305 and 302Cu are used for cold heading wire and generally are necessary for severe upsetting. Other grades commonly cold formed include 303Se, 304, 316, 321, 347, 384, 410, 420, 430, and 431.

**Spring wire** is drawn from annealed rod. The types of stainless steel in which spring wire is commonly produced include 302, 304, 316, and 20Cb-3 (N08020).

Spring wire in large sizes can be furnished in a variety of finishes such as dry-drawn lead, copper, lime and soap, or oxide and soap. Fine sizes usually are wet drawn, although they can be dry drawn.

**Rope wire** is used to make rope, cable, and cord for a variety of uses such as aircraft control cables, marine ropes, elevator cables, slings, and anchor cables.

Rope wire is made of type 302 or 304 unless a higher level of corrosion resistance is required, in which case type 316 is generally selected. Special nonmagnetic characteristics may be required, which necessitates selection of heats having little or no ferrite or martensite in the microstructure and use of special drawing practices to limit or avoid deformation-induced transformation to martensite.

**Weaving wire** is used in weaving of screens for many different applications in coal mines, sand-and-gravel pits, paper mills, chemical plants, dairy plants, oil refineries, and food-processing plants. Annealing and final drawing must be carefully controlled to maintain uniform temper and finish throughout each coil or spool. Because weaving wire must be ductile, it usually is furnished in the annealed temper with a bright annealed finish or in the soft temper with either a lime-soap finish or an oil- or grease-drawn finish. Most types of stainless steels are available as weaving wire.

**Stainless welding wire** is available for many grades to provide good weldability with optimized mechanical properties and corrosion resistance of the weldment. Stainless steel weld wire is produced in layer-level wound spools, straight lengths (both included in the American Welding Society AWS A5.9), and coated electrodes (AWS A5.4).

**Semifinished Products.** Blooms, billets, and slabs are hot rolled, hot forged, or hot pressed to approximate cross-sectional dimensions and generally have rounded corners. Round billets are also produced, typically for extrusion or closed-die forging. These semifinished products, as well as tube rounds, are produced in random lengths or are cut to specified lengths or to specified weights. There are no invariable criteria for distinguishing between the terms bloom and billet, and often they are used interchangeably.

The nominal cross-sectional dimensions of blooms, billets, and slabs are designated in inches and fractions of an inch. The size ranges commonly listed as hot-rolled stainless steel blooms, billets, and slabs include square sections  $100 \times 100$  mm ( $4 \times 4$  in.) and larger, and rectangular sections at least  $10,300 \text{ mm}^2$  ( $16 \text{ in.}^2$ ) in cross-sectional area.

**Pipe, tubes, and tubing** are made either by piercing rounds or by rolling and welding strip. They are used for conveying gases, liquids, and solids and for diverse mechanical and structural purposes. (Cylindrical forms intended for use as containers for storage and shipping purposes, and products cast to tubular shape, are not included in this category.)

Pipe is distinguished from tubes chiefly by the fact that it is commonly produced in relatively few standard sizes. Tubing is generally made to more exacting specifications regarding dimensions, finish, chemical composition, and mechanical properties than either pipe or tubes.

Stainless steel tubular products are classified as follows according to intended service:

- Stainless steel tubing for general corrosion-resistant service
- Stainless steel pressure pipe
- Seamless steel pressure tubes
- Stainless steel sanitary tubing
- Stainless steel mechanical tubing
- Stainless steel aircraft tubing
- Aircraft structural tubing
- Aircraft hydraulic-line tubing

### Notch Toughness and Transition Temperature

Notched-bar impact testing of stainless steels is likely to show a wide scatter in test results, regardless of type or test conditions. Because of this wide scatter, only general behavior of the different classes can be described.

Austenitic types have good notched-bar impact resistance. Charpy impact energies of 150 J (110 ft · lbf) or greater are typical of all austenitic types at room temperature (Table 7). Cryogenic temperatures have little or no effect on notch toughness; ordinarily, austenitic stainless steels maintain values exceeding 130 J (95 ft · lbf), even at very low temperatures (Table 10). Conversely, cold work lowers the resistance to impact at all temperatures.

**Table 10 Typical cryogenic properties of selected annealed austenitic stainless steels**

Alloy	Temperature		0.2% yield strength		Ultimate tensile strength		Elongation in 4D, %	Reduction of area, %	Charpy V-notch strength	
	°C	°F	MPa	ksi	MPa	ksi			J	ft · lbf

-196	-320	1000	145	1641	238	16	30	38	28

Martensitic and ferritic stainless steels exhibit a decreasing resistance to impact with decreasing temperature, and the fracture appearance changes from a ductile mode at mildly elevated temperatures to a brittle mode at low temperatures. This fracture transition is characteristic of martensitic and ferritic materials. Both the upper-shelf energy and the lower-shelf energy are not greatly influenced by heat treatment in these stainless steels. However, the temperature range over which transition occurs is affected by heat treatment, minor variations in composition, and cold work. Heat treatments that result in high hardness move the transition range to higher temperatures, and those that result in low hardness move the transition range to lower temperatures.

### Fracture Toughness

Fracture toughness data are not available for many of the standard types of stainless steels. Most of the testing has been concentrated on the high-strength martensitic PH stainless steels because these materials have been used in critical applications where fracture-toughness testing has been found most useful for evaluating materials. Although  $K_{Ic}$  values are dependent on the testing conditions, specimen orientation, and condition (heat treatment) of the material, studies have shown that average  $K_{Ic}$  values for martensitic PH steels range from approximately  $50 \text{ MPa}\sqrt{\text{m}}$  ( $45 \text{ ksi}\sqrt{\text{in.}}$ ) to  $120 \text{ MPa}\sqrt{\text{m}}$  ( $110 \text{ ksi}\sqrt{\text{in.}}$ ).

Fracture toughness data for austenitic stainless steels are limited because of the high ductility and high toughness of these grades. The fracture toughness data that are available were obtained by the  $J$ -integral method ( $J_c$  initial toughness values) and are given in units of  $\text{kJ/m}^2$ . Extensive fracture toughness testing of types 304 and 316 stainless steels shows that they are extremely resistant to fracture. Both types exhibit a ductile fracture response under a wide variety of conditions, but  $J_c$  values are highly variable, typically ranging from 169 to 1660  $\text{kJ/m}^2$  at room temperature and from 130 to 1420  $\text{kJ/m}^2$  at approximately 400 °C (750 °F).

### Fatigue Properties

**Fatigue crack initiation** tests are procedures in which a specimen or part is subjected to cyclic loading to failure. A large portion of the total number of cycles in these tests is spent initiating the crack. Although crack initiation tests conducted on small specimens do not precisely establish the fatigue life of a large part, such tests do provide data on the intrinsic fatigue crack initiation behavior of a stainless steel. As a result, such data can be used to develop criteria to prevent fatigue failures in engineering design. Examples of the use of small-specimen fatigue test data can be found in the basis of the fatigue design codes for boilers and pressure vessels, complex welded, riveted, or bolted structures, and automotive and aerospace components. Factors influencing the fatigue life of stainless steels include temperature, specimen orientation (e.g., longitudinal versus transverse), heat treatment (e.g., annealed versus quench hardened), hardness, and surface condition (Fig. 6).

Fig. 6 Factors affecting fatigue properties of stainless steels

Three types of fatigue tests are used to develop data on fatigue behavior of stainless steels. The most common of these tests is the rotating-beam test, which most closely approximates the kind of loading to which shafts and axles are subjected. The flexural fatigue test is used to evaluate the behavior of sheet and most closely simulates the action of leaf springs, which are expected to flex without deforming or breaking. The axial-load fatigue test subjects a fatigue specimen to unidirectional loading that can range from full reversal (tension-compression) to tension-tension loading, and can have virtually any conceivable ratio of maximum stress to minimum stress. In general, fatigue conditions involving tension-compression loading (stress ratio,  $R$ , between 0 and -1) lead to shorter fatigue lives than conditions involving tension-tension loading (stress ratio,  $R$ , between 0 and +1) at the same value of maximum stress.

**Fatigue crack growth (FCG)** rates of austenitic stainless steels have been extensively studied, given their widespread use in high-temperature structural parts with cyclic stressing over a wide range of frequencies, temperatures, environments, and load ratios. Results of FCG tests have been analyzed on the basis of fracture mechanics concepts, leading to a well-documented collection of fatigue crack growth rate data for the austenitic stainless steels--particularly types 304 and 316. Data are also available on duplex grades; martensitic grades; and martensitic, semi-austenitic, and austenitic PH stainless steels. Figure 7 shows the effects of condition (annealed versus cold worked) and temperature on the FCG rates of type 304 stainless steel. This figure shows that the high- $\Delta K$  crack growth rates were lower for the cold-worked specimens than for the annealed specimens. Crack growth rates were higher for the specimens tested at 427 °C (800 °F) than for corresponding specimens tested at room temperature.

Fig. 7 Fatigue crack growth rates for annealed and cold worked type 304 stainless steel at 25 and 427 °C (77 and 800 °F), 0.17 Hz, and an  $R$  ratio of 0

## Elevated-Temperature Mechanical Properties

Many stainless steels--particularly the austenitic types 304, 309, 310, 316, 321, 330, and 347; certain precipitation-hardening types such as PH 15-7 Mo, 15-5 PH, 17-4 PH, 17-7 PH, AM-350 and AM-355; and certain martensitic types such as the so-called "Super 12 Chrome" steels that contain molybdenum (up to 3%), tungsten (up to 3.5%), and/or vanadium--are used extensively for elevated-temperature applications. As shown in Fig. 8, the austenitic types retain their strength at higher temperatures (up to 815 °C, or 1500 °F) than do the other types of stainless steels. For the best creep strength and creep-rupture strength, the H grades of austenitic stainless steels are specified. These steels have carbon contents of 0.04 to 0.10% (Table 3) and are solution annealed at temperatures high enough to produce improved creep properties.

**Fig. 8** General comparison of the hot-strength characteristics of austenitic, martensitic, and ferritic stainless steels with those of low-carbon unalloyed steel and semiaustenitic precipitation- and transformation-hardening steels

Valve steels are austenitic nitrogen-strengthened steels that have been used extensively in automotive/internal combustion engine valve applications. Examples of such alloys include 21-2N (21Cr, 8Mn, 2Ni + N), 21-4N (21Cr, 9Mn, 4Ni + N), 21-12N (21Cr, 12Ni, 1.25Mn + N), and 23-8N (21Cr, 8Ni, 3.5Mn + N) (see Table 3). The nitrogen contents in these alloys range from 0.20 to 0.50%. These engine valve grades are used at temperatures up to 760 °C (1400 °F), but they provide fairly low strength at the upper end of their temperature capability.

As described in the section "Thermally Induced Embrittlement," extended service at elevated temperature can result in embrittlement (sensitization) of austenitic stainless steels, which degrades the ability of the material to withstand corrosion and induces embrittlement. Most often, such degradation is caused by the precipitation of secondary phases such as carbides and sigma phase. Precipitation depends on both time and temperature: longer times at temperature and higher temperatures both promote more extensive precipitation.

## Thermally Induced Embrittlement

Stainless steels are susceptible to embrittlement during thermal treatment or elevated-temperature service. These thermally induced forms of embrittlement of stainless steels include sensitization, 475 °C (885 °F) embrittlement, and  $\sigma$ -phase embrittlement.

### *Sensitization*

Stainless steels become susceptible to localized intergranular corrosion when chromium carbides form at the grain boundaries during high-temperature exposure. This depletion of chromium at the grain boundaries is termed "sensitization" because the alloys become more sensitive to localized attack in corrosive environments.

**Austenitic Stainless Steels.** At temperatures above approximately 1035 °C (1900 °F), chromium carbides are completely dissolved in austenitic stainless steels. However, when these steels are slowly cooled from these high temperatures or reheated into the range of 425 to 815 °C (800 to 1500 °F), chromium carbides are precipitated at the grain boundaries. These carbides contain more chromium than the matrix contains.

The precipitation of the carbides depletes the matrix of chromium adjacent to the grain boundary. The diffusion rate of chromium in austenite is slow at the precipitation temperatures; therefore, the depleted zone persists, and the alloy is sensitized to intergranular corrosion. This sensitization occurs because the depleted zones have higher corrosion rates than the matrix in many environments. Loss of toughness also results from sensitization.

If the austenitic stainless steels are cooled rapidly to below approximately 425 °C (800 °F), the carbides do not precipitate, and the steels are immune to intergranular corrosion. Reheating the alloys to 425 to 815 °C (800 to 1500 °F), as for stress relief, will cause carbide precipitation and sensitivity to intergranular corrosion. The maximum rate of carbide precipitation occurs at approximately 675 °C (1250 °F). Because this is a common temperature for the stress relief of carbon and low-alloy steels, care must be exercised in selecting stainless steels to be used in dissimilar-metal joints that are to be stress relieved.

Welding is the common cause of the sensitization of stainless steels to intergranular corrosion. Although the cooling rates in the weld itself and the base metal immediately adjacent to it are sufficiently high to avoid carbide precipitation, the weld thermal cycle will bring part of the heat-affected zone (HAZ) into the precipitation range. Carbides will precipitate, and a zone somewhat removed from the weld will become susceptible to intergranular corrosion. Welding does not always sensitize austenitic stainless steels. In thin sections, the thermal cycle may be such that no part of the HAZ is at sensitizing temperatures long enough to cause carbide precipitation. Once the precipitation has occurred, it can be removed by reheating the alloy to above 1035 °C (1895 °F) and cooling it rapidly.

Susceptibility to intergranular corrosion in austenitic stainless steels can be avoided by controlling their carbon contents or by adding elements whose carbides are more stable than those of chromium. For most austenitic stainless steels, restricting their carbon contents to 0.03% or less will prevent sensitization during welding and most heat treatment. This

method is not effective for eliminating sensitization that would result from long-term service exposure at 425 to 815 °C (800 to 1500 °F).

Titanium and niobium form more stable carbides than chromium and are added to stainless steels to form these stable carbides, which remove carbon from solid solution and prevent precipitation of chromium carbides. The most common of these stabilized grades are types 321 and 347. Type 321 contains a minimum of  $[5 \times (C + N)]\%$  titanium, and type 347 contains a minimum of  $(8 \times C)\%$  niobium. Nitrogen must be considered when titanium is used as a stabilizer, not because the precipitation of chromium nitride is a problem in austenitic steels, but because titanium nitride is very stable. Titanium will combine with any available nitrogen; therefore, this reaction must be considered when determining the total amount of titanium required to combine with the carbon.

The stabilized grades are more resistant to sensitization by long-term exposure at 425 to 815 °C (800 to 1500 °F) than the low-carbon grades, and the stabilized grades are the preferred materials when service involves exposure at these temperatures. For maximum resistance to intergranular corrosion, these grades are given a stabilizing heat treatment at approximately 900 °C (1650 °F). The purpose of the treatment is to remove carbon from solution at temperatures where titanium and niobium carbides are stable, but chromium carbides are not. Such treatments prevent the formation of chromium carbide when the steel is exposed to lower temperatures.

**Ferritic Stainless Steels.** The mechanism for intergranular corrosion in ferritic stainless steels is largely accepted as being the same as that in austenitic stainless steels. Chromium compounds precipitate at grain boundaries, and this causes chromium depletion in the grains immediately adjacent to the boundaries. This lowering of the chromium content leads to increased corrosion rates in the oxidizing solutions usually used to evaluate intergranular corrosion.

There are several differences between the sensitization of ferritic and austenitic stainless steels to intergranular corrosion. The first is that the solubility of nitrogen in austenite is great enough that chromium nitride precipitation is not a significant cause of intergranular corrosion in austenitic steels. It is, however, a significant cause in ferritic stainless steels. The second is the temperature at which it occurs. Sensitization in austenitic steels is produced by heating between 425 and 815 °C (800 and 1500 °F). In conventional ferritic alloys, sensitization is caused by heating above 925 °C (1700 °F). This difference is the result of the relative solubilities of carbon and nitrogen in ferrite and austenite.

The most straightforward method of preventing intergranular attack in ferritic stainless steels is to restrict their carbon and nitrogen interstitial contents. For example, more recently developed third-generation ferritic alloys such as 26Cr-1Mo and 29Cr-4Mo (Table 2) have low interstitial contents of 20 ppm C and 100 ppm N. Stabilized grades also help prevent sensitization. Both titanium- and niobium-stabilized steels can be used, and each has advantages. In general, weld ductility is somewhat better in the titanium-containing alloys, but the toughness of the niobium steels is better. However, titanium-stabilized alloys are not recommended for service in nitric acid, but the niobium-containing steels can be used in this environment.

**Duplex stainless steels** with low carbon contents (0.03%) and approximately equal amounts of austenite and ferrite have very good resistance to sensitization.

### ***475 °C Embrittlement***

Iron-chromium alloys containing 13 to 90% Cr are susceptible to embrittlement when held within or cooled slowly through the temperature range of 550 to 400 °C (1020 to 750 °F). This phenomenon, called 475 °C (885 °F) embrittlement, increases tensile strength and hardness and decreases tensile ductility, impact strength, electrical resistivity, and corrosion resistance.

475 °C embrittlement occurs with iron-chromium ferritic and duplex ferritic-austenitic stainless steels, but not with austenitic grades. Aging at 475 °C (885 °F) can cause a rapid rate of hardening with aging between about 20 and 120 h because of homogeneous precipitation. The rate of hardening is much slower with continued aging from 120 to 1000 h. During this aging period, precipitation increases. Aging beyond 1000 h produces little increase in hardness because of the stability of the precipitates.

Even for a severely embrittled alloy, 475 °C embrittlement is reversible. Properties can be restored within minutes by reheating the alloy to 675 °C (1250 °F) or above. The degree of embrittlement increases with chromium content; however, embrittlement is negligible below 13% Cr. Carbide-forming alloying additions, such as molybdenum, vanadium, titanium, and niobium, appear to increase embrittlement, particularly with higher chromium levels. Increased

levels of carbon and nitrogen also enhance embrittlement and, of course, are detrimental to nonembrittled properties as well. Cold work prior to 475 °C (885 °F) exposure accelerates embrittlement, particularly for higher-chromium alloys.

### ***Sigma-Phase Embrittlement***

The formation of  $\sigma$  phase in ferritic, austenitic, and duplex stainless steels during long periods of exposure to temperatures between approximately 560 and 980 °C (1050 and 1800 °F) results in considerable embrittlement after cooling to room temperature. Sigma phase, an iron-chromium compound approximately equivalent to FeCr, has a tetragonal crystal structure and a hardness equivalent to approximately 68 HRC (940 HV). Because of its brittleness,  $\sigma$  often fractures during indentation.

Sigma phase is formed by either (a) slow cooling from temperatures of 1040 to 1150 °C (1900 to 2100 °F) or (b) water quenching from 1040 to 1150 °C followed by heating at 560 to 980 °C, with heating at 850 °C (1560 °F) producing the greatest effect. The embrittlement is most detrimental after the steel has cooled to temperatures below 260 °C (500 °F). At higher temperatures, stainless steels containing  $\sigma$  phase usually can withstand normal design stresses. However, cooling to 260 °C or below results in essentially complete loss of toughness.

The presence of  $\sigma$  phase greatly increases notch sensitivity, particularly in ferritic stainless steels and austenitic alloys that also contain some ferrite. The hardness and tensile strengths are usually not significantly affected by the presence of  $\sigma$  phase, but the impact strength is greatly affected. Sigma phase exerts a strengthening effect at high temperatures; however, the impact strength at high temperatures of an alloy containing  $\sigma$  phase is lower than the impact strength at room temperature of an alloy without  $\sigma$  phase.

In commercial austenitic and ferritic stainless steels, even small amounts of silicon markedly accelerate the formation of  $\sigma$ . In general, all of the elements that stabilize ferrite promote  $\sigma$  formation. Molybdenum has an effect similar to that of silicon; aluminum has a lesser influence. Increasing the chromium content also favors  $\sigma$  formation. Small amounts of nickel and manganese increase the rate of  $\sigma$  formation, but large amounts, which stabilize austenite, retard  $\sigma$  formation. Carbon additions decrease  $\sigma$  formation by forming chromium carbides, thereby reducing the amount of chromium in solid solution. Additions of tungsten, vanadium, titanium, and niobium also promote  $\sigma$  formation.

As might be expected,  $\sigma$  forms more readily in ferritic than in austenitic stainless steels. Coarse grain sizes from high solution-annealing temperatures retard  $\sigma$  formation, and prior cold working enhances it. The influence of cold work on  $\sigma$  formation depends on the amount of cold work and its effect on recrystallization. If the amount of cold work is sufficient to produce recrystallization at the service temperature,  $\sigma$  formation is enhanced. If recrystallization does not occur, the rate of  $\sigma$  formation may not be affected. Small amounts of cold work that do not promote recrystallization may actually retard  $\sigma$  formation.

Duplex alloys are usually high in chromium (25 to 27%) and molybdenum (2 to 4%). As a result, these alloys are prone to the formation of intermetallic phases such as  $\sigma$  and chi ( $\chi$ ) if they are not cooled rapidly through the 900 to 700 °C (1650 to 1290 °F) range. Although these intermetallic compounds do affect the corrosion resistance of the alloys, they have a more drastic effect on mechanical properties. If a duplex alloy has satisfactory mechanical properties, it probably will not experience intergranular corrosion.

# Fabrication of Wrought Stainless Steels

## Introduction

FABRICATION of wrought stainless steels differs from fabrication of carbon and low-alloy steels primarily because stainless steels (a) are stronger, harder, and more ductile; (b) work harden more readily; and (c) generally must present a corrosion-resistant surface in the finished product. These characteristics dictate use of greater power, more frequent repair or replacement of processing equipment, and application of procedures to minimize or correct surface contamination.

## Forming

The method chosen for forming stainless steel should be based on the characteristics of the type to be used and the thickness of the part to be formed. As indicated previously, power requirements are higher for forming stainless steels than for forming carbon steels—particularly austenitic types, which work harden more rapidly than ferritic types. Warm or hot forming can be necessary for thicknesses that can be formed cold in carbon steel.

Because of their high ductility, austenitic types are the most readily formed stainless steels: austenitic stainless steel sheet can be severely drawn. Austenitic types 201 and 301 can be formed with biaxial stretching in excess of 35% because partial transformation to martensite during deformation helps the metal resist necking and deform more uniformly. (For unusually severe forming, composition may have to be adjusted to suit the particular job, and slow forming may be necessary to prevent buildup of heat and loss of the martensite effect.) Ferritic and lower-alloy martensitic types also can be extensively cold formed. However, they are less ductile than austenitic types, and thus forming of these alloys is more limited, and intermediate annealing is more likely to be needed. The higher-carbon martensitic types such as 440A, 440B, and 440C have only limited cold formability. The higher strength of duplex stainless steels relative to their austenitic counterparts necessitates greater loads in cold-forming operations. Because elongation is less, they should be formed to more generous radii than fully austenitic materials. Heavily cold-formed (>15%) sections should be fully annealed and quenched whenever applications for the alloy present the possibility of stress-corrosion cracking in the service environment.

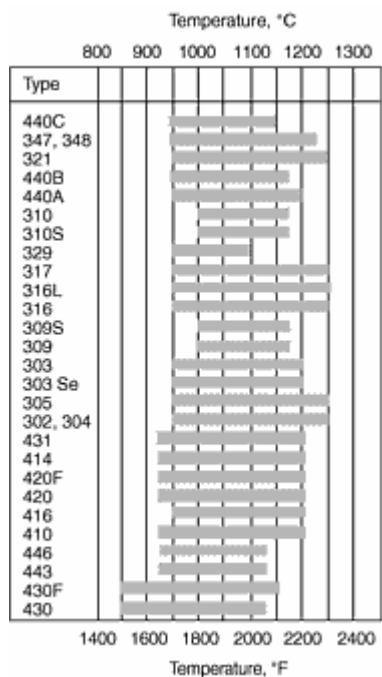

Stainless steels generally gall more readily than other steels and thus require more attention to lubrication during forming. Straight mineral oils rarely provide adequate lubrication where sliding contact occurs in forming, and lubricants with extreme-pressure additives are often used. Surface contamination during forming and handling should be kept to a minimum by thoroughly cleaning equipment and providing proper lubrication.

Cold formed stainless steel parts usually are used in the as-formed condition. However, for applications in which stress-corrosion cracking can occur, austenitic types susceptible to this failure process should be solution annealed after forming to remove residual stresses. Under all but the mildest service conditions, hot formed parts require postforming annealing to restore corrosion resistance and/or ductility.

## Forging

All standard types of stainless steel can be forged. However, as alloy content increases within a given group, forging becomes more difficult. Forging difficulties are most common in initial breakdown of high-alloy ingots, and precautions may be needed to avoid surface ruptures.

**Working Temperatures.** Figure 1 shows typical forging-temperature ranges for most standard stainless steels. A wide range of forging temperatures can be used for most of the common austenitic types because of the natural workability of austenite and the absence of allotropic transformation. The conventional 18-8 types often are forged at temperatures up to 1260 °C (2300 °F). However, the upper temperature limit is lower for the higher-alloy grades due to metallurgical changes at higher temperatures that can cause surface ruptures. Maximum temperature is lowest for types 309, 310, and 330. Adherence to maximum temperature limits is particularly important for ingot breakdown, where severe tearing along grain boundaries in the cast metal can occur if temperature is too high.

**Fig. 1** Typical forging temperature ranges for stainless steels. Alloys toward the top of the figure are more difficult to hot work; those toward the bottom are easier to hot work.

Small amounts of delta ferrite can impair the forgeability of some austenitic types--particularly in upset forging, where some of the tangential tensile forces are perpendicular to ferrite stringers. Types 304, 309, 316, 317, and 321 are especially likely to contain significant amounts of ferrite, and it may be advisable to limit ferrite content of these grades for severe forging applications. Ferrite can be particularly troublesome in initial ingot breakdown; a homogenization treatment at approximately 1150 °C (2100 °F), to transform some of the delta ferrite to austenite before heating to forging temperature, can be helpful.

Austenitic stainless steel forgings should be solution annealed to restore corrosion resistance and maximum ductility. For some applications, annealing can be omitted if working is finished above 870 °C (1600 °F) and the forging is rapidly cooled below 425 °C (800 °F), in order to prevent carbide precipitation. This approach should be used with caution and should incorporate metallurgical checks to determine that detrimental carbide precipitation has actually been avoided. The stabilized types (321, 347, and 348) and extra-low-carbon types (304L and 316L) will not precipitate carbides as readily,

and can be used in the as-forged condition with fewer precautions if maximum corrosion resistance and ductility are not essential.

The lower-carbon martensitic stainless steels can be hot worked over a wide temperature range. Finishing temperature is limited only by the allotropic transformation, which begins near 800 °C (1500 °F). The higher-carbon types (420 and 440) have a more limited forging-temperature range because of lower hot ductility. Because all martensitic types are highly hardenable, they require some type of heat treatment (generally annealing) after forging. Except for type 410, which can be used in the annealed condition, martensitic types should be further heat treated, if not for higher hardness then for best corrosion resistance, before being put into service.

Figure 1 shows a broad range of forging temperatures for the ferritic steels. Forging is completed at slightly lower temperatures than for austenitic types because the ferritic types tend to exhibit grain growth and structural weakness. Finishing temperatures are closely restricted only for types 405, 430, and 442. These alloys require special consideration because of grain-boundary weakness due to development of a small amount of austenite. The other ferritic types are commonly finished at temperatures as low as 700 °C (1300 °F). For fully ferritic types such as type 446, at least the final 10% reduction (and preferably more) should be performed below 870 °C (1600 °F) to achieve grain refinement and to develop optimum room-temperature ductility. Annealing after forging is recommended for ferritic types because most of them contain substantial amounts of brittle martensite in the as-forged condition even though this may not be apparent from hardness measurements.

## Cold Working

The cold working operations that can be successfully performed on most stainless steels include cold heading, cold drawing, cold extrusion, and cold riveting. Cold working of stainless steel is more difficult than cold working of carbon steel because of differences in strength and work hardening, and power requirements are proportionately greater.

**Cold Heading.** As a result of the wide differences in work-hardening capabilities among stainless steels, some types are much more adaptable than others to cold heading. The more commonly cold-headed grades include the austenitic types 302, 304, 305, 316, 321, and 384; the ferritic and martensitic types 410, 430, and 431 can also be cold headed. One of the most widely used cold-heading stainless steels is UNS S30430, which is identified by some cold-heading engineers as 302 HQ. It is similar in composition to type 304 except that it contains 3 to 4% Cu, which results in a significant reduction in cold-work hardening characteristics.

The surface finish of the part depends largely on the finish of the wire, which suggests the use of lightly drawn rather than annealed wire. Forming pressure increases with severity of shape, and lubrication of dies is difficult when upsetting is severe. Ferritic and lower-carbon martensitic types behave like carbon or low-alloy steels in cold heading.

Cold headed parts made of austenitic and ferritic stainless steels are most often used in the as-headed condition, although annealing may be needed if service conditions are likely to cause stress-corrosion cracking. Martensitic types are usually heat treated after heading.

## Machining

Stainless steels as a class are more difficult to machine than carbon and low-alloy steels because of their higher strength and higher work-hardening rates ("gummy" nature). These characteristics require greater power and lower machining speed, shorten tool life, and sometimes lead to difficulty in obtaining a fine finish on the machined surface. Wide variations exist in these characteristics among the different stainless steels.

**Procedures.** In machining of stainless steels, special attention must be paid to equipment in order to control the effects of strength and work hardening. Rigid equipment and tooling are necessary to prevent chatter. Chip-curler tools are generally recommended because of the tough, stringy chips produced--particularly in machining austenitic and high-alloy ferritic types. Both high-speed tool steels and cemented carbide cutting tools provide acceptable tool life at production machining speeds.

The following precautions should be instituted to avoid work hardening. Tools should never be permitted to ride or glaze without cutting because the surface can work harden to the extent that cutting tools will become burned before they penetrate the surface. Care should be taken to ensure that hardening from one operation does not interfere with subsequent

machining. For example a tripod punch rather than a conventional center punch is preferred for hole location to prevent work hardening at the spot that will be touched first by the drill.

Heavier feeds and lower speeds than those used in machining low-alloy steels are used to minimize work hardening.

**Type Variations.** Low-alloy martensitic and ferritic stainless steels have machining characteristics much like those of low-alloy steels, whereas the higher-carbon martensitic stainless steels are among the most difficult metals to machine. Austenitic and precipitation-hardening stainless steels vary more widely in machining characteristics within each class than do the ferritic and martensitic grades. Most easily machined are the free-machining alloys, which contain a free-machining additive to form inclusions that significantly improve overall machining characteristics.

The structures of low-alloy martensitic and ferritic stainless steels make these types somewhat brittle, resulting in reasonably good chip breakage. However, hardness levels generally are higher than those of annealed low-alloy steels. The low-alloy martensitic stainless steels often must be machined in the hardened-and-tempered condition (up to 38 HRC), which produces excellent dimensional accuracy and surface finish.

Higher-carbon martensitic stainless steels such as types 420 and 440, and particularly type 440C, are progressively more difficult to machine because of their high annealed hardnesses (up to 240 HB) and the presence of hard, abrasive chromium carbides in their microstructures. The high-chromium ferritic stainless steels such as type 446 are difficult to machine because, like austenitic types, they are "gummy" and produce stringy chips.

Austenitic stainless steels such as types 304 and 316 have tensile strengths of 550 to 620 MPa (80 to 90 ksi) in the annealed condition--the same range of strength as that of annealed 1050 carbon steel. However, austenitic stainless steels exhibit much greater spreads between yield and ultimate strengths and much higher work-hardening rates--particularly the leaner alloys such as types 302 and 304. The machinability of duplex stainless steels is limited by their high annealed strength level, and they are considered less machinable than most standard austenitic grades.

Precipitation-hardening types vary considerably in machining characteristics because of differences in structure. They can be ferritic, martensitic, austenitic or two-phase, so machining characteristics will be characteristic of the structure that exists at the time of machining. Like martensitic types, precipitation-hardening stainless steels sometimes are machined after being heat treated to high strength in order to produce parts with closer tolerances than those obtainable by machining before heat treatment.

As stated previously, free-machining stainless steels are significantly more machinable than their non-free-machining counterparts because they contain small amounts of various free-machining additives. The most common additive is sulfur, which minimizes buildup of metal on cutting edges and promotes chip breakage, thereby permitting higher machining speeds and lower power consumption and promoting longer tool life. The sulfur is present in nonmetallic inclusions, usually complex manganese sulfides. Selenium, which is the second most commonly used free-machining agent in stainless steels, has beneficial effects similar to those of sulfur, but generally gives a better surface finish. Selenium also imparts improved cold formability and somewhat improved corrosion resistance to free-machining stainless steels than does sulfur. Other free-machining additives include tellurium, lead, and bismuth. However, alloys containing these elements are commercially limited due to problems associated with reduced hot workability, erratic machinability associated with the difficulty in obtaining a uniform structure (inclusion morphology) in the steel and/or toxicity.

Because of the high costs of labor and capital, the economic benefits of free-machining stainless steels can be substantial. The free-machining types are slightly more expensive, but this is more than offset by savings in machining costs when extensive machining is required. As a rule, a free-machining type may be cost effective in any application where more than 10% of the material must be machined away.

The characteristics of free-machining types must be carefully considered to ensure that parts will perform satisfactorily in service. Properties that can be degraded by the addition of a free-machining agent include corrosion resistance, transverse ductility and toughness, hot workability, cold formability, and weldability. In some cases, variants of the basic free-machining alloy are available to provide an optimum combination of machinability with another property. However, the tradeoff among the various properties must still be considered when selecting an alloy; that is, the ease of machining must be balanced against the possible reduction in other important properties, such as corrosion resistance.

Table 1 lists some non-free-machining and free-machining alloys within the ferritic, martensitic, and austenitic families. Free-machining alloys are currently unavailable in the duplex or precipitation-hardenable families. Because duplex alloys are noted for excellent corrosion resistance but have somewhat limited hot workability, the addition of a free-machining agent, which would likely degrade both properties, would be undesirable. Similarly, precipitation-hardenable alloys are noted for good toughness at high strength levels, making it undesirable to add a free-machining agent, which would degrade toughness.

**Table 1 Available free-machining stainless steel grades**

Non-free-machining alloys	Related free-machining alloys	
	Selenium-bearing	Sulfur-bearing
Ferritic

(a) Does not contain titanium.

(b) Contains high manganese.

(c) Contains aluminum.

(d) Contains lead.

(e) Contains lower copper

## Heat Treating

Stainless steels are subjected to various heat treatments depending on the type and on the requirements of the application. These treatments, which include annealing, hardening, and stress relieving, restore desirable properties such as corrosion resistance and ductility to metal altered by prior fabrication operations. Heat treatment is often performed in controlled atmospheres to prevent detrimental surface effects.

**Annealing.** All types of stainless steels can be annealed. Annealing of austenitic types not only recrystallizes the grains and softens the metal, but also takes chromium carbides into solution in the austenite. Because of the latter effect, the process is sometimes referred to as solution annealing. Temperatures must exceed an intermediate range to avoid sensitization due to carbide precipitation along grain boundaries. Annealing temperatures usually are above 1040 °C (1900 °F), although some types can be annealed at closely controlled temperatures as low as 1010 °C (1850 °F) when fine grain size is important. Time at temperature is kept short to hold surface scaling to a minimum and to control grain growth, which can lead to "orange peel" in forming.

Annealing of austenitic stainless steels is occasionally called quench annealing because the metal must be cooled rapidly, usually by water quenching, to prevent sensitization (except for stabilized and extra-low-carbon types). Precipitation of chromium carbides can severely impair corrosion resistance because chromium is depleted in the matrix immediately adjacent to the carbides and/or because the carbides themselves can induce galvanic corrosion. Therefore, if water quenching is not used, thorough investigation is needed to ensure that sensitization does not occur. The investigation must take actual composition into account because the rate of carbide precipitation varies markedly with composition: a heat of type 304 containing 0.05% carbon may be free of precipitation under cooling conditions that would produce heavy sensitization in the same alloy containing 0.08% carbon. Austenitic stainless steels are softened by recrystallization at the annealing temperature and, unlike most other steels, are not hardened by quenching.

A stabilizing anneal is sometimes performed after conventional annealing for types 321, 347, and 348. Most of the carbon content is combined with titanium in type 321 or with niobium in types 347 and 348 when these types are annealed in the usual manner. A further anneal at 870 to 900 °C (1600 to 1650 °F) for 2 to 4 h followed by rapid cooling precipitates all possible carbon as a titanium or niobium carbide and prevents subsequent precipitation of chromium carbide. It is believed that this special protective treatment is sometimes useful when service conditions are rigorously corrosive--especially when service also involves temperatures from approximately 400 to 870 °C (750 to 1600 °F).

Before annealing or other heat treating operations are performed on austenitic stainless steels, the steel should be cleaned to remove oil, grease, and other carbonaceous residues. Such residues lead to carburization during heat treating, which degrades corrosion resistance.

All martensitic and most ferritic stainless steels can be subcritical annealed (process annealed) by heating into the upper part of the ferrite temperature range or full annealed by heating above the critical temperature into the austenite range, followed by slow cooling. Usual temperatures are 760 to 830 °C (1400 to 1525 °F) for subcritical annealing and 845 to 900 °C (1550 to 1650 °F) for full annealing. When material has been previously heated above the critical temperature, such as in hot working, at least some martensite is present even in ferritic stainless steels such as type 430. Relatively slow cooling at approximately 25 °C/h (50 °F/h) from full annealing temperature, or holding for one hour or more at subcritical annealing temperature, is required to produce the desired soft structure of ferrite and spheroidized carbides. However, parts that have undergone only cold working after full annealing can be subcritically annealed satisfactorily in less than 30 minutes.

The ferritic types that retain predominantly single-phase structures throughout the working temperature range (types 409, 442, 446, and 26Cr-1Mo) require only short recrystallization annealing in the range from 760 to 955 °C (1400 to 1750 °F). The higher-chromium types such as 446 and 26Cr-1Mo require rapid cooling through the range from 540 to 370 °C (1000 to 700 °F) to avoid "885 °F" embrittlement and consequent loss of ductility.

**Hardening.** Martensitic stainless steels are hardened by austenitizing, quenching, and tempering much like lower-alloy steels. Austenitizing temperatures normally are 980 to 1010 °C (1800 to 1850 °F)--well above the critical temperature. As-quenched hardness increases with austenitizing temperature to approximately 980 °C (1800 °F) and then decreases due to retention of austenite. For some types, the optimum austenitizing temperature may depend on the subsequent tempering temperature.

Preheating before austenitizing is recommended to prevent cracking in high-carbon types and in intricate sections of low-carbon types. Preheating at 790 °C (1450 °F) and then heating to the austenitizing temperature is the most common practice, but very large or extremely intricate parts sometimes are successively preheated at 540 °C (1000 °F) and then at 790 °C (1450 °F) before austenitizing.

Martensitic stainless steels have high hardenability because of their high alloy content. Air cooling from the austenitizing temperature is usually adequate to produce full hardness. Oil quenching is sometimes used, particularly for larger sections. Tempering temperature must be chosen for the optimum combination of hardness, toughness, and corrosion resistance. Parts should be tempered as soon as they have cooled to room temperature--particularly if oil quenching has been used--to avoid delayed cracking. Parts sometimes are refrigerated to -75 °C (-100 °F) before tempering to transform retained austenite--particularly where dimensional stability is important, such as in gage blocks made of type 440C. Tempering at temperatures above 510 °C (950 °F) should be followed by relatively rapid cooling to below 400 °C (750 °F) to avoid "885 °F" embrittlement.

Some precipitation-hardening stainless steels require more complicated heat treatments than standard martensitic types. For instance, a semiaustenitic precipitation-hardening type may require annealing, solution treatment (to condition austenite for transformation on cooling to room temperature), subzero cooling (to complete the transformation of austenite), and aging (to fully harden the alloy). Conversely, martensitic precipitation-hardening types often require nothing more than a simple aging treatment.

**Stress Relieving.** Stainless steel weldments generally are heated to temperatures below the usual annealing temperature to decrease high residual stresses when full annealing after welding is impossible. Most often, stress relieving is performed on weldments that are too large or intricate for full annealing or on dissimilar-metal weldments consisting of austenitic stainless steel welded to alloy steel. Stress relieving at temperatures below 400 °C (750 °F) is an acceptable practice but results in only modest stress relief.

Stress relieving at 425 to 925 °C (800 to 1700 °F) significantly reduces residual stresses that otherwise might lead to stress-corrosion cracking or dimensional instability in service. One hour at 870 °C (1600 °F) typically relieves approximately 85% of the residual stresses. However, stress relieving in this temperature range also precipitates grain-boundary carbides, resulting in sensitization that severely impairs corrosion resistance in many media. Sensitized austenitic stainless steels are susceptible to intergranular corrosion or stress-assisted intergranular corrosion even in some media that are considered mild. To avoid these effects, it is strongly recommended that a stabilized stainless steel (type 321, 347, or 348) or a low-carbon type (304L or 316L) be used, particularly when lengthy stress relieving is required.

When austenitic stainless steels have been cold worked to develop high strength, low-temperature stress relieving will increase the proportional limit and yield strength (particularly compressive yield strength). A two-hour treatment at 345 to 370 °C (650 to 700 °F) is normally used; temperatures up to 425 °C (800 °F) can be used if resistance to intercrystalline corrosion is not required for the application. Higher temperatures will reduce strength and sensitize the metal and generally are not used for stress relieving cold worked products.

Stress relieving of martensitic or ferritic stainless steel weldments will simultaneously temper both weld and heat-affected zones and for most types will restore corrosion resistance to some degree. However, annealing temperatures are relatively low for these grades, and normal subcritical annealing is the heat treatment usually selected if the weldment is to be heat treated at all.

## Joining Processes

Stainless steels are commonly joined by welding, brazing, and soldering. Arc welding is the overwhelming choice for joining stainless steel to stainless steel because it gives a relatively crevice-free joint of high joint efficiency. Procedures and precautions appropriate for the various types are important if optimum corrosion resistance and mechanical properties are to be attained in the completed assembly. Brazing usually is preferred for joining stainless steels to dissimilar metals.

**Welding.** Stainless steels of all types are weldable by virtually all welding processes. In part, process selection is often dictated by available equipment. Perhaps the simplest and most universal welding process is manual shielded-metal arc welding (SMAW) with coated electrodes. It has been applied to material as thin as 1.2 mm (0.05 in.), and there is no upper limit on thickness. Other very commonly used processes for stainless steels are gas-tungsten arc welding (GTAW), gas-metal arc welding (GMAW), submerged arc welding (SAW), flux-cored arc welding (FCAW), and several forms of resistance welding. The plasma arc welding (PAW), laser-beam welding (LBW), and electron-beam welding (EBW) processes are also used. Stainless steels are rarely joined by gas welding. In oxyacetylene welding of stainless steels, great skill in controlling the welding atmosphere is required to prevent either oxidation or carburization of the weld pool. Regardless of the welding process chosen, major factors that must be considered are (a) corrosion resistance in the weld and heat-affected zones; (b) residual stress, which can lead to distortion, weld cracking, or fissuring; and (c) for martensitic and ferritic types, mechanical properties in the weld, and heat-affected zones.

Austenitic types are the most weldable stainless steels but are also the stainless steels most different in welding behavior from carbon and low-alloy steels. Probably the most important metallurgical factor to consider in planning for austenitic stainless steel weldments is susceptibility to grain-boundary carbide precipitation (sensitization) at moderately elevated temperatures. Material immediately adjacent to the weld is heated to or above the annealing temperature and is free of precipitation. At some distance away--perhaps 3 mm ( $\frac{1}{8}$  in.) or more, depending on welding parameters--the base metal is heated to 650 to 870 °C (1200 to 1600 °F), and grain-boundary carbides can precipitate despite the short time at temperature. Carbide precipitation severely impairs corrosion resistance in many media, including the acids most often used for pickling to remove oxide. Nevertheless, because sensitization occurs in such a narrow region of the heat-affected zone, many austenitic stainless steel weldments are used in the as-welded condition without concern.

**Brazing.** All stainless steels can be brazed, and this process is frequently used for joining stainless steels to other metals. All brazing techniques can be used, but furnace brazing is employed more often than any other technique because it permits brazing to be done in a protective environment (usually hydrogen or vacuum) that prevents oxidation of the stainless steel. Most brazing of austenitic types is performed at temperatures in the sensitization range, and solution annealing after brazing is impossible. Therefore, stabilized or extra-low-carbon types must be used if service conditions might lead to intergranular corrosion of sensitized material. In brazing of martensitic and ferritic types, a brazing filler metal that melts below the critical temperature of 830 °C (1525 °F) is normally used to avoid martensitic hardening. The heat of brazing will temper, and possibly soften, hardened martensitic stainless steels.

Virtually all types of brazing filler metals are used, including silver, nickel, gold, and copper alloys. High-phosphorus, copper-base filler metals should be avoided, however, because they have harmful effects on stainless steels. Certain austenitic types (21Cr-6Ni-9Mn, for instance) should not be brazed with any copper-base filler metal because molten copper attacks the stainless steel during brazing.

Destructive penetration of stainless steel is possible during brazing. A form of stress-corrosion cracking develops in some types if they are brazed while in a highly stressed condition. Penetration during brazing can be prevented by annealing before brazing, by heating parts slowly enough to relieve stresses before the brazing temperature is reached, or by selecting a brazing filler metal that inhibits such penetration. Grain-boundary penetration can also occur if high-

temperature brazing alloys that melt above 980 °C (1800 °F) are used. This problem can be minimized by selecting a favorable brazing alloy, using as little brazing alloy as possible and keeping time at temperature short. Welding through or near a brazed joint can also cause penetration of stainless steel and should be avoided.

Use of a silver brazing alloy to which nickel and tin have been added helps minimize crevice corrosion of brazed joints exposed to certain corrosive media such as seawater. Brazing should be done in a protective atmosphere without flux.

**Soldering.** Although all of the stainless steels can be joined by soldering when the proper techniques are used, these materials are not generally soldered because they are used in applications which involve high strength and/or corrosion/heat resistance. Nevertheless, soldered stainless steel joints still find applications in architecture, food processing, and plumbing. As with brazing, chromium oxide films must be adequately removed to enhance solderability. Types of soldering processes used to join stainless steels include iron soldering (the soldering iron or bit), torch soldering, furnace and infrared soldering, dip soldering, resistance soldering, induction soldering, and laser soldering.

Principal soldering alloys used to join stainless steels are the tin-lead alloys. Pure tin, tin-antimony, and tin-silver solders are used for food handling and other applications where lead would be hazardous.

## Precautions in Welding

The most obvious problem associated with welding of stainless steel is maintenance of uniform resistance to corrosion across the weld zone and the adjacent base-metal zones. This problem is commonly overcome by close control of composition and welding conditions. Sometimes, postweld heat treatment is required to restore corrosion properties altered during welding--particularly in material subject to sensitization.

**Sensitization** (harmful carbide precipitation) can be avoided, where necessary, by any of three methods:

- *Solution annealing after welding* relieves any residual stresses and improves the structure and corrosion resistance of the weld metal itself. However, solution annealing and the postanneal pickling that it necessitates are costly and inconvenient. Distortion can be a serious problem, particularly if water quenching is used to ensure that general reprecipitation of carbides does not occur during cooling. Postweld annealing is impossible for large weldments such as tanks and pressure vessels.
- *Limitation of carbon content.* Carbides will not precipitate in a weld heat-affected zone if carbon content is low enough. Extra-low-carbon stainless steels such as types 304L and 316L (0.030% max carbon) are commonly used in the United States, and such low carbon contents are necessary for weldments that are to be stress relieved. Even the restriction of carbon content to 0.030% max may not completely protect against sensitization and loss of corrosion resistance in the higher-nickel alloys or in any austenitic stainless steel that has been mildly cold worked. Limitation of carbon to 0.05% max will prevent sensitization in the heat-affected zone under most welding conditions, particularly in light sections. When exposed to strongly oxidizing corrosive media such as hot nitric acid, molybdenum-bearing types 316 and 317 are susceptible to intergranular corrosion in the heat-affected zone due to formation of grain-boundary sigma phase, even when carbides are not precipitated. When weldments of molybdenum-bearing grades are to be used in oxidizing media, it is common practice to subject sensitized samples from each heat to corrosion testing for assessment of susceptibility to intergranular corrosion.
- *Stabilization of carbon.* Sensitization in the heat-affected zone can be prevented by tying up the carbon in titanium carbides (as in type 321) or in niobium carbides (as in types 347 and 348) so that detrimental chromium carbides cannot form. The stabilized grades are also recommended for applications involving long-time exposure to temperatures in the sensitization range, such as in prolonged stress relief or service at high temperatures. However, weldments of stabilized grades heated into the sensitization range and later exposed to certain corrosive media can suffer from severe localized corrosion called "knifeline attack." The stable carbides are partly dissolved in a very narrow zone immediately adjacent to the weld, and during later exposure in the sensitization range, chromium carbides can precipitate. This unusual type of sensitization can be prevented by annealing or stabilization annealing, even locally, after welding.

**Weld Cracking.** Austenitic stainless steel welds are extremely tough and ductile, and thus cold weld cracking is almost never a problem. However, austenitic stainless steels are susceptible to hot cracking or microfissuring as they cool from the solidus to approximately 980 °C (1800 °F). Microfissuring can be prevented or kept to a minimum by eliminating or reducing tensile stress imposed on the weld during cooling through this range. To some degree, microfissuring can be controlled by controlling concentrations of residual elements such as phosphorus. However, the most common control measure is to ensure the presence of at least 3 to 4% ferrite in the as-deposited weld. Small amounts of this phase seem to prevent the cracking that often occurs in fully austenitic weld metal. Ferrite content is usually estimated on the basis of composition by use of the DeLong diagram, which is a modification of the long-used Schaeffler diagram, or more recently developed weld constitution diagrams developed by the Welding Research Council for more highly alloyed weld metals. DeLong's modification takes into account the potent austenitic stabilization effect of nitrogen. Because ferrite contents calculated in this manner are not completely precise, it is recommended that for critical applications actual ferrite content be determined by magnetic analysis of as-deposited weld metal. For production welds, measurement is especially preferred to calculation in the common instance where a high-ferrite welding electrode is used to weld lower-ferrite base metal. Weld composition then varies with the degree of dilution.

Control of ferrite content is not always an acceptable solution to microfissuring. Ferrite is a magnetic phase, reduces corrosion resistance in some media, and can lead to embrittlement in long-time, elevated-temperature service exposure due to precipitation of sigma phase. Ferrite content in the weld can be reduced significantly (typically by 2 to 4%) by annealing after welding; but where postweld annealing is not possible, fully austenitic welds may be required. Some steels such as type 310 are fully austenitic through the entire specified composition range. Weld cracking can be minimized in fully austenitic stainless steels by welding with low heat input, minimizing restraint, designing for low constraint, and keeping residual elements at low concentrations.

Ferritic types are less ductile than austenitic types and therefore are more susceptible to weld cracking. Certain ferritic stainless steels (type 430, for instance) form significant amounts of martensite on cooling after welding, which increases susceptibility to cold cracking. Preheating at 150 to 230 °C (300 to 450 °F) is recommended to minimize weld cracking in all ferritic types.

In fully ferritic types such as 409, 446, and 26Cr-1Mo, welding causes grain coarsening in the base metal immediately adjacent to the weld. Toughness therefore is reduced, particularly in heavy sections and cannot be restored by postweld heat treatment. Ferritic stainless steels that form austenite at elevated temperatures are not coarsened significantly, but postweld annealing is recommended to transform the resulting martensite and enhance ductility in the heat-affected zone.

Martensitic stainless steels are even more susceptible to weld cracking than ferritic types. Preheating at 200 to 300 °C (400 to 600 °F) generally is required. Postweld annealing is standard practice, particularly for steels with carbon contents greater than 0.20%.

Duplex stainless steels can suffer from weld metal, hydrogen cracking. But the reported incidences have been restricted to cases in which the alloy was heavily cold worked or weld metals experienced high levels of restraint or possessed very high ferrite contents in combination with very high hydrogen levels, as a result of poor control of covered electrodes or the use of hydrogen-containing shielding gas.

## **Cleaning and Finishing**

Proper cleaning and finishing of stainless steel parts are essential for maintenance of the corrosion resistance and appearance for which stainless steels are specified. The degree of care required depends on the nature of the application; the most stringent precautions (such as clean-room assembly and sophisticated postassembly cleaning) are used for critical applications such as nuclear-reactor cores, pharmaceutical and food-handling equipment, and some aerospace applications.

# **Corrosion of Wrought Stainless Steels**

## **Introduction**

THE MECHANISM OF CORROSION PROTECTION for stainless steels differs from that for carbon steels, alloy steels, and most other metals. In these other cases, the formation of a barrier of true oxide separates the metal from the surrounding atmosphere. The degree of protection afforded by such an oxide is a function of the thickness of the oxide

layer, its continuity, its coherence and adhesion to the metal, and the diffusivities of oxygen and metal in the oxide. In high-temperature oxidation, stainless steels use a generally similar model for corrosion protection. However, at low temperatures, stainless steels do not form a layer of true oxide. Instead, a passive film is formed. One mechanism that has been suggested is the formation of a film of hydrated oxide, but there is not total agreement on the nature of the oxide complex on the metal surface. However, the oxide film should be continuous, nonporous, insoluble, and self healing if broken in the presence of oxygen.

Passivity exists under certain conditions for particular environments. The range of conditions over which passivity can be maintained depends on the precise environment and on the family and composition of the stainless steel. When conditions are favorable for maintaining passivity, stainless steels exhibit extremely low corrosion rates. If passivity is destroyed under conditions that do not permit restoration of the passive film, then stainless steel will corrode much like a carbon or low-alloy steel.

The presence of oxygen is essential to the corrosion resistance of a stainless steel. The corrosion resistance of stainless steel is at its maximum when the steel is boldly exposed and the surface is maintained free of deposits by a flowing bulk environment. Covering a portion of the surface--for example, by biofouling, painting, or installing a gasket--produces an oxygen-depleted region under the covered region. The oxygen-depleted region is anodic relative to the well-aerated boldly exposed surface, and a higher level of alloy content in the stainless steel is required to prevent corrosion.

With appropriate grade selection, stainless steel will perform for very long times with minimal corrosion, but an inadequate grade can corrode and perforate more rapidly than a plain carbon steel will fail by uniform corrosion. Selection of the appropriate grade of stainless steel is then a balancing of the desire to minimize cost and the risk of corrosion damage by excursions of environmental conditions during operation or downtime.

Confusion exists regarding the meaning of the term passivation. It is not necessary to chemically treat a stainless steel to obtain the passive film; the film forms spontaneously in the presence of oxygen. Most frequently, the function of passivation is to remove free iron, oxides, and other surface contamination. For example, in the steel mill, the stainless steel can be pickled in an acid solution, often a mixture of nitric and hydrofluoric acids ( $\text{HNO}_3\text{-HF}$ ), to remove oxides formed in heat treatment. Once the surface is cleaned and the bulk composition of the stainless steel is exposed to air, the passive film forms immediately.

## Effects of Composition

**Chromium** is the one element essential in forming the passive film. Other elements can influence the effectiveness of chromium in forming or maintaining the film, but no other element can, by itself, create the properties of stainless steel. The film is first observed at approximately 10.5% Cr, but it is rather weak at this composition and affords only mild atmospheric protection. Increasing the chromium content to 17 to 20%, as typical of the austenitic stainless steels, or to 26 to 29%, as possible in the newer ferritic stainless steels, greatly increases the stability of the passive film. However, higher chromium can adversely affect mechanical properties, fabricability, weldability, or suitability for applications involving certain thermal exposures. Therefore, it is often more efficient to improve corrosion resistance by altering other elements, with or without some increase in chromium.

**Nickel**, in sufficient quantities, will stabilize the austenitic structure; this greatly enhances mechanical properties and fabrication characteristics. Nickel is effective in promoting repassivation, especially in reducing environments. Nickel is particularly useful in resisting corrosion in mineral acids. Increasing nickel content to approximately 8 to 10% decreases resistance to stress-corrosion cracking (SCC), but further increases begin to restore SCC resistance. Resistance to SCC in most service environments is achieved at approximately 30% Ni. In the newer ferritic grades, in which the nickel addition is less than that required to destabilize the ferritic phase, there are still substantial effects. In this range, nickel increases yield strength, toughness, and resistance to reducing acids, but it makes the ferritic grades susceptible to SCC in concentrated magnesium chloride ( $\text{MgCl}_2$ ) solutions.

**Manganese** in moderate quantities and in association with nickel additions will perform many of the functions attributed to nickel. However, total replacement of nickel by manganese is not practical. Very high manganese steels have some unusual and useful mechanical properties, such as resistance to galling. Manganese interacts with sulfur in stainless steels to form manganese sulfides. The morphology and composition of these sulfides can have substantial effects on corrosion resistance, especially pitting resistance.

**Molybdenum** in combination with chromium is very effective in terms of stabilizing the passive film in the presence of chlorides. Molybdenum is especially effective in increasing resistance to the initiation of pitting and crevice corrosion.

**Carbon** is useful to the extent that it permits hardenability by heat treatment, which is the basis of the martensitic grades, and that it provides strength in the high-temperature applications of stainless steels. In all other applications, carbon is detrimental to corrosion resistance through its reaction with chromium. In the ferritic grades, carbon is also extremely detrimental to toughness.

**Nitrogen** is beneficial to austenitic stainless steels in that it enhances pitting resistance, retards the formation of the chromium-molybdenum  $\sigma$  phase, and strengthens the steel. Nitrogen is essential in the newer duplex grades for increasing the austenite content, diminishing chromium and molybdenum segregation, and for raising the corrosion resistance of the austenitic phase. Nitrogen is highly detrimental to the mechanical properties of the ferritic grades and must be treated as comparable to carbon when a stabilizing element is added to the steel.

**Aluminum.** Additions of aluminum enhance high-temperature oxidation resistance.

**Niobium** is used to combine with carbon, thus reducing the formation of chromium carbides. This reduces the possibility of intergranular corrosion when the stainless is welded or heat treated.

**Titanium** serves the same purpose as niobium. In some alloys titanium and niobium are used together.

**Copper.** In some stainless steels copper is added to provide corrosion resistance to sulfuric acid ( $\text{H}_2\text{SO}_4$ ).

**Silicon.** In some alloys silicon is added for high-temperature oxidation resistance. Silicon has also been shown to provide resistance to SCC, as well as resistance to corrosion by oxidizing acids.

## Effects of Heat Treatment

Improper heat treatment can produce deleterious changes in the microstructure of stainless steels. The most troublesome problems are carbide precipitation (sensitization) and precipitation of various intermetallic phases, such as sigma ( $\sigma$ ), chi ( $\chi$ ), and laves ( $\eta$ ).

**Sensitization**, or carbide precipitation at grain boundaries, can occur when austenitic stainless steels are heated for a period of time in the range of approximately 425 to 870 °C (800 to 1600 °F). Time at temperature will determine the amount of carbide precipitation. When the chromium carbides precipitate in grain boundaries, the area immediately adjacent is depleted of chromium. When the precipitation is relatively continuous, the depletion renders the stainless steel susceptible to intergranular corrosion, which is the dissolution of the low-chromium layer or envelope surrounding each grain. Sensitization also lowers resistance to other forms of corrosion, such as pitting, crevice corrosion, and SCC.

Time-temperature-sensitization curves are available that provide guidance for avoiding sensitization and illustrate the effect of carbon content on this phenomenon (Fig. 1). The curves shown in Fig. 1 indicate that a type 304 stainless steel with 0.062% C would have to cool below 595 °C (1100 °F) within approximately 5 min to avoid sensitization, but a type 304L with 0.030% C could take approximately 20 h to cool below 480 °C (900 °F) without becoming sensitized. These curves are general guidelines and should be verified before they are applied to various types of stainless steels.

**Fig. 1** Time-temperature-sensitization curves for type 304 stainless steel in a mixture of  $\text{CuSO}_4$  and  $\text{H}_2\text{SO}_4$  containing free copper. Curves show the times required for carbide precipitation in steels with various carbon contents. Carbides precipitate in the areas to the right of the various carbon content curves.

Another method of avoiding sensitization is to use stabilized steels. Such stainless steels contain titanium and/or niobium. These elements have an affinity for carbon and form carbides readily; this allows the chromium to remain in solution even for extremely long exposures to temperatures in the sensitizing range. Type 304L can avoid sensitization during the relatively brief exposure of welding, but it will be sensitized by long exposures.

Annealing is the only way to correct a sensitized stainless steel. Because different stainless steels require different temperatures, times, and quenching procedures, the user should contact the material supplier for such information. A number of tests can detect sensitization resulting from carbide precipitation in austenitic and ferritic stainless steels. The most widely used tests are described in ASTM standards A 262 and A 763. More detailed information on sensitization of stainless steels can be found in the article "Wrought Stainless Steels: Selection and Application" in this Section.

**Precipitation of Intermetallic Phases.** Sigma-phase precipitation and precipitation of other intermetallic phases also increase susceptibility to corrosion. Sigma phase is a chromium-molybdenum-rich phase that can render stainless steels susceptible to intergranular corrosion, pitting, and crevice corrosion. It generally occurs in higher-alloyed stainless steels (high-chromium, high-molybdenum stainless steels). Sigma phase can occur at a temperature range between 540 and 900 °C (1000 and 1650 °F). Like sensitization, it can be corrected by solution annealing. Precipitation of intermetallic phases in stainless steels is also covered in the article "Wrought Stainless Steels: Selection and Application" in this Section.

**Cleaning Procedures.** Any heat treatment of stainless steel should be preceded and followed by cleaning. Steel should be cleaned before heat treating to remove any foreign material that can be incorporated into the surface during the high-temperature exposure. Carbonaceous materials on the surface can result in an increase in the carbon content on the surface, causing carbide precipitation. Salts could cause excessive intergranular oxidation. Therefore, the stainless steel must be clean before it is heat treated.

After heat treatment, unless an inert atmosphere was used during the process, the stainless steel surface will be covered with an oxide film. Such films are not very corrosion resistant and must be removed to allow the stainless steel to form a passive film and provide the corrosion resistance for which it was designed. There are numerous cleaning methods that can be used before and after heat treating. An excellent guide is ASTM A 380.

## Effects of Welding

The main problems encountered in welding stainless steels are the same as those seen in heat treatment. The heat of welding (portions of the base metal adjacent to the weld may be heated to 430 to 870 °C, or 800 to 1600 °F) can cause sensitization and formation of intermetallic phases, thus increasing the susceptibility of stainless steel weldments to

intergranular corrosion, pitting, crevice corrosion, and SCC. These phenomena often occur in the heat-affected zone of the weld. Sensitization and intermetallic phase precipitation can be corrected by solution annealing after welding. Alternatively, low carbon or stabilized grades can be used.

Another problem in high heat input welds is grain growth, particularly in ferritic stainless steels. Excessive grain growth can increase susceptibility to intergranular attack and reduce toughness. Thus, when welding most stainless steels, it is wise to limit weld heat input as much as possible.

**Cleaning Procedures.** Before any welding begins, all materials, chill bars, clamps, hold down bars, work tables, electrodes, and wire, as well as the stainless steel, must be cleaned of all foreign matter. Moisture can cause porosity in the weld that would reduce corrosion resistance. Organic materials, such as grease, paint, and oils, can result in carbide precipitation. Copper contamination can cause cracking. Other shop dirt can cause weld porosity and poor welds in general.

**Weld design and procedure** are very important in producing a sound corrosion-resistant weld. Good fit and minimal out-of-position welding will minimize crevices and slag entrapment. The design should not place welds in critical flow areas. When attaching such devices as low-alloy steel supports and ladders on the outside of a stainless steel tank, a stainless steel intermediate pad should be used. In general, stainless steels with higher alloy content than type 316 should be welded with weld metal richer in chromium, nickel, and molybdenum than the base metal. Every attempt should be made to minimize weld spatter.

After welding, all weld spatter, slag, and oxides should be removed by brushing, blasting, grinding, or chipping. All finishing equipment must be free of iron contamination. It is advisable to follow the mechanical cleaning and finishing with a chemical cleaning. Such a cleaning will remove any foreign particles that may have been embedded in the surface during mechanical cleaning without attacking the weldment. Procedures for such cleaning or descaling are given in ASTM A 380.

## Effects of Surface Condition

To ensure satisfactory service life, the surface condition of stainless steels must be given careful attention. Smooth surfaces, as well as freedom from surface imperfections, blemishes, and traces of scale and other foreign material, reduce the probability of corrosion. In general, a smooth, highly polished, reflective surface has greater resistance to corrosion. Rough surfaces are more likely to catch dust, salts, and moisture, which tend to initiate localized corrosive attack.

Oil and grease can be removed by using hydrocarbon solvents or alkaline cleaners, but these cleaners must be removed before heat treatment. Hydrochloric acid (HCl) formed from residual amounts of trichloroethylene, which is used for degreasing, has caused severe attack of stainless steels. Surface contamination can be caused by machining, shearing, and drawing operations. Small particles of metal from tools become embedded in the steel surface and, unless removed, can cause localized galvanic corrosion. These particles are best removed by the passivation treatments described in the section "Passivation Techniques."

Shotblasting or sandblasting should be avoided unless iron-free silica is used; metal shot, in particular, will contaminate the stainless steel surface. If shotblasting or shotpeening with metal grit is unavoidable, the parts must be cleaned after blasting or peening by immersing them in an  $\text{HNO}_3$  solution.

**Passivation Techniques.** During handling and processing operations, such as machining, forming, tumbling, and lapping, particles of iron, tool steel, or shop dirt can be embedded in or smeared on the surfaces of stainless steel components. These contaminants can reduce the effectiveness of the natural oxide (passive) film that forms on stainless steels exposed to oxygen at low temperatures (see the introductory paragraphs to this article). If allowed to remain, these particles can corrode and produce rustlike spots on the stainless steel. To prevent this condition, semifinished or finished parts are given a passivation treatment. This treatment consists of cleaning and then immersing stainless steel parts in a solution of  $\text{HNO}_3$  or of  $\text{HNO}_3$ , plus oxidizing salts. The treatment dissolves the embedded or smeared iron, restores the original corrosion-resistant surface, and maximizes the inherent corrosion resistance of the stainless steel. As shown in Table 1, the composition of the acid bath depends on the grade of stainless steel. The 300 series stainless steels can be passivated in 20 vol%  $\text{HNO}_3$ . A sodium dichromate ( $\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$ ) addition or an increased concentration of  $\text{HNO}_3$  is used for less corrosion-resistant stainless steels to reduce the potential for flash attack.

**Table 1 Passivating solutions for stainless steels (non-free-machining grades)**

Grade	Passivation treatment
<b>Austenitic 300 series grades or grades with <math>\geq 17\%</math> Cr (except 440 series)</b>	20 vol% HNO <sub>3</sub> at 50-60 °C (120-140 °F) for 30 min
<b>Straight chromium grades (12-14% Cr), high-carbon/high-chromium grades (440 series), or precipitation-hardening grades</b>	20 vol% HNO <sub>3</sub> plus 22 g/L (3 oz/gal) Na <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> ·2H <sub>2</sub> O at 50-60 °C (120-140 °F) for 30 min or 50 vol% HNO <sub>3</sub> at 50-60 °C (120-140 °F) for 30 min

Free-machining grades require specialized alkaline-acid-alkaline passivation treatments

## Forms of Corrosion of Stainless Steels

**General (uniform) corrosion** of a stainless steel suggests an environment capable of stripping the passive film from the surface and preventing repassivation. Such an occurrence could indicate an error in grade selection. An example is the exposure of a lower-chromium ferritic stainless steel to a moderate concentration of hot sulfuric acid (H<sub>2</sub>SO<sub>4</sub>).

**Galvanic corrosion** results when two dissimilar metals are in electrical contact in a corrosive medium. As a highly corrosion-resistant metal, stainless steel can act as a cathode when in contact with a less noble metal, such as steel. The corrosion of steel parts--for example, steel bolts in a stainless steel construction--can be a significant problem. However, the effect can be used in a beneficial way for protecting critical stainless steel components within a larger steel construction. In the case of stainless steel connected to a more noble metal, consideration must be given to the active-passive condition of the stainless steel. If the stainless steel is passive in the environment, galvanic interaction with a more noble metal is unlikely to produce significant corrosion. If the stainless steel is active or only marginally passive, galvanic interaction with a more noble metal will probably produce sustained rapid corrosion of the stainless steel without repassivation. The most important aspect of galvanic interaction for stainless steels is the necessity of selecting fasteners and weldments of adequate corrosion resistance relative to the bulk material, which is likely to have a much larger exposed area.

**Pitting** is a localized attack that can produce penetration of a stainless steel with almost negligible weight loss to the total structure. Pitting is associated with a local discontinuity of the passive film. It can be a mechanical imperfection, such as an inclusion or surface damage, or it can be a local chemical breakdown of the film. Chloride is the most common agent for initiation of pitting. Once a pit is formed, it in effect becomes a crevice; the local chemical environment is substantially more aggressive than the bulk environment. This explains why very high flow rates over a stainless steel surface tend to reduce pitting corrosion; the high flow rate prevents the concentration of corrosive species in the pit. The stability of the passive film with respect to resistance to pitting initiation is controlled primarily by chromium and molybdenum. Minor alloying elements can also have an important effect by influencing the amount and type of inclusions (for example, sulfides) in the steel that can act as pitting sites.

Pitting initiation can also be influenced by surface condition, including the presence of deposits, and by temperature. For a particular environment, a grade of stainless steel can be characterized by a single temperature, or a very narrow range of temperatures, above which pitting will initiate and below which pitting will not initiate. It is therefore possible to select a grade that will not be subject to pitting attack if the chemical environment and temperature do not exceed the critical levels. If the range of operating conditions can be accurately characterized, a meaningful laboratory evaluation is possible. Formation of deposits in service can reduce the pitting temperature. Figure 2 compares the relative resistance to pitting of a range of commercial stainless steels.

**Fig. 2** Effect of molybdenum content on the ferric chloride ( $\text{FeCl}_3$ ) critical pitting temperature of commercial stainless steels. The more resistant steels have higher critical pitting temperatures.

Although chloride is known to be the primary agent of pitting attack, it is not possible to establish a single critical chloride limit for each grade. The corrosivity of a particular concentration of chloride solution can be profoundly affected by the presence or absence of various other chemical species that may accelerate or inhibit corrosion. Chloride concentration can increase where evaporation or deposits occur. Because of the nature of pitting attack--rapid penetration with little total weight loss--it is rare that any significant amount of pitting will be acceptable in practical applications.

**Crevice corrosion** can be considered a severe form of pitting. Any crevice, whether the result of a metal-to-metal joint, a gasket, fouling, or deposits, tends to restrict oxygen access, resulting in attack. In practice, it is extremely difficult to prevent all crevices, but every effort should be made to do so. Higher-chromium, and especially higher-molybdenum, grades are more resistant to crevice attack. Just as there is a critical pitting temperature for a particular environment, there is also a critical crevice temperature (CCT). This temperature is specific to the geometry and nature of the crevice and to the precise corrosion environment for each grade. The CCT can be useful in selecting an adequately resistant grade for particular applications. Table 2 compares the CCT for duplex and austenitic steel grades. The more resistant grades have higher CCTs.

**Table 2 Comparison of critical crevice temperature (CCT) for duplex and austenitic stainless steels**

UNS No.	Alloy name	CCT in 10% FeCl <sub>3</sub> ·6H <sub>2</sub> O, pH = 1, 24 h exposure	
		°C	°F
Duplex grades			
S32900	Type 329	5	41
S31200	44LN	5	41
S31260	DP-3	10	50

<b>S32950</b>	7-Mo PLUS	15	60
<b>S31803</b>	2205	17.5	63.5
<b>S32250</b>	Ferralium 255	22.5	72.5
Austenitic grades			
<b>S30400</b>	Type 304	<-2.5	<27.5
<b>S31600</b>	Type 316	-2.5	27.5
<b>S31703</b>	Type 317L	0	32
<b>N08020</b>	20Cb-3	0	32
<b>N08366</b>	AL-6N	17.5	63.5
<b>N08367</b>	AL-6XN	32.5	90.5

**Intergranular corrosion** is a preferential attack at the grain boundaries of a stainless steel. It is generally the result of sensitization. This condition occurs when a thermal cycle leads to grain-boundary precipitation of a carbide, nitride, or intermetallic phase without providing sufficient time for chromium diffusion to fill the locally depleted region. A grain-boundary precipitate is not the point of attack; instead, the low-chromium region adjacent to the precipitate is susceptible.

Sensitization is not necessarily detrimental unless the grade is to be used in an environment capable of attacking the region. For example, elevated-temperature applications for stainless steel can operate with sensitized steel, but concern for intergranular attack must be given to possible corrosion during downtime when condensation might provide a corrosive medium. Because chromium provides corrosion resistance, sensitization also increases the susceptibility of chromium-depleted regions to other forms of corrosion, such as pitting, crevice corrosion, and SCC. The thermal exposures required to sensitize a steel can be relatively brief, as in welding, or can be very long, as in high-temperature service.

**Stress-corrosion cracking** is a corrosion mechanism in which the combination of a susceptible alloy, sustained tensile stress, and a particular environment leads to cracking of the metal. Stainless steels are particularly susceptible to SCC in chloride environments; temperature and the presence of oxygen tend to aggravate chloride SCC of stainless steels. Most ferritic and duplex stainless steels are either immune or highly resistant to SCC. All austenitic grades, especially AISI types 304 and 316, are susceptible to some degree. The highly alloyed austenitic grades are resistant to sodium chloride (NaCl) solutions but crack readily in  $MgCl_2$  solutions. Although some localized pitting or crevice corrosion probably precedes SCC, the amount of pitting or crevice attack can be so small as to be undetectable. Stress corrosion is difficult to detect while in progress, even when pervasive, and can lead to rapid catastrophic failures of pressurized equipment.

It is difficult to alleviate the environmental conditions that lead to SCC. The level of chlorides required to produce stress corrosion is very low. In operation, there can be evaporative concentration or a concentration in the surface film on a heat-rejecting surface. Temperature is often a process parameter, as in the case of a heat exchanger. Tensile stress is one parameter that might be controlled. However, the residual stresses associated with fabrication, welding, or thermal cycling, rather than design stresses, are often responsible for SCC, and even stress-relieving heat treatments do not completely eliminate these residual stresses.

**Erosion Corrosion.** Corrosion of a metal or alloy can be accelerated when there is an abrasive removal of the protective oxide layer. This form of attack is especially significant when the thickness of the oxide layer is an important factor in determining corrosion resistance. In the case of a stainless steel, erosion of the passive film can lead to some acceleration of attack.

**Oxidation.** Because of their high chromium contents, stainless steels tend to be very resistant to oxidation. Important factors to be considered in the selection of stainless steels for high-temperature service are the stability of the composition and microstructure of the grade upon thermal exposure and the adherence of the oxide scale upon thermal cycling. Because many of the stainless steels used for high temperatures are austenitic grades with relatively high nickel contents, it is also necessary to be alert to the possibility of sulfidation attack.

## **Corrosion in Specific Environments**

Selection of a suitable stainless steel for a specific environment requires consideration of several criteria. The first is corrosion resistance. Alloys are available that provide resistance to mild atmospheres (for example, type 430) or to many food-processing environments (for example, type 304 stainless). Chemicals and more severe corrodents require type 316 or a more highly alloyed material, such as 20Cb-3. Factors that affect the corrosivity of an environment include the concentration of chemical species, pH, aeration, flow rate (velocity), impurities (such as chlorides), and temperature, including effects from heat transfer.

The second criterion is mechanical properties, or strength. High-strength materials often sacrifice resistance to some form of corrosion, particularly SCC.

Third, fabrication must be considered, including such factors as the ability of the steel to be machined, welded, or formed. Resistance of the fabricated article to the environment must be considered--for example, the ability of the material to resist attack in crevices that cannot be avoided in the design.

Fourth, total cost must be estimated, including initial alloy price, installed cost, and the effective life expectancy of the finished product. Finally, consideration must be given to product availability.

## ***Atmospheric Corrosion***

The atmospheric contaminants most often responsible for the rusting of structural stainless steels are chlorides and metallic iron dust. Chloride contamination can originate from the calcium chloride ( $\text{CaCl}_2$ ) used to make concrete or from exposure in marine or industrial locations. Iron contamination can occur during fabrication or erection of the structure. Contamination should be minimized, if possible.

The corrosivity of different atmospheric exposures can vary greatly and can dictate application of different grades of stainless steel. Rural atmospheres, uncontaminated by industrial fumes or coastal salt, are extremely mild in terms of corrosivity for stainless steel, even in areas of high humidity. Industrial or marine environments can be considerably more severe.

Most grades of stainless steel are suitable for use in industrial atmospheres, although lower-chromium grades can be unsuitable for more severely contaminated atmospheres. Application often depends on the appearance required. Lower-chromium grades can fulfill service requirements but will tarnish severely. If appearance is important, type 430 is the lowest-alloy grade that can be used, and a higher-alloy grade usually is required.

In atmospheres free from chloride contamination, stainless steels have excellent corrosion resistance. Types 430, 302, 304, and 316 normally do not show even superficial rust. Some rusting can occur in marine atmospheres or in industrial exposures where surfaces become contaminated with chloride salts. Rusting is most likely to be severe on sheltered surfaces that are not well washed by rain.

Although marine environments can be severe, stainless steels often provide good resistance. Table 3 compares several AISI 300 series stainless steels after a 15 year exposure to a marine atmosphere 250 m (800 ft) from the ocean at Kure Beach, NC. Materials containing molybdenum exhibited only extremely slight rust stain, and all grades were easily cleaned to reveal a bright surface. Type 304 stainless steel can provide satisfactory resistance in many marine applications, but more highly alloyed grades are often selected when the stainless is sheltered from washing by the weather and is not cleaned regularly.

**Table 3 Corrosion of AISI 300 series stainless steels in a marine atmosphere**

AISI type	Average depth of pits		Appearance
	mm	mils	
<b>301</b>	0.04	1.6	Light rust and rust stain on 20% of surface
<b>302</b>	0.03	1.2	Spotted with rust stain on 10% of surface
<b>304</b>	0.028	1.1	Spotted with slight rust stain on 15% of surface
<b>321</b>	0.067	2.6	Spotted with slight rust stain on 15% of surface
<b>347</b>	0.086	3.4	Spotted with moderate rust stain on 20% of surface
<b>316</b>	0.025	1.0	Extremely slight rust stain on 15% of surface
<b>317</b>	0.028	1.1	Extremely slight rust stain on 20% of surface
<b>308</b>	0.04	1.6	Spotted by rust stain on 25% of surface
<b>309</b>	0.028	1.1	Spotted by slight rust stain on 25% of surface
<b>310</b>	0.01	0.4	Spotted by slight rust stain on 20% of surface

Based on 15 year exposures 250 m (800 ft) from the ocean at Kure Beach, NC. The average corrosion rate for all specimens tested

Type 302 and 304 stainless steels have had many successful architectural applications. Type 430 stainless steel has been used in many locations, but there have been problems. For example, type 430 stainless steel rusted in sheltered areas after exposure for only a few months in an industrial environment. The type 430 stainless steel was replaced by type 302, which provided satisfactory service. In more aggressive environments, such as marine or severely contaminated atmospheres, type 316 stainless steel is especially useful.

Stress-corrosion cracking is generally not a concern when austenitic or ferritic stainless steels are used in atmospheric exposures. Several austenitic stainless steels were exposed to a marine atmosphere at Kure Beach, NC. Annealed and quarter-hard wrought AISI types 201, 301, 302, 304, and 316 stainless steels were not susceptible to SCC. In the as-welded condition, only type 301 stainless steel experienced failure. Following sensitization at 650 °C (1200 °F) for 1.5 h and furnace cooling, failures were obtained only for materials with carbon contents of 0.043% or more. Stress-corrosion cracking must be considered when quench-hardened martensitic stainless steels or precipitation-hardening grades are used in marine environments or in industrial locations where chlorides are present.

Resistance to SCC is of particular interest in the selection of high-strength stainless steels for fastener applications. Cracking of high-strength fasteners is possible and often results from hydrogen generation due to corrosion or contact with a less noble materials, such as aluminum. Resistance to SCC can be improved by optimizing the heat treatment.

Fasteners for atmospheric exposure have been fabricated from a wide variety of alloys. Type 430 and unhardened type 410 stainless steels have been used when moderate corrosion resistance is required in a lower-strength material. Better-than-average corrosion resistance has been obtained by using type 305 and Custom Flo 302HQ (S30430 containing ~ 3.5% Cu) stainless steels when lower strength is acceptable.

## Corrosion in Waters

Waters can vary from extremely pure to chemically treated water to highly concentrated chloride solutions, such as brackish water or seawater, further concentrated by recycling. This chloride content poses the danger of pitting or crevice attack of stainless steels. When the application involves moderately increased temperatures, even as low as 45 °C (110 °F), and particularly when there is heat transfer into the chloride-containing medium, there is the possibility of SCC. It is useful to consider water with two general levels of chloride content: freshwater, which can have chloride levels up to approximately 600 ppm, and seawater, which encompasses brackish and severely contaminated waters. The corrosivity of a particular level of chloride can be strongly affected by the other chemical constituents present, making the water either more or less corrosive.

**In freshwater**, type 304 stainless steel has provided excellent service for such items as valve parts, weirs, fasteners, and pump shafts in water and wastewater treatment plants. Custom 450 stainless steel has been used as shafts for large butterfly valves in potable water. The higher strength of a precipitation-hardenable stainless steel permits reduced shaft diameter and increased flow. Type 201 stainless steel has seen service in revetment mats to reduce shoreline erosion in freshwater. Type 316 stainless steel has been used as wire for microstrainers in tertiary sewage treatment and is suggested for waters containing minor amounts of chloride.

**Seawater** is a very corrosive environment for many materials. Stainless steels are more likely to be attacked in low-velocity seawater or at crevices resulting from equipment design or attachment of barnacles. Type 304 and 316 stainless steels suffer deep pitting if the seawater flow rate decreases below approximately 1.5 m/s (5 ft/s) because of the crevices produced by fouling organisms.

The choice of stainless steel for seawater service can depend on whether or not stagnant conditions can be minimized or eliminated. For example, boat shafting of 17Cr-4Ni stainless steel has been used for trawlers where stagnant exposure and the associated pitting would not be expected to be a problem. When seagoing vessels are expected to lie idle for extended periods of time, more resistant boat shaft materials, such as 22Cr-13Ni-5Mn stainless steel, are considered. Boat shafts with intermediate corrosion resistance are provided by 18Cr-2Ni-12Mn and high-nitrogen type 304 (type 304HN) stainless steels.

The most severe exposure conditions are often used in seawater test programs. In one example of such data, flat-rolled specimens of eleven commercially available alloys with several mill finishes were exposed to seawater (Table 4). Triplicate samples were prepared with plastic multiple-crevice washers, each containing 20 plateaus or crevices. These washers were affixed to both sides of each panel by using a torque of either 2.8 or 8.5 N · m (25 or 75 in. · lb). The panels were exposed for up to 90 days in filtered seawater flowing at a velocity of less than 0.1 m/s (<0.33 ft/s).

**Table 4 Crevice corrosion indexes of several alloys in tests in filtered seawater**

Alloy	UNS designation	Number of sides (S) attacked <sup>(a)</sup>	Maximum pit depth (D)		Crevice corrosion index (S × D)
			mm	mils	
<b>AL-29-4C</b>	S44735	0	Nil	Nil	0
<b>MONIT</b>	S44635	3	0.01	0.4	0.03
<b>Ferralium 255</b>	S32550	1	0.09	3.5	0.09

<b>Alloy 904L</b>	N08904	3	0.37	14.6	1.1 <sup>(b)</sup>
<b>254SMO</b>	S31254	6	0.19	7.5	1.1
<b>Sea-Cure</b>	S44660	14	0.11	4.3	1.5
<b>AL-6X</b>	N08366	8	0.34	13.4	2.7
<b>JS777</b>	...	6	2.3	90.6	14 <sup>(b)</sup>
<b>JS700</b>	N08700	14	1.8	70.9	24
<b>AISI type 329</b>	...	17	1.6	63	28 <sup>(c)</sup>
<b>Nitronic 50</b>	S20910	17	1.2	47.2	20

Mill-finished panels exposed for 30, 60, and 90 days to seawater at 30 °C (85 °F) flowing at <0.1 m/s (<0.33 ft/s). Crevice washers tightened to 2.8 or 8.5 N · m (25 or 75 in. · lb).

(a) Total number of sides was 18.

(b) Also showed tunneling attack perpendicular to the upper edge, or attack at edges.

(c) Perforated by attack from both sides

The results given in Table 4 show the number of sides that experienced crevice attack and the maximum attack depth at any crevice for that alloy. A crevice corrosion index (CCI) was calculated by multiplying the maximum attack depth times the number of sides attacked. This provided a ranking system that accounts for both initiation and growth of attack. Lower values of the CCI imply improved resistance.

Attack in the previously mentioned test does not mean that materials with high CCIs cannot be used in seawater. For example, 22Cr-13Ni-5Mn stainless steel with a CCI of 20 has proved to be a highly resistant boat shaft alloy. Some of the more resistant materials in the previously mentioned tests have been used for utility condenser tubing. These alloys include MONIT, AL-29-4C, 254SMO, Sea-Cure, and AL-6XN.

The possibility of galvanic corrosion must be considered if stainless steel is to be used in contact with other metals in seawater. Preferably, only those materials that exhibit closely related electrode potentials should be coupled to avoid attack of the less noble material. Galvanic differences have been used to advantage in the cathodic protection of stainless steel in seawater. Crevice corrosion and pitting of austenitic type 302 and 316 stainless steels have been prevented by cathodic protection, but type 410 and 430 stainless steels develop hydrogen blisters at current densities below those required for complete protection.

Other factors that should be noted when applying stainless steels in seawater include the effects of high velocity, aeration, and temperature. Stainless steels generally show excellent resistance to high velocities, impingement attack, and cavitation in seawater. Also, stainless steels provide optimum service in aerated seawater because a lack of aeration at a specific site often leads to crevice attack. Very little oxygen is required to maintain the passive film on a clean stainless surface. Increasing the temperature from ambient to approximately 50 °C (120 °F) often reduces attack of stainless steels, possibly because of differences in the amount of dissolved oxygen, changes in the surface film, or changes in the

resistance of the boldly exposed sample area. Further temperature increases can result in increased corrosion, such as SCC.

### ***Selection Criteria for Chemical Environments***

Selection of stainless steels for service in chemicals requires consideration of all forms of corrosion, along with impurity levels and degree of aeration. When an alloy with sufficient general corrosion resistance has been selected, care must be taken to ensure that the material will not fail by pitting or SCC due to chloride contamination. Aeration can be an important factor in corrosion, particularly in cases of borderline passivity. If dissimilar-metal contact or stray currents occur, the possibility of galvanic attack or hydrogen embrittlement must be considered.

Alloy selection also depends on fabrication and operation details. If a material is to be used in the as-welded or stress-relieved condition, it must resist intergranular attack in service after these thermal treatments. In chloride environments, the possibility of crevice corrosion must be considered when crevices are present because of equipment design or the formation of adherent deposits. Higher flow rates can prevent the formation of deposits, but in extreme cases can also cause accelerated attack due to erosion or cavitation. Increased operating temperatures generally increase corrosion. In heat transfer applications, higher metal wall temperatures result in higher rates than expected from the lower temperature of the bulk solution.

Some generalizations can be made regarding the performance of various categories of stainless steels in certain types of chemical environments. These observations relate to the compositions of the grades. For example, the presence of nickel and copper in some austenitic grades greatly enhances resistance to  $\text{H}_2\text{SO}_4$  compared to the resistance of the ferritic grades. However, combinations of chemicals that are encountered in practice can be either more or less corrosive than might be expected from the corrosivity of the individual components. Testing in actual or simulated environments is always recommended as the best procedure for selecting a stainless steel grade. Additional information describing service experience is available from alloy suppliers.

### ***Corrosion in Mineral Acids***

The resistance of stainless steel to acids depends on the hydrogen ion ( $\text{H}^+$ ) concentration and the oxidizing capacity of the acid, along with such material variables as chromium content, nickel content, carbon content, and heat treatment. For example, annealed stainless steel resists strong  $\text{HNO}_3$  in spite of the low pH of the acid, because  $\text{HNO}_3$  is highly oxidizing and forms a passive film due to the chromium content of the alloy. Conversely, stainless steels are rapidly attacked by strong  $\text{HCl}$  because a passive film is not easily attained. Even in strong  $\text{HNO}_3$ , stainless steels can be rapidly attacked if they contain sufficient carbon and are sensitized. Oxidizing species, such as ferric salts, result in reduced general corrosion in some acids, but can cause accelerated pitting attack if chloride ions ( $\text{Cl}^-$ ) are present.

**Nitric Acid.** As noted previously, stainless steels have broad applicability in  $\text{HNO}_3$  primarily because of their chromium content. Most AISI 300 series stainless steels exhibit good or excellent resistance in the annealed condition in concentrations from 0 to 65% up to the boiling point. Figure 3 illustrates the good resistance of type 304 stainless steel, particularly when compared with the lower-chromium type 410 stainless steel. More severe environments at elevated temperatures require alloys with higher chromium. In  $\text{HNO}_3$  cooler-condensers, such stainless alloys as 7-Mo PLUS (UNS S32950) and 2RE10 (UNS S31008), are candidates for service.

**Fig. 3** Corrosion rates of various stainless steels in boiling HNO<sub>3</sub>

**In sulfuric acid**, stainless steels can approach the borderline between activity and passivity. Conventional ferritic grades, such as type 430, have limited use in H<sub>2</sub>SO<sub>4</sub>, but the newer ferritic grades containing higher chromium and molybdenum (for example, 28% Cr and 4% Mo) with additions of at least 0.25% Ni have shown good resistance in boiling 10% H<sub>2</sub>SO<sub>4</sub>, but corrode rapidly when acid concentration is increased.

The conventional austenitic grades exhibit good resistance in very dilute or highly concentrated H<sub>2</sub>SO<sub>4</sub> at slightly elevated temperatures. Acid of intermediate concentration is more aggressive, and conventional grades have very limited utility. Figure 4 shows resistance of several stainless steels in up to approximately 50% H<sub>2</sub>SO<sub>4</sub>. Aeration or the addition of oxidizing species can significantly reduce the attack of stainless steels in H<sub>2</sub>SO<sub>4</sub>. This occurs because the more oxidizing environment is better able to maintain the chromium-rich passive oxide film.

Fig. 4 Corrosion rates of various stainless steels in unaerated H<sub>2</sub>SO<sub>4</sub> at 20 °C (70 °F)

Improved resistance to H<sub>2</sub>SO<sub>4</sub> has been obtained by using austenitic grades containing high levels of nickel and copper, such as 20Cb-3 stainless steel. In addition to reducing general corrosion, the increased nickel provides resistance to SCC. Because of resistance to these forms of corrosion, 20Cb-3 stainless steel has been used for valve springs in H<sub>2</sub>SO<sub>4</sub> service.

**Phosphoric Acid.** Conventional straight-chromium stainless steels have very limited general corrosion resistance in phosphoric acid (H<sub>3</sub>PO<sub>4</sub>) and exhibit lower rates only in very dilute or more highly concentrated solutions. Conventional austenitic stainless steels provide useful general corrosion resistance over the full range of concentrations up to approximately 65 °C (150 °F); use at temperatures up to the boiling point is possible for acid concentrations up to approximately 40%.

In commercial applications, however, wet-process H<sub>3</sub>PO<sub>4</sub> environments include impurities derived from the phosphate rock, such as chlorides, fluorides, and H<sub>2</sub>SO<sub>4</sub>. These three impurities accelerate corrosion, particularly pitting or crevice corrosion in the presence of the halogens. Higher-alloyed materials than the conventional austenitic stainless steels are required to resist wet-process H<sub>3</sub>PO<sub>4</sub>. Candidate materials include alloy 904L, alloy 28, 20Cb-3, 20Mo-4, and 20Mo-6 stainless steels.

**Hydrochloric Acid.** Stainless steels are generally not used for HCl service, except perhaps for very dilute solutions at room temperature. Stainless materials can be susceptible to accelerated general corrosion, SCC, and pitting in HCl environments.

**Sulfurous Acid.** Although sulfurous acid (H<sub>2</sub>SO<sub>3</sub>) is a reducing agent, several stainless steels have provided satisfactory service in H<sub>2</sub>SO<sub>3</sub> environments. Conventional austenitic stainless steels have been used in sulfite digestors, and type 316, type 317, and 20Cb-3 have seen service in wet sulfur dioxide (SO<sub>2</sub>) and H<sub>2</sub>SO<sub>3</sub> environments. Service life is improved by eliminating crevices, including those from settling of suspended solids, or by using molybdenum-containing grades. In some environments, SCC is also a possibility.

**Hydrofluoric Acid.** Only austenitic stainless steels are recommended for use in hydrofluoric acid (HF), and even these materials have limited resistance to dilute HF. Type 304 has poor resistance to any significant concentration, but type 316 has useful resistance at ambient temperatures and concentrations below 10%. Cold-worked materials--for example type

303 used as a fastener material--have failed rapidly in HF plants. Annealed austenitic stainless steels are also susceptible to SCC in HF environments. Higher alloys such as 20Cb-3 have good resistance to all concentrations of HF at ambient temperatures and to 0 to 10% concentrations at 70 °C (160 °F).

### Corrosion in Organic Acids and Compounds

Organic acids and compounds are generally less aggressive than mineral acids because they do not ionize as completely, but they can be corrosive to stainless steels, especially when impurities are present. The presence of oxidizing agents in the absence of chlorides can reduce corrosion rates.

**Acetic Acid.** Table 5 lists corrosion rates for several stainless steels in acetic acid. Resistance to pure acetic acid has been obtained by using type 316 and 316L stainless steels over all concentrations up to the boiling point. Type 304 stainless steel can be considered in all concentrations below approximately 90% at temperatures up to the boiling point. Impurities present in the manufacture of acetic acid, such as acetaldehyde, formic acid, chlorides, and propionic acid, are expected to increase the attack of stainless steels. Chlorides can cause pitting or SCC.

**Table 5 Corrosion of austenitic stainless steels in boiling glacial acetic acid**

AISI type	Corrosion rate	
	mm/yr	mils/yr
304	0.46	18
321	1.19	47
347	1.04	41
308	1.35	53
310	0.99	39
316	0.015	0.6

**Formic acid** is one of the more aggressive organic acids, and corrosion rates can be higher in the condensing vapor than in the liquid. Type 304 stainless steel has been used at moderate temperatures. However, type 316 stainless steel or higher alloys, such as 20Cb-3, are often preferred, and high-alloy ferritic stainless steels containing 26% Cr and 1% Mo or 29% Cr and 4% Mo also show some promise.

**Other Organic Acids.** The corrosivity of propionic and acrylic acids at a given temperature is generally similar to that of acetic acid. Impurities are important and can strongly affect the corrosion rate. In citric and tartaric acids, type 304 stainless steel has been used for moderate temperatures, and type 316 has been suggested for all concentrations up to the boiling point.

**Organic Halides.** Most dry organic halides do not attack stainless steels, but the presence of water allows halide acids to form and can cause pitting or SCC. Therefore, care should be exercised when using stainless steels in organic halides to ensure that water is excluded.

**Other Organic Compounds.** Type 304 stainless steel has generally been satisfactory in aldehydes, in cellulose acetate at lower temperatures, and in fatty acids up to approximately 150 °C (300 °F). At higher temperatures, these chemicals require type 316 or 317. Type 316 stainless steel is also used in amines, phthalic anhydride, tar, and urea service.

Stainless steels have been used in the plastic and synthetic fiber industries. Type 420 and 440C stainless steels have been used as plastic mold steels. More resistant materials, such as Custom 450, have been used for extruding polyvinyl chloride (PVC) pipe. Spinnerettes, pack parts, and metering pumps of Custom 450 and Custom 455 stainless steels have been used in the synthetic fiber industry to produce nylon, rayon, and polyesters.

### ***Corrosion in Foods and Beverages***

Stainless steels have been relied on in the food and beverage industry because of the lack of corrosion products that could contaminate the process environment and because of the superior cleanability of the stainless steels. The corrosion environment often involves moderately to highly concentrated chlorides on the process side, often mixed with significant concentrations of organic acids. The water side can range from steam heating to brine cooling. Purity and sanitation standards require excellent resistance to pitting and crevice corrosion.

Foods such as vegetables represent milder environments and can generally be handled by using type 304 stainless steel. Sauces and pickle liquors, however, are more aggressive and can pit even type 316 stainless steel. For improved pitting resistance, such alloys as 22Cr-13Ni-5Mn, 904L, 20Mo-4, 254SMO, Al-6XN, and MONIT stainless steels should be considered.

At elevated temperatures, materials must be selected for resistance to pitting and SCC in the presence of chlorides. Stress corrosion must be avoided in heat transfer applications, such as steam jacketing for cooking or processing vessels or in heat exchangers. Cracking can occur from the process or water side or can initiate outside the unit under chloride-containing insulation. Brewery applications of austenitic stainless steels have been generally successful except for a number of cases of SCC of high-temperature water lines. The use of ferritic or duplex stainless steels is an appropriate remedy for the SCC.

Stainless steel equipment should be cleaned frequently to prolong service life. The equipment should be flushed with fresh water, scrubbed with a nylon brush and detergent, then rinsed. On the other hand, consideration should be given to the effect of very aggressive cleaning procedures on the stainless steels, as in the chemical sterilization of commercial dishwashers. In some cases, it may be necessary to select a more highly alloyed stainless steel grade to deal with these brief exposures to highly aggressive environments.

Conventional AISI grades provide satisfactory service in many food and beverage applications. Type 304 stainless steel is widely used in the dairy industry, and type 316 finds application as piping and tubing in breweries. These grades, along with type 444 and Custom 450 stainless steels, have been used for chains to transfer food through processing equipment. Machined parts for beverage-dispensing equipment have been fabricated from type 304, 304L, 316, 316L, and 303Al MODIFIED, 302HQ-FM, and 303BV stainless steels. When the free-machining grades are used, it is important to passivate and rinse properly before service in order to optimize corrosion resistance.
