Food-handling equipment should be designed without crevices in which food can become lodged. In more corrosive food products, extra-low-carbon stainless steels should be used when possible. Improved results have been obtained when equipment is finished with a 2B (general-purpose cold-rolled) finish rather than No. 4 (general-purpose polished) finish. Alternatively, an electropolished surface may be considered.

### ***Corrosion in Alkalies***

All stainless steels resist general corrosion by all concentrations of sodium hydroxide (NaOH) up to approximately 65 °C (150 °F). Type 304 and 316 stainless steels exhibit low rates of general corrosion in boiling NaOH up to nearly 20% concentration. Stress-corrosion cracking of these grades can occur at approximately 100 °C (212 °F). Good resistance to general corrosion and SCC in 50% NaOH at 135 °C (275 °F) is provided by E-Brite and 7-Mo stainless steels. In ammonia (NH<sub>3</sub>) and ammonium hydroxide (NH<sub>4</sub>OH), stainless steels have shown good resistance at all concentrations up to the boiling point.

### ***Corrosion in Salts***

Stainless steels are highly resistant to most neutral or alkaline nonhalide salts. In some cases, type 316 is preferred for its resistance to pitting, but even the higher-molybdenum type 317 stainless steel is readily attacked by sodium sulfide (Na<sub>2</sub>S) solutions.

**Halogen salts** are more corrosive to stainless steels because of the ability of the halide ions to penetrate the passive film and cause pitting. Pitting is promoted in aerated or mildly acidic oxidizing solutions. Chlorides are generally more aggressive than the other halides in their ability to cause pitting.

### ***Corrosion in Gases***

**Chlorine and Fluorine Gas.** At lower temperatures, most austenitic stainless steels resist chlorine or fluorine gas if the gas is completely dry. The presence of even small amounts of moisture results in accelerated attack, especially pitting and possibly SCC.

**Oxidation.** At elevated temperatures, stainless steels resist oxidation primarily because of their chromium content. Increased nickel minimizes spalling when temperature cycling occurs. Table 6 lists generally accepted maximum safe service temperatures for wrought stainless steels. Maximum temperatures for intermittent service are lower for the austenitic stainless steels, but are higher for most of the martensitic and ferritic stainless steels listed.

**Table 6 Generally accepted maximum service temperatures in air for AISI stainless steels**

AISI type	Maximum service temperature			
	Intermittent service		Continuous service

<b>440</b>	815	1500	760	1400

Contamination of the air with water and CO<sub>2</sub> often increases corrosion at elevated temperatures. Increased attack can also occur because of sulfidation as a result of sulfur dioxide, hydrogen sulfide, or sulfur vapor.

**Carburization** of stainless steels can occur in carbon monoxide (CO), methane (CH<sub>4</sub>), and other hydrocarbons. Carburization can also occur when stainless steels contaminated with oil or grease are annealed without sufficient oxygen to burn off the carbon. This can occur during vacuum or inert gas annealing as well as open air annealing of oily parts with shapes that restrict air access. Chromium, silicon, and nickel are useful in combating carburization.

**Nitriding** can occur in dissociated ammonia (NH<sub>3</sub>) at high temperatures. Resistance to nitriding depends on alloy composition as well as NH<sub>3</sub> concentration, temperature, and pressure. Stainless steels are readily attacked in pure NH<sub>3</sub> at approximately 540 °C (100 °F).

### ***Corrosion in Liquid Metals***

The 18-8 stainless steels are highly resistant to liquid sodium or sodium-potassium alloys. Mass transfer is not expected up to 540 °C (1000 °F) and remains at moderately low levels up to 870 °C (1600 °F). Accelerated attack of stainless steels in liquid sodium occurs with oxygen contamination, with a noticeable effect occurring at approximately 0.02% oxygen by weight.

Exposure to molten lead under dynamic conditions often results in mass transfer in common stainless alloy systems. Particularly severe corrosion can occur in strongly oxidizing conditions. Stainless steels are generally attacked by molten aluminum, zinc, antimony, bismuth, cadmium, and tin.

# Cast Stainless Steels

## Introduction

CAST STAINLESS STEELS are widely used for their corrosion resistance in aqueous media at or near room temperature and for service in hot gases and liquids at elevated temperatures. These high-alloy cast steels generally have more than 10% Cr and primarily consist of stainless steel. Stainless steel castings are usually classified as either corrosion-resistant castings (which are used in aqueous environments below 650 °C, or 1200 °F) or heat-resistant castings (which are suitable for service temperatures above 650 °C, or 1200 °F). However, this line of demarcation in terms of application is not always distinct, particularly for steel castings used in the range from 480 to 650 °C (900 to 1200 °F). The usual distinction between heat-resistant and corrosion-resistant cast steels is based on carbon content, with the heat-resistant grades normally having higher carbon contents.

## Comparison of Cast and Wrought Grades

In general, the cast and wrought stainless steels possess equivalent resistance to corrosive media, and they are frequently used in conjunction with each other. Important differences do exist, however, between some cast stainless steels and their wrought counterparts.

**Benefits of Ferrite Content.** One significant difference between cast and wrought grades is in the microstructure of cast austenitic stainless steels. There is usually a small amount of ferrite present in austenitic stainless steel castings, in contrast to the single-phase austenitic structure of the wrought alloys. The presence of ferrite in the castings is desirable for facilitating weld repair, but ferrite also increases resistance to stress-corrosion cracking (SCC). There have been only a few SCC failures with cast stainless steels in comparison to the approximately equivalent wrought compositions. The principal reasons for this resistance are apparently that silicon added for fluidity gives added benefit from the standpoint of SCC, and that sand castings are usually tumbled or sandblasted to remove molding sand and scale, which probably tends to put the surface in compression.

**Ferrite can be detrimental** in some applications. One concern may be the reduced toughness from ferrite, although this is not a major concern, given the extremely high toughness of the austenite matrix. A much greater concern is for applications that require exposure to elevated temperatures, usually 315 °C (600 °F) and higher, where the metallurgical changes associated with the ferrite can be severe and detrimental. In applications requiring that these steels be heated in the range from 425 to 650 °C (800 to 1200 °F), carbide precipitation occurs at the edges of the ferrite pools in preference to the austenite grain boundaries. When the steel is heated above 540 °C (1000 °F), the ferrite pools transform to a  $\sigma$ - or  $\chi$ -phase. If these pools are distributed in such a way that a continuous network is formed, embrittlement or a network of corrosion penetration can result. Also, if the amount of ferrite is too great, the ferrite can form continuous stringers where corrosion can take place, producing a condition similar to grain boundary attack.

**Ferrite Control.** The major elemental components of cast stainless steels are in competition to promote austenite or ferrite phases in the alloy microstructure. Chromium, silicon, molybdenum, and niobium promote the presence of ferrite in the alloy microstructure; nickel, carbon, nitrogen, and manganese promote the presence of austenite. By balancing the contents of ferrite- and austenite-forming elements within the specified ranges for the elements in a given alloy, it is possible to control the amount of ferrite present in the austenitic matrix. The alloy can usually either be made fully austenitic or be given ferrite contents up to 30% or more in the austenite matrix.

**Property Comparisons.** Wrought and cast stainless steels may also differ in mechanical properties, magnetic properties, and chemical content. Because of the possible existence of large dendritic grains, intergranular phases, and

alloy segregation, typical mechanical properties of cast stainless steels can vary more and generally are inferior to those of any wrought structure.

## Grade Designations and Compositions

Cast stainless steels are most often specified on the basis of composition using the designation system of the High Alloy Product Group of the Steel Founders' Society of America. (The High Alloy Product Group has replaced the Alloy Casting Institute, or ACI, which formerly administered these designations.) The first letter of the designation indicates whether the alloy is intended primarily for liquid corrosion service (C) or high-temperature service (H). The second letter denotes the nominal chromium-nickel type of the alloy (Fig. 1). As nickel content increases, the second letter of the designation is changed. The numeral or numerals following the first two letters indicate maximum carbon content (percentage  $\times 100$ ) of the alloy. Finally, if further alloying elements are present, these are indicated by the addition of one or more letters as a suffix. Thus, the designation of CF-8M refers to an alloy for corrosion-resistant service (C) of the 19Cr-9Ni type (Fig. 1), with a maximum carbon content 0.08% and containing molybdenum (M). Similarly, the designation HK-40 refers to an alloy for heat-resistant service (H) of the 26Cr-20Ni type (Fig. 1), with a maximum carbon content of 0.40%.

Fig. 1 Chromium and nickel contents in ACI standard grades of heat- and corrosion-resistant steel castings. See text for details.

Some of the high-alloy cast steels exhibit many of the same properties of cast carbon and low-alloy steels. Some of the mechanical properties of these grades (for example, hardness and tensile strength) can be altered by a suitable heat treatment. The cast high-alloy grades that contain more than 20 to 30% Cr plus nickel, however, do not show the phase changes observed in plain carbon and low-alloy steels during heating or cooling between room temperature and the melting point. These materials are therefore nonhardenable, and their properties depend on composition rather than heat treatment. Therefore, special consideration must be given to each grade of high-alloy cast steel with regard to casting design, foundry practice, and subsequent thermal processing (if any).

## Corrosion-Resistant Steel Castings

**Compositions.** The C-type steel castings for liquid corrosion service are often classified on the basis of composition, although it should be recognized that classification by composition often involves microstructural distinction.

Table 1 lists the compositions of the commercial cast corrosion-resistant alloys. Alloys are grouped as chromium steels, chromium-nickel steels (in which chromium is the predominant alloying element), and nickel-chromium steels (in which nickel is the predominant alloying element).

(a) Type numbers of wrought alloys are listed only for nominal identification of corresponding wrought and cast grades. Composition ranges of cast alloys are not the same as for corresponding wrought alloys; cast alloy designations should be used for castings only.

(b) M, martensite; F, ferrite; C, carbides; AH, age hardenable; A, austenite.

(c) Maximum unless a range is given. The balance of all compositions is iron.

(d) Sulfur content is 0.04% in all grades except: CG-6MMN, 0.030% S (max); CF-10SMnN, 0.03% S (max); CT-15C, 0.03% S (max); CK-3MCuN, 0.010% S (max); CN-3M, 0.030% S (max), CA-6N, 0.020% S (max); CA-28MWV, 0.030% S (max); CA-40F, 0.20-0.40% S; CB-7Cu-1 and -2, 0.03% S (max). Phosphorus content is 0.04% (max) in all grades except: CF-16F, 0.17% P (max); CF-10SMnN, 0.060% P (max); CT-15C, 0.030% P (max); CK-3MCuN, 0.045% P (max); CN-3M, 0.030% P (max); CA-6N, 0.020% P (max); CA-28MWV, 0.030% P (max); CB-7Cu-1 and -2, 0.035% P (max).

(e) Molybdenum not intentionally added.

- (f) CF-3A, CF-3MA, and CF-8A have the same composition ranges as CF-3, CF-3M, and CF-8, respectively, but have balanced compositions so that ferrite contents are at levels that permit higher mechanical property specifications than those for related grades. They are covered by ASTM A 351.
- (g) Nb,  $8 \times \%C$  min (1.0% max); or Nb + Ta  $\times \%C$  (1.1% max).
- (h) For CN-7MS, silicon ranges from 2.50 to 3.50%.

The serviceability of cast corrosion-resistant steels depends greatly on the absence of carbon, and especially precipitated carbides, in the alloy microstructure. Therefore, cast corrosion-resistant alloys are generally low in carbon (usually lower than 0.20% and sometimes lower than 0.03%).

All cast corrosion-resistant steels contain more than 11% Cr, and most contain from 1 to 30% Ni (a few have less than 1% Ni). About two-thirds of the corrosion-resistant steel castings produced in the United States are of grades that contain 18 to 22% Cr and 8 to 12% Ni.

In general, the addition of nickel to iron-chromium alloys improves ductility and impact strength. An increase in nickel content increases resistance to corrosion by neutral chloride solutions and weakly oxidizing acids.

The addition of molybdenum increases resistance to pitting attack by chloride solutions. It also extends the range of passivity in solutions of low oxidizing characteristics.

The addition of copper to duplex (ferrite in austenite) nickel-chromium alloys produces alloys that can be precipitation hardened to higher strength and hardness. The addition of copper to single-phase austenitic alloys greatly improves their resistance to corrosion by sulfuric acid. In all Fe-Cr-Ni stainless alloys, resistance to corrosion by environments that cause intergranular attack can be improved by lowering the carbon content.

**Room-Temperature Mechanical Properties.** Table 2 gives representative room-temperature tensile properties, hardness, and Charpy impact values for corrosion-resistant cast steels. These properties are representative of the alloys rather than the specification requirements. Minimum specified mechanical properties for these alloys are given in ASTM A 351, A 743, A 744, and A 747. A wide range of mechanical properties are attainable, depending on the selection of alloy composition and heat treatment. Tensile strengths ranging from 475 to 1310 MPa (69 to 190 ksi) and hardnesses from 130 to 400 HB are available among the cast corrosion-resistant alloys. Similarly, wide ranges exist in yield strength, elongation, and impact toughness.

**Table 2 Room-temperature mechanical properties of cast corrosion-resistant alloys**

Alloy	Heat treatment <sup>(a)</sup>	Tensile strength		Yield strength (0.2% offset)		Elongation in 50 mm (2 in.), %	Reduction in area, %	Hardness, HB	Charpy impact energy

**Corrosion Characteristics.** As stated earlier, the corrosion characteristics of cast and wrought stainless steels are quite similar (refer to the article "Corrosion of Wrought Stainless Steels" in this Section). Table 3 compares the general corrosion resistance of the C-type cast steels.

**Table 3 Summary of applications for various corrosion-resistant cast steels**

Alloy	Characteristics
<b>CA-15</b>	Widely used in mildly corrosive environments; hardenable; good erosion resistance
<b>CA-40</b>	Similar to CA-15 at higher strength level
<b>CA-6NM</b>	Improved properties over CA-15, especially improved resistance to cavitation
<b>CA-6N</b>	Outstanding combinations of strength, toughness, and weldability with moderately good corrosion resistance
<b>CB-30</b>	Improved performance in oxidizing environments compared to CA-15; excellent resistance to corrosion by nitric acid, alkaline solutions, and many organic chemicals
<b>CB-7Cu-1</b>	Hardenable with good corrosion resistance
<b>CB-7Cu-2</b>	Superior combination of strength, toughness, and weldability with moderately good corrosion resistance
<b>CC-50</b>	Used in highly oxidizing media (hot HNO <sub>3</sub> , acid mine waters)
<b>CD-4MCu</b>	Similar to CF-8 in corrosion resistance, but higher strength, hardness, and stress-corrosion cracking resistance; excellent resistance to environments involving abrasion or erosion corrosion; usefully employed in handling both oxidizing and reducing corrodents
<b>CE-30</b>	Similar to CC-50, but nickel imparts higher strength and toughness levels. A grade available with controlled ferrite

<b>CF-3, CF-8, CF-20, CF-3M, CF-8M, CF-8C, CF-16F</b>	CF types; most widely used corrosion-resistant alloys at ambient and cryogenic temperatures M variations: enhanced resistance to halogen ion and reducing acids C and F variations: used where application does not permit postweld heat treat
<b>CG-8M</b>	Greater resistance to pitting and corrosion in reducing media than CF-8M; not suitable for nitric acids or other strongly oxidizing environments
<b>CH-20</b>	Superior to CF-8 in specialized chemical and paper applications in resistance to hot H <sub>2</sub> SO <sub>3</sub> , organic acids, and dilute H <sub>2</sub> SO <sub>4</sub> ; the high nickel and chromium contents also make this alloy less susceptible to intergranular corrosion after exposure to carbide-precipitating temperatures
<b>CK-20</b>	Improved corrosion resistance compared to CH-20
<b>CN-7M</b>	Highly resistant to H <sub>2</sub> SO <sub>4</sub> , H <sub>3</sub> PO <sub>4</sub> , H <sub>2</sub> SO <sub>3</sub> , salts, and seawater. Good resistance to hot chloride salt solutions, nitric acid, and many reducing chemicals

### Heat-Resistant Steel Castings

As previously mentioned, castings are classified as heat resistant if they are capable of sustained operation while exposed, either continuously or intermittently, to operating temperatures that result in metal temperatures in excess of 650 °C (1200 °F). The major difference between heat-resistant alloys and their corrosion-resistant counterparts is their carbon content. With only a few exceptions, carbon in the cast heat-resistant alloys falls in a range from 0.3 to 0.6%, compared with 0.01 to 0.25% C normally associated with the wrought and cast corrosion-resistant grades. This difference in carbon results in significant changes in properties, for example, the increased carbon content imparts higher creep-rupture strength in the cast heat-resistant steels.

Table 4 lists the compositions of standard cast heat-resistant grades. These materials, which are also recognized in ASTM specifications, fall in a range of 0 to 68% Ni and 8 to 32% Cr with the balance consisting of iron plus up to 2.5% Si and 2.0% Mn.

- (a) Type numbers of wrought alloys are listed only for nominal identification of corresponding wrought and cast grades. Composition ranges of cast alloys are not the same as for corresponding wrought alloys; cast alloy designations should be used for castings only.
- (b) Balance Fe in all compositions. Manganese content: 0.35 to 0.65% for HA, 1% for HC, 1.5% for HD, and 2% for the other alloys. Phosphorus and sulfur contents: 0.04% (max) for all but HP-50WZ. Molybdenum is intentionally added only to HA, which has 0.90 to 1.20% Mo; maximum for other alloys is set at 0.5% Mo. HH also contains 0.2% N (max).
- (c) Also contains 4 to 6% W, 0.1 to 1.0% Zr, and 0.035% S (max) and P (max)

Standard heat-resistant alloys can also be simply classified on the basis of structure alone. Grades HA and HC with 8 to 30% Cr and up to 4% Ni are ferritic. Grades HD, HE, HF, and HH may exhibit duplex structures of ferrite and austenite, while the remaining alloys HK to HX are fully austenitic.

A third alternative classification is based on the order of increasing quantity of major elements, which breaks down into the following four groups:

- Iron-chromium
- Iron-chromium-nickel

- Iron-nickel-chromium
- Nickel-iron-chromium

**Iron-Chromium Alloys.** The three alloys normally considered in this group are HA, HC, and HD, although only the first of these is technically an iron-chromium alloy. The other two grades contain 26 to 30% Cr and up to 7% Ni. These grades are mainly used in environments containing sulfur-bearing gases, where high-temperature strength is not an important consideration.

**Iron-Chromium-Nickel Alloys.** Alloys in this group contain 18 to 32% Cr and 8 to 22% Ni, with chromium always exceeding nickel, and include the grades HE, HF, HH, HI, HK, and HL. While these alloys are considered to be austenitic, the lower nickel compositions will contain some ferrite. Transformation of the ferrite to brittle  $\sigma$  phase is a concern with this group, even in the higher nickel grades, particularly if their compositional balance leans to ferrite. The high-temperature strength of this group is greater than that of the iron-chromium alloys, and their creep and rupture strengths increase as nickel is raised.

**Iron-Nickel-Chromium Alloys.** The four standard grades in this group, HN, HP, HT, and HU, contain 15 to 28% Cr and 23 to 41% Ni. Nickel always exceeds the chromium content. These alloys have stable austenitic structures, good high-temeprature strength, and enhanced resistance to thermal cycling and thermal stresses, combined with high resistance to oxidizing and reducing environments.

**Nickel-Iron-Chromium Alloys.** Two standard grades, HX and HW, fall into this group, which contains 58 to 68% Ni and 10 to 19% Cr. Usually referred to as high-alloy steels, these materials are more correctly described as nickel-base alloys. While possessing moderate high-temperature rupture strength, their creep strength is low. These grades have the highest carburization resistance of the standard alloys.

**Nonstandard Grade Compositions.** Nonstandard (proprietary) grades of heat-resistant alloys are generally more highly alloyed. Single or multiple additions of the elements aluminum, cobalt (up to 15%), molybdenum (0.5 to 1.5%), niobium (0.5 to 1.5%), the rare earth metals (cerium, lanthanum, and yttrium), titanium (0.1 to 0.3%), tungsten (generally 1 to 5%, but as high as 16%), and zirconium are added to enhance specific properties, such as high-temperature strength, carburization resistance, and resistance to thermal cycling.

**General Properties.** Table 5 gives typical room-temperature tensile properties of heat-resistant steels castings, creep properties of selected alloys are listed in Table 6, and high-temperature corrosion characteristics are compared in Table 7. Minimum specified mechanical properties for these alloys are given in ASTM A 297, A 351, A 447, and A 608.

**Table 7 General corrosion characteristics of heat-resistant cast steels**

Alloy	Corrosion characteristics
<b>HA</b>	Good oxidation resistance to 650 °C (1200 °F); widely used in oil refining industry
<b>HC</b>	Good sulfur and oxidation resistance up to 1095 °C (2000 °F); minimal mechanical properties; used in applications where strength is not a consideration or for moderate load bearing up to 650 °C (1200 °F)
<b>HD</b>	Excellent oxidation and sulfur resistance plus weldability
<b>HE</b>	Higher temperature and sulfur resistant capabilities than HD
<b>HF</b>	Excellent general corrosion resistance to 815 °C (1500 °F) with moderate mechanical properties

<b>HH</b>	High strength; oxidation resistant to 1090 °C (2000 °F); most widely used
<b>HI</b>	Improved oxidation resistance compared to HH
<b>HK</b>	Because of high-temperature strength, widely used for stressed parts in structural applications up to 1150 °C (2100 °F); offers good resistance to corrosion by hot gases, including sulfur-bearing gases, in both oxidizing and reducing conditions (although HC, HE, and HI are more resistant in oxidizing gases); used in air, ammonia, hydrogen, and molten neutral salts; widely used for tubes and furnace parts
<b>HL</b>	Improved sulfur resistance compared to HK; especially useful where excessive scaling must be avoided
<b>HN</b>	Very high strength at high temperatures; resistant to oxidizing and reducing flue gases
<b>HP</b>	Resistant to both oxidizing and carburizing atmospheres at high temperatures
<b>HP-50WZ</b>	Improved creep rupture strength at 1090 °C (2000 °F) and above compared to HP
<b>HT</b>	Widely used in thermal shock applications; corrosion resistant in air, oxidizing and reducing flue gases, carburizing gases, salts, and molten metals; performs satisfactorily up to 1150 °C (2100 °F) in oxidizing atmospheres and up to 1095 °C (2000 °F) in reducing atmospheres, provided that limiting creep stress values are not exceeded
<b>HU</b>	Higher hot strength than HT and often selected for superior corrosion resistance
<b>HW</b>	High hot strength and electrical resistivity; performs satisfactorily to 1120 °C (2050 °F) in strongly oxidizing atmospheres and up to 1040 °C (1900 °F) in oxidizing or reducing products of combustion that do not contain sulfur; resistant to some salts and molten metals
<b>HX</b>	Resistant to hot-gas corrosion under cycling conditions without cracking or warping; corrosion resistant in air, carburizing gases, combustion gases, flue gases, hydrogen, molten cyanide, molten lead, and molten neutral salts at temperatures up to 1150 °C (2100 °F)

# Powder Metallurgy Stainless Steels

## Introduction

STAINLESS STEEL powder metallurgy (P/M) parts represent an important and growing segment of the P/M industry. Commercial production of P/M stainless steels in North America began in the late 1950s. In the first decade of rapid commercialization of P/M stainless steel, use increased at a compound rate of nearly 20% to reach a consumption of 2000 tons/year in 1973 in North America. Since that time, the industry has continued to grow at a compound rate of approximately 4.6%. According to the Metal Powder Industries Federation (MPIF), the annual production of sintered stainless steel parts in North America is presently (circa 1997 to 1998) approximately 500 tons. The primary market for P/M stainless steels is the automotive industry. Major applications include antilock brake system (ABS) sensor rings, rear-view mirror brackets, and flanges for connecting various exhaust system components. Hardware (e.g., lock components and fasteners), electrical and electronic components (e.g., switches and magnetic clutches), and controlled porosity components for filtration and metering of gases and liquids also consume substantial quantities of P/M stainless steels.

This article will describe the processing and properties of medium-density and high-density P/M stainless steels. Medium-density materials are processed by pressing and sintering prealloyed stainless powders. They achieve densities in the range of 6.4 to 7.2 g/cm<sup>3</sup> (approximately 80 to 90% of theoretical density). High-density materials are produced by hot isostatic pressing, cold isostatic pressing followed by extrusion, or metal injection molding. Densities in these materials approach (95 to 99%) or reach 100% of theoretical density.

## Sintered P/M Stainless Steels

### Processing

**Powder Production.** All commercial compacting-grade stainless steel powders are produced by atomization. Most powders that are conventionally pressed and sintered are water atomized. This process produces a powder that is fully alloyed and that has an irregular particle shape and sufficient compressibility and green strength to be suitable for P/M fabrication. Gas (nitrogen) atomization is used to produce spherical powder for high-density applications. These powder morphologies are similar to the tool steel powders shown in the preceding Section "Tool Steels" in this Handbook.

**Compaction and Lubrication.** Design and processing of stainless steel P/M parts are subject to the same basic considerations as for other P/M materials. However, compared with low-alloy ferrous powders, stainless steel powders require higher compacting pressures and have lower green strength. Figure 1 shows typical compaction characteristics of austenitic and martensitic grades. Compaction pressures ranging from 550 to 830 MPa (40 to 60 tsi) are common in commercial practice.

**Fig. 1** Typical compaction behavior of stainless steel powders. Lubrication 1% lithium stearate

The green strength of stainless steel compacts, which is about half that of P/M iron, is influenced by compaction pressure and the type of lubricant. (For the manufacture of P/M structural parts, a lubricant is used with the prealloyed powder to facilitate compaction of the powder and the ejection of the part from the die.) Lubricants that provide high green strength, such as stearic acid, generally cause lower compressibility. Therefore, lubricant selection is an important factor in determining successful application and fabrication of stainless steel. Lithium stearate and synthetic waxes are popular lubricants.

**Lubricant removal (delubrication),** prior to the actual sintering operation, is vitally important for several reasons. Generally, this removal is accomplished during the sintering preheat operation and is referred to as "burn off." Because of highly adverse effects of residual lubricant carbon when sintering stainless steel, resulting in lowered corrosion resistance,

burn-off temperatures ranging from 425 to 480 °C (800 to 900 °F) in conjunction with the use of synthetic wax lubricants are commonly employed.

**Sintering.** Most commercial sintering of stainless steel parts is completed in belt, pusher, walking beam, and vacuum furnaces. Typical sintering atmospheres include dissociated ammonia (75 vol% H and 25 vol% N), H<sub>2</sub>-N<sub>2</sub> mixtures, and hydrogen, all with a low dew point (-40 to -55 °C, or -40 to -65 °F), and vacuum. Sintering temperatures range from 1120 to 1345 °C (2050 to 2450 °F)--higher sintering temperatures are used when improved mechanical properties and corrosion resistance are required--and sintering times range from 20 to 60 min. Insufficient sintering, either too short a time or at too low a temperature, will result in sintered parts showing insufficient bonding, original particle boundaries, and sharp, angular pores. Such sintering produces parts with a high concentration of interstitials (carbon and oxygen), low corrosion resistance, and inferior mechanical properties.

**Sintering in Dissociated Ammonia (DA).** Sintering at 1120 °C (2050 °F) in DA was the most widely used method for sintering stainless steels in the 1960s and 1970s. Dissociated ammonia is not only less expensive than hydrogen, but it also increases strength (with some reduction in ductility) to levels comparable to wrought stainless steels of the same designation. Densities of approximately 85 to 90% of theoretical are achieved. The strengthening is the result of nitrogen absorption during sintering. Nitrogen absorption, however, leads to the formation of chromium nitride (Cr<sub>2</sub>N) precipitation with accompanying chromium depletion and deterioration of corrosion resistance (i.e., sensitization, or grain-boundary corrosion). Nitrogen absorption can be decreased by very rapid cooling rates (>200 °C/min, or 360 °F/min) combined with higher dew points, but such sintering practices lead to excessive oxidation. It should also be noted that such cooling rates are not attainable with most commercial atmosphere furnaces.

**Sintering in 90% H<sub>2</sub>-10% N<sub>2</sub> mixtures** is a compromise between sintering in DA and hydrogen atmospheres. Such mixed atmospheres reduce the high cooling rate requirements of DA atmospheres while still supplying solid-solution strengthening and improved corrosion resistance.

**Sintering in Hydrogen.** With increasing demands for improved corrosion resistance of P/M stainless steels, and as more quantitative information on the effects of sintering in DA atmospheres became available, stainless steel parts producers increasingly shifted toward the use of the more expensive hydrogen atmospheres. The combination of a high sintering temperature (1230 °C, or 2250 °F), low dew point (-50 °C, or -60 °F), and a rapid cooling rate (85 °C/min, or 150 °F/min) produces stainless steel parts containing less than 3000 ppm N<sub>2</sub> and leads to optimum corrosion performance, lower strength, and higher ductility.

**Sintering in Vacuum.** The principal alternative to DA-based or hydrogen-base atmospheres is vacuum. With a state-of-the-art vacuum furnace, it is much easier to maintain a low dew point and to obtain rapid cooling than is possible with a typical atmosphere furnace. For maximum corrosion resistance of vacuum-sintered stainless steel, surface depletion of chromium due to high vapor pressure and the presence of original surface oxides must be minimized. Sintering under a partial pressure of nitrogen or argon of approximately 1500 μm Hg effectively reduces chromium losses. For minimizing interstitials (carbon, oxygen, and nitrogen), high-temperature vacuum sintering is superior to high-temperature atmosphere sintering. As a result, magnetic properties of vacuum-sintered ferritic stainless steels are superior to those obtained with atmosphere sintering.

## ***Compositions and Properties***

**Compositions** of widely used commercial grades of stainless steels are given in Table 1. Modified versions of these standard MPIF grades include alloys containing 1 to 2% Sn, 2% Cu, or 6% Mo for improved corrosion resistance; alloys containing 3% Si to facilitate liquid-phase sintering to achieve higher densities (7.4 g/cm<sup>3</sup>) and improved corrosion resistance; and alloys containing manganese sulfide additions for improved machinability.

**Table 1 Compositions of standard (MPIF) P/M stainless steels**

(a) Composition may include other elements (2.0% max) added for specific purposes.

(b) Also includes niobium ( $8 \times \%C$  to 0.80% max).

**Mechanical properties** of sintered stainless steels are determined by powder characteristics, the sintered density, and the sintering parameters. As with other P/M materials, sintered stainless steels with higher density exhibit higher strength. Higher sintering temperatures and longer sintering times produce more pore rounding and grain growth, both of which impart ductility and impact strength to the part. Low carbon, nitrogen, and oxygen contents also raise ductility. High residual carbon increases strength and hardness. Sintering in lower dew point hydrogen increases densification and ductility. If vacuum sintering is done with optimized additions of graphite, low oxygen contents of 600 to 800 ppm will

result in improved ductility and toughness. Figure 2 compares the yield strength and ductility of type 316L stainless steel sintered in DA and H<sub>2</sub>. As stated earlier, parts sintered in DA exhibit higher strength and lower ductility than hydrogen-sintered parts. The mechanical properties of vacuum-sintered stainless steels are similar to those of hydrogen-sintered stainless steels. Table 2 lists the mechanical properties of standard (MPIF) austenitic, ferritic, and martensitic grades.

Minimum strength values (in ksi) are specified by the numerical suffix in the first column of the table. Typical values are given in the remaining columns.

Source: MPIF Standard 35, 1997 Edition

- (a) Codes for the stainless steel designations: N1, nitrogen alloyed with good strength and low elongation, sintered at 1150 °C (2100 °F) in dissociated ammonia; N2, nitrogen alloyed with high strength and medium elongation, sintered at 1290 °C (2350 °F) in dissociated ammonia; L, low carbon with lower strength and highest elongation, sintered at 1290 °C (2350 °F) in partial vacuum, cooled to avoid nitrogen absorption; HT, martensitic grade, sinter hardened at 1150 °C (2100 °F) in dissociated ammonia to highest strength.

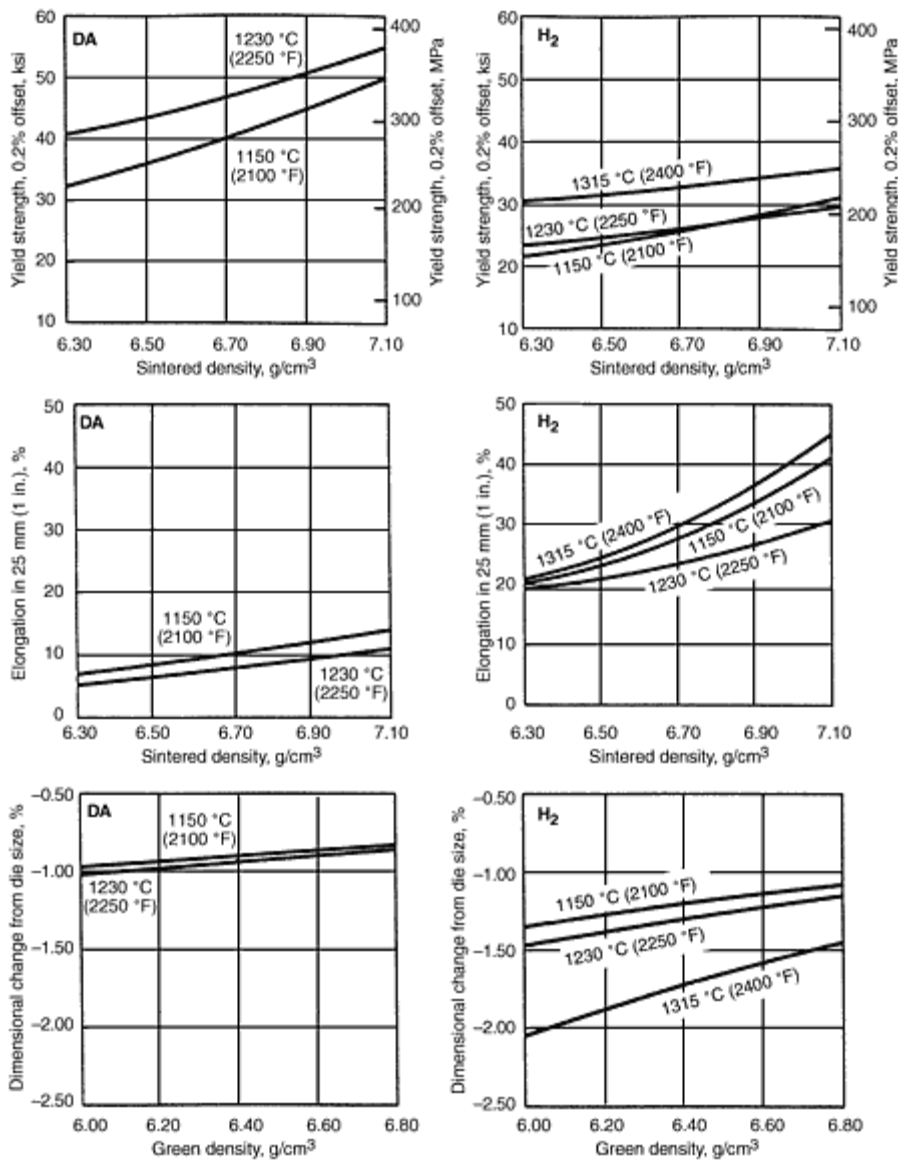

- (b) The numerical suffix represents the minimum yield strength in ksi.

- (c) The numerical suffix represents the ultimate tensile strength in ksi.

- (d) Yield and ultimate tensile strength are approximately the same for heat treated materials.

- (e) Or a matrix (converted) hardness of 55 HRC.

**Fig. 2** Comparison of yield strength, ductility, and shrinkage of type 316L austenitic stainless steel compacts sintered in dissociated ammonia (DA) and hydrogen (H<sub>2</sub>)

**Dimensional Changes.** As shown at the bottom of Fig. 2, sintering in hydrogen (or under vacuum), particularly at higher temperatures, produces significant shrinkage, which in turn impairs the dimensional accuracy of the part. For this reason, such parts are often sized after sintering.

**Corrosion Resistance.** The most frequent processing problems in the P/M stainless steel parts producing industry are related to improper lubrication, excessive dew points in sintering furnaces, slow cooling rates after sintering, and contamination with iron or low-alloy steel powders. Improper delubrication can lead to high residual carbon and/or oxygen contents, which can cause intergranular corrosion and pitting corrosion. Excessive dew points most often result in the oxidation of the surface layers of the sintered parts during cooling. The amount of absorbed oxygen is usually too small to be identified by conventional oxygen analysis or to be noticed as discoloration on the surface. This condition produces low pitting resistance. Slow cooling rates can cause precipitation of carbides at the grain boundaries, in the same manner as sensitization occurs in wrought stainless steels. Slow cooling in nitrogen-bearing atmospheres can lead to absorption of nitrogen on the surface of the part, forming chromium nitrides, which can also impair corrosion resistance. Contamination with less noble metal powders produces galvanic corrosion. Table 3 summarizes the effects of process variables on the corrosion resistance of P/M stainless steels.

**Table 3 Effect of iron, carbon, nitrogen, oxygen, and density on the corrosion resistance of sintered austenitic stainless steels in neutral NaCl solution**

Variable	Origin of problem	Effect on corrosion resistance	Suggested solutions
<b>Iron</b>	Contamination of prealloyed powder with iron or iron-base powder at powder or parts producer's facility	Lowering of corrosion resistance by more than 99% due to galvanic corrosion	Utmost cleanliness at both powder and parts producer's manufacturing facilities, preferably separate and dedicated equipment and facilities
<b>Carbon</b>	Inadequate lubricant removal; carburizing sintering atmosphere; soot in sintering furnace; high-carbon powder	Inferior resistance to intergranular corrosion	Use L-grade designation of stainless steel powder. Ensure adequate lubricant removal (before sintering). Use clean soot-free sintering furnace and carbon-free sintering atmospheres; carbon content of austenitic sintered parts should be $\leq 0.03\%$ and even lower for ferritics.
<b>Nitrogen</b>	Sintering in dissociated $\text{NH}_3$ or other nitrogen-containing atmosphere combined with slow cooling	Inferior resistance to intergranular corrosion	Reduce percentage of nitrogen in sintering atmosphere. Use fast cooling of parts preferably $>150$ to $200\text{ }^\circ\text{C/min}$ ( $270$ to $360\text{ }^\circ\text{F/min}$ ) through critical temperature range ( $700$ to $1000\text{ }^\circ\text{C}$ , or $1290$ to $1830\text{ }^\circ\text{F}$ ). Use higher sintering temperature. Use intermediate dew points ( $-37$ to $-45\text{ }^\circ\text{C}$ , or $-35$ to $-50\text{ }^\circ\text{F}$ ) in cooling zone of furnace. Use tin-modified stainless steel powders.
<b>Oxygen</b>	Excessive oxygen in powder; excessive dew point of sintering atmosphere; slow cooling after sintering	Inferior resistance to general corrosion	Use low-oxygen content powder, preferably $<2000$ ppm. Control dew point within sintering furnace to ensure reducing conditions. Fast cooling, preferably $>200\text{ }^\circ\text{C/min}$ ( $360\text{ }^\circ\text{F/min}$ ) For nitrogen-containing atmospheres, use dew point of $-37$ to $-45\text{ }^\circ\text{C}$ ( $-35$ to $-50\text{ }^\circ\text{F}$ ) in cooling zone. For sintering in $\text{H}_2$ , ensure that water vapor content of atmosphere is below $50$ ppm.
<b>Density of sintered part</b>	High sintered density	Inferior resistance to crevice corrosion	Avoid sintered densities in the range of approximately $6.7$ to $7.4\text{ g/cm}^3$ , or impregnate pores in this density range. In acidic environments, corrosion resistance improves with increasing density due to a decrease of specific surface area.

## High-Density P/M Stainless Steels

Fully dense stainless steels are made predominantly by hot isostatic pressing (HIP), cold isostatic pressing (CIP) plus extrusion, and metal injection molding (MIM). The mechanical properties and corrosion resistance of parts produced by these techniques are generally similar to those of their conventional wrought counterparts. Hot isostatically pressed parts include flanges, fitting, valve bodies, and pump components made from duplex stainless steel used for offshore applications. Cold isostatically pressed-and-extruded austenitic stainless steel seamless tubing is also used for offshore applications.

Metal injection molding technology is utilized for high-strength applications where shape complexity is a factor. Stainless steel powders that are most commonly injection molded include austenitic, duplex, and precipitation-hardening grades. Tables 4 and 5 list compositions and properties of standardized injection-molded stainless steels. Applications for injection-molded stainless steels include dental bracket components, disk drive components, firing pins, blades for crimping/cutting tools used for telephone terminal wire connections, and assorted automotive components.

# Superalloys

Matthew J. Donachie, Rensselaer at Hartford; Stephen J. Donachie, Special Metals Corporation

## Introduction

SUPERALLOYS are nickel-, iron-nickel-, and cobalt-base alloys generally used at temperatures above approximately 540 °C (1000 °F). They have a face-centered cubic (fcc, austenitic) structure. Iron, cobalt, and nickel are transition metals with consecutive positions in the periodic table of elements. The iron-nickel-base superalloys are an extension of stainless steel technology and generally are wrought, whereas cobalt-base and nickel-base superalloys may be wrought or cast, depending on the application/composition involved.

Appropriate compositions of all superalloy base metals can be forged, rolled to sheet, or otherwise formed into a variety of shapes. The more highly alloyed compositions normally are processed as castings. Fabricated structures can be built up by welding or brazing, but many highly alloyed compositions containing a high amount of hardening phase are difficult to weld.

Properties can be controlled by adjustments in composition and by processing (including heat treatment), and excellent elevated-temperature strengths are available in finished products. Figure 1 compares stress rupture behavior of the three alloy classes.

Fig. 1 General stress-rupture behavior of superalloys

## General Background

### Important Metal Characteristics

Pure iron has a density of 7.87 g/cm<sup>3</sup> (0.284 lb/in.<sup>3</sup>), and pure nickel and cobalt have densities of approximately 8.9 g/cm<sup>3</sup> (0.322 lb/in.<sup>3</sup>). Iron-nickel-base superalloys have densities of approximately 7.9 to 8.3 g/cm<sup>3</sup> (0.285 to 0.300 lb/in.<sup>3</sup>); cobalt-base superalloys, approximately 8.3 to 9.4 g/cm<sup>3</sup> (0.300 to 0.340 lb/in.<sup>3</sup>); and nickel-base superalloys, approximately 7.8 to 8.9 g/cm<sup>3</sup> (0.282 to 0.322 lb/in.<sup>3</sup>). Superalloy density is influenced by alloying additions: aluminum,

titanium, and chromium reduce density, whereas tungsten, rhenium, and tantalum increase it. The corrosion resistance of superalloys depends primarily on the alloying elements added and the environment experienced.

The melting temperatures of the pure elements are as follows: nickel, 1453 °C (2647 °F); cobalt, 1495 °C (2723 °F); and iron, 1537 °C (2798 °F). Incipient melting temperatures and melting ranges of superalloys are functions of composition and prior processing. Generally, incipient melting temperatures are greater for cobalt-base than for nickel- or iron-nickel-base superalloys. Nickel-base superalloys may show incipient melting at temperatures as low as 1204 °C (2200 °F). Advanced nickel-base single-crystal superalloys with limited amounts of melting-point depressants tend to have incipient melting temperatures equal to or in excess of those of cobalt-base alloys.

Iron and cobalt both undergo allotropic transformations and become fcc at high temperatures; nickel, on the other hand, is fcc at all temperatures. In superalloys based on iron and cobalt, the fcc forms of these elements generally are stabilized by alloying additions. The upper limit of usage for superalloys is not restricted by the occurrence of allotropic transformation reactions, but rather is a function of incipient melting temperature and dissolution of strengthening phases. Some tendency toward transformation of the fcc phase to stable lower-temperature phases occasionally occurs in cobalt-base superalloys. The austenitic fcc matrices of superalloys have extended solubility for some alloying additions, excellent ductility, and favorable characteristics for precipitation of uniquely effective strengthening phases (iron-nickel- and nickel-base superalloys).

Superalloys typically have moduli of elasticity in the vicinity of 207 GPa ( $30 \times 10^6$  psi), although moduli of specific polycrystalline alloys can vary from 172 to 241 GPa ( $25$  to  $35 \times 10^6$  psi) at room temperature, depending on the alloy system. Processing that leads to directional grain or crystal orientation can result in moduli of approximately 124 to 310 GPa (about  $18$  to  $45 \times 10^6$  psi), depending on the relation of grain or crystal orientation to testing direction. Physical properties (electrical conductivity, thermal conductivity, and thermal expansion) tend to be low compared to other metal systems. These properties are influenced by the nature of the base metals (transition elements) and the presence of refractory-metal additions.

The superalloys are relatively ductile, although the ductilities of cobalt-base superalloys generally are less than those of iron-nickel- and nickel-base superalloys. Iron-nickel- and nickel-base superalloys are readily available in extruded, forged, or rolled form; the higher-strength alloys generally are found only in the cast condition. Hot deformation is the preferred forming process, cold forming usually being restricted to thin sections (sheet). Cold rolling may be used to increase short-time strength properties for applications at temperatures below the lower temperature level of 540 °C (1000 °F) established in this article for superalloy use.

## ***Phases and Structures of Superalloys***

Superalloys consist of the austenitic fcc matrix phase  $\gamma$  plus a variety of secondary phases. Secondary phases of value in controlling properties are the carbides MC,  $M_{23}C_6$ ,  $M_6C$ , and  $M_7C_3$  (rare) in all superalloy types; the  $\gamma'$  fcc ordered  $Ni_3(Al,Ti)$ ,  $\gamma''$  bct (body-centered tetragonal) ordered  $Ni_3Nb$ ,  $\eta$  hexagonal ordered  $Ni_3Ti$ , and  $\delta$  orthorhombic  $Ni_3Nb$  intermetallic compounds in nickel- and iron-nickel-base superalloys. The superalloys derive their strength from solid-solution hardeners and precipitated phases. Principal strengthening precipitate phases are  $\gamma'$  and  $\gamma''$ . Carbides may provide limited strengthening directly (e.g., through dispersion hardening) or, more commonly, indirectly (e.g., by stabilizing grain boundaries against excessive shear). The  $\delta$  and  $\eta$  phases are useful (along with  $\gamma'$ ) in control of structure of wrought superalloys during processing. The extent to which they directly contribute to strengthening depends on the alloy and its processing.

In addition to those elements that produce solid-solution hardening and/or promote carbide and  $\gamma'$  formation, other elements (e.g., boron, zirconium, and hafnium) are added to enhance mechanical or chemical properties. Some carbide- and  $\gamma'$ -forming elements may contribute significantly to chemical properties as well. Tables 1(a) and 1(b), respectively, give a generalized list of the ranges of alloying elements and their effects in superalloys. Typical operating microstructures of representative superalloys are shown in Fig. 2.

**Table 1(a) Common ranges of major alloying additions in superalloys**

Note script carbides in (a) and (b) as well as eutectic carbide-cobalt grain-boundary structures in (a), spheroidal and cuboidal  $\gamma'$  as well as grain-boundary carbides in (c), and spheroidal  $\gamma'$  as well as grain-boundary carbides or grain-boundary and intragranular  $\delta$  phase in (d).  $\gamma''$  not obvious but present in (d) (right).

### ***Superalloy Systems***

The three types of superalloys--iron-nickel-, nickel-, and cobalt-base--may be further subdivided into cast and wrought. A large number of alloys have been invented and studied; many have been patented. However, the many alloys have been winnowed down over the years, and only a few are extensively used. Alloy usage is a function of industry (gas turbines, steam turbines, etc.). Not all alloys can be mentioned; examples of older and newer alloys will be used to demonstrate the physical metallurgy response of superalloy systems. Representative superalloys and compositions emphasizing alloys developed in the United States are listed in Tables 2 and 3.

**Iron-Nickel-Base.** The most important class of iron-nickel-base superalloys includes those strengthened by intermetallic compound precipitation in an fcc matrix. The most common precipitate is  $\gamma'$ , typified by A-286, V-57, or Incoloy 901. Some alloys, typified by Inconel (IN) 718, which precipitate  $\gamma''$ , were formerly classed as iron-nickel-base but now are considered to be nickel-base. Other iron-nickel-base superalloys consist of modified stainless steels primarily strengthened by solid-solution hardening. Alloys in this last category vary from 19-9DL (18-8 stainless with slight chromium and nickel adjustments, additional solution hardeners, and higher carbon) to Incoloy 800H (21 chromium, high nickel with small additions of titanium and aluminum, which yields some  $\gamma'$  phase).

**Nickel-Base.** The most important class of nickel-base superalloys is that strengthened by intermetallic-compound precipitation in an fcc matrix. For nickel-titanium/aluminum alloys the strengthening precipitate is  $\gamma'$ . Such alloys are typified by the wrought alloys Waspaloy and Udimet (U) 720, or by the cast alloys René 80 and IN 713. For nickel-niobium alloys the strengthening precipitate is  $\gamma''$ . These alloys are typified by IN 718. Some nickel-base alloys may contain both niobium plus titanium and/or aluminum and utilize both  $\gamma'$  and  $\gamma''$  precipitates in strengthening. Alloys of this type are IN 706 and IN 909. Another class of nickel-base superalloys is essentially solid-solution strengthened. Such alloys are Hastelloy X and IN 625. The solid-solution strengthened nickel-base alloys may derive some additional strengthening from carbide and/or intermetallic-compound precipitation. A third class includes oxide-dispersion strengthened (ODS) alloys such as IN MA-754 and IN MA-6000E, which are strengthened by dispersion of inert particles such as yttria, coupled in some cases with  $\gamma'$  precipitation (MA 6000E).

Nickel-base superalloys are utilized in both cast and wrought forms, although special processing (powder metallurgy/isothermal forging) is frequently used to produce wrought versions of the more highly alloyed compositions (René 95, Astroloy, IN 100). An additional dimension of nickel-base superalloys has been the introduction of grain-aspect ratio and orientation as a means of controlling properties. In some instances, in fact, grain boundaries have been removed (see the subsequent discussion of investment casting). Wrought powder metallurgy (P/M) alloys of the ODS class and cast alloys such as MAR-M 247 have demonstrated property improvements owing to control of grain morphology by directional recrystallization or solidification.

**Cobalt-Base.** The cobalt-base superalloys are invariably strengthened by a combination of carbides and solid-solution hardeners. The essential distinction in these alloys is between cast and wrought structures. Cast alloys are typified by X-40 and wrought alloys by L605. No intermetallic compound possessing the same degree of utility as the  $\gamma'$  precipitate in nickel- or iron-nickel-base superalloys has been found to be operative in cobalt-base systems.

## Applications

Superalloys have been used in cast, rolled, extruded, forged, and powder-processed forms. Sheet, bar, plate, tubing, shafts, airfoils, disks, and pressure vessels (cases) are some of the shapes that have been produced. These metals have been used in aircraft, industrial, and marine gas turbines; nuclear reactors; aircraft skins; spacecraft structures; petrochemical production; orthopedic and dental prostheses; and environmental protection applications. Although developed for high-temperature use, some are used at cryogenic temperatures and others at body temperature. Applications continue to expand but at lower rates than in previous decades. Aerospace usage remains the predominant application on a volume basis.

## Processing

### Primary and Secondary Melting

A number of superalloys, particularly cobalt- and iron-nickel-base alloys, are air melted by various methods applicable to stainless steels. However, for most nickel- or iron-nickel-base superalloys, vacuum induction melting (VIM) is required as the primary melting process.

**Vacuum induction melting** consists of melting the required components of an alloy under high vacuum and pouring into an ingot or article mold. The use of VIM reduces interstitial gases to low levels, enables higher and more reproducible levels of aluminum and titanium (along with other relatively reactive elements) to be achieved, and results in less contamination from slag or dross formation than air melting. The benefits of reduced gas content and ability to control aluminum plus titanium are shown in Fig. 3 and 4.

**Fig. 3** Improvement of rupture life at 870 °C (1600 °F) and 170 MPa (25 ksi) by reduced oxygen content produced by vacuum melting

**Fig. 4** Effects of vacuum melting, incorporating beneficial modifications in composition, on properties of two nickel-base superalloys

Segregation (on a microscale) occurs during the solidification of all superalloys. The solidification region consists of a zone where the alloy is partially solid and partially liquid (the liquid + solid zone). The solidification mode is generally dendritic and the first (primary) dendrites to form are lower in precipitate-forming elements (titanium, aluminum, niobium, and carbon) than the average melt composition. The interdendritic areas are correspondingly enriched in these solute elements. As cooling rates become slower (increasing casting size), the primary dendrites and interdendritic regions

become larger. The slower the cooling rate and the more highly alloyed the melt, the larger the interdendritic regions. At some point, the interdendritic regions become large enough to interconnect and form macroscale defects. Driven by density differences between the solute-rich interdendritic liquid and the nominal melt composition, these regions become self-perpetuating continuous channels in the solidification structure. Such channel defects may grow vertically (but not truly perpendicular) from the solidification front for low-density interdendritic fluids or may grow horizontally (parallel) to the solidification front for high-density interdendritic liquids.

Solute-rich channel defects are referred to as "freckles" because, when viewed in a cross section perpendicular to their growth axis, they are seen as round, dark, circular spots. Freckle regions may form hard intermetallic compounds that cannot be removed by subsequent processing. The presence of such compounds in wrought alloys is extremely detrimental to fatigue life. If the large ingot sizes required for production of wrought alloys are direct static cast, the formation of unacceptable solute-rich defects is essentially unavoidable. Superalloys for wrought production are thus generally remelted (secondary melting) to control the solidification structure. Three types of secondary melting practices are in use: vacuum arc remelting (VAR), electroslag remelting (ESR), and ESR-VAR.

**The vacuum arc remelting process** utilizes a cast (generally VIM) electrode as the cathode in a direct-current (dc) system. Under vacuum, in a water-cooled crucible, an arc is struck between the electrode and the bottom of the crucible. The heat of the arc melts the bottom surface of the electrode at a controlled rate. The molten metal is resolidified in the crucible, with the electrode melt rate being controlled by the applied power. The melting/solidification parameters control the depth and angle of the solidification front (pool shape). Pool shape can be maintained such that unacceptable solute-rich solidification structures do not occur.

In addition to establishing a controlled solidification structure, VAR reduces the amounts of high-vapor-pressure elements in the alloy. Elements such as bismuth and lead (which can be present in low concentrations even after VIM) are highly undesirable, but are reduced to negligible levels by the VAR process. Magnesium, which is considered desirable for improved workability (and is an addition element in VIM), is reduced in concentration but not completely removed. With the exception of high-vapor-pressure elements, the VIM chemistry is representative of the VAR chemistry. The flotation of oxides and nitrides to the melt surface in VAR improves the cleanliness and reduces the gas content of material processed through VAR.

Figure 5 schematically illustrates the relationship between the VAR electrode, the solidifying ingot, and the shape and depth of the solidification front. In VAR, the first metal to solidify against the water-cooled crucible has low solute content (solute lean). The upper part of this solidification layer is built up of splash from the melt pool and is called the "crown." After the crown is melted back by the advancing molten metal front, an alloy-lean layer remains on the outside of the ingot. This is called "shelf." During the remelting operation, the residual oxides/nitrides in the VIM electrode are swept across the top of the molten pool and incorporated into the shelf.

**Fig. 5** Schematic of solidification relationships in VAR (left) and ESR (right) melting processes. Source: After

Other important variables of the VAR process are illustrated in Fig. 5. The distance between the side of the electrode and the crucible wall is the annulus. The distance between the bottom of the electrode and the top of the molten pool is the arc gap. As the ingot solidifies, a shrinkage gap is opened between the ingot and the water-cooled crucible. For segregation-sensitive alloys, helium gas is often introduced into the shrinkage gap to improve heat transfer and thus minimize the depth of the molten pool. As shown in Fig. 5, the heat extraction in VAR is concentrated near the top of the molten pool. Vacuum arc remelting is thus a process with low thermal inertia in which very rapid responses (change in pool shape) occur in response to changes in power input.

Freckles, although the most serious defect to occur in secondary melting, are not the only melt-related defect that can be produced. Solute-lean segregation can occur from a number of different sources. The most common mechanism for formation of solute-lean segregation is the undercutting (by the arc) of the shelf, causing a "drop-in" defect. Pieces of the shelf dropping into the pool may not be completely remelted. The result is the incorporation into the structure of a defect with the chemistry of the shelf and which may also contain oxide/nitride stringers. These solute-lean regions are often detected by macroetching of parts/test wafers, where they are seen as light-etching regions in a dark-etching matrix. Thus, they are described as "discrete white spots."

Discrete white spots may also form from drop-in of dendrites from porous regions of the electrode. If the electrode is cracked, pieces larger than dendrites may drop into the melt. While this also produces a light-etching defect, the defect is larger than a discrete white spot and contains dark-etching regions (remnant cast structure). Such structures are often called "dendritic white spots." Although VAR practice and control may be optimized to minimize the frequency of discrete white spot formation, due to the inherent instability of the arc discrete white spots cannot be eliminated. Design of components from VAR-processed material must take into consideration the historical frequency of white spot occurrence for a given process or alloy.

Control of the VAR process is considered from two different aspects: control of pool depth and shape (control of solidification structure) and control of arc stability (control of drop-in defect formation). Pool shape and depth are controlled by regulating heat input and heat extraction. Heat input is determined by the melt rate of the electrode. Melt rate is often monitored and corrected over very short time periods by changes in melt current (melt rate control). Alternatively, control of the median melt rate over the duration of a melt may be maintained by operating at constant melt amperage (amperage control). Heat extraction is a function of the contact surface/ingot volume (ingot size) being melted. Larger ingots have poorer heat extraction (lower surface/volume) and must be melted at proportionately lower melt rates to prevent the formation of large liquid + solid zones and thus the formation of unacceptable positive segregation. While, for a given ingot size, high melt rate may promote positive segregation, a melt rate that is too low may cause the formation of visible solute-lean structures. The mechanism of formation of these "solidification white spots" is not completely understood. They differ from discrete white spots in that they are a solidification effect, not a shelf or electrode drop-in, and therefore do not contain oxide/nitride stringers. Nevertheless, such solute-lean regions are potentially detrimental as they may make it difficult to control grain growth in subsequent processing.

Active control of arc stability is primarily by control of the arc gap throughout the melting of an electrode. (Annulus is a fixed parameter for a given standard process.) For melting of superalloys, arc gaps are generally controlled in the range of 6.4 to 12.7 mm ( $\frac{1}{4}$  to  $\frac{1}{2}$  in.). To maintain constant arc gap, the electrode is fed into the melt either faster or slower (ram drive) according to the fluctuation in voltage that occurs when the resistance of the system changes in response to changes in the arc gap. Modern control systems for superalloys generally do not use voltage for arc gap control, but rather use a related voltage measurement: the drip short frequency (DSF). A drip short is the transient downward voltage spike that occurs when a molten metal droplet is in contact with both the electrode and the molten pool. The number of shorts occurring in a given time period is proportional to the arc gap. (The relationship for arc gap versus DSF is not melt rate independent.) Passive control of arc stability is maintained by controlling the annulus and controlling the quality of the electrode being remelted. Electrodes for VIM generally contain porosity and low levels of residual refractory, both of which may act to destabilize the arc. Vacuum induction melting and pouring practice is thus a significant factor in ensuring VAR arc stability and in minimizing the formation of drop-in type defects.

**The electroslag remelting process**, as applied to superalloys, utilizes a cast (generally VIM) electrode as a consumable element in an alternating-current (ac) system operated open to the atmosphere. A "slag" charge of fluorides and oxides is also part of the system and is kept in a molten state by the passage of electric current through it. The electrode is immersed in the slag and the surface of the electrode melts as droplets, which pass through the slag to solidify

(similarly to VAR) in a water-cooled crucible. The melt rate is controlled by the applied power. Heat extraction is controlled by the selection of ingot size. By balancing the melting/solidification parameters, the depth and angle of the liquid + solid zone can be maintained such that unacceptable solute-rich solidification defects do not occur.

Unlike VAR, high-vapor-pressure tramp elements are not removed by ESR. Thus, magnesium may be retained at higher levels than is possible in VAR (with beneficial effects on hot workability). A beneficial chemical reaction related to workability is the removal of sulfur. Detrimental compositional changes may occur in reactive elements (notably titanium and aluminum), as these elements change to attain chemical equilibrium with components of the slag.

Oxides incorporated in the electrode being melted are effectively removed by the ESR process, producing an ingot that is generally cleaner than a VAR ingot. The structures in the solidified ingot are governed by the same principles as those governing a solidifying VAR ingot, but the nature of the heat transfer (through an oxide skin) and the presence of a heat reservoir (the molten slag) at the top of the ingot/molten pool make ESR structure inherently different from that of VAR.

Figure 5 schematically illustrates the relationship between the ESR electrode, the solidifying ingot, and the shape and depth of the molten pool. A major feature of ESR solidification is that a "skin" of oxide is incorporated between the ingot surface and the crucible wall. Similar to VAR, the distance between the side of the electrode and the crucible wall is called the annulus. The depth of the slag pool is an important operating parameter which controls the electrical resistance of the system. The depth of immersion of the electrode into the slag is an important parameter in controlling the molten pool shape. As shown in Fig. 5, the heat extraction in ESR is of a much greater magnitude than for VAR. Due to the insulating characteristic of the ingot slag skin, heat extraction in ESR is inherently less efficient than in VAR. Thus, ESR is a process with high thermal inertia, and slow responses (change in pool shape) that occur in response to changes in power input.

The presence of an ingot slag skin not only improves the ingot surface quality but also, more importantly, eliminates the presence of a solute-lean shelf layer on ESR ingots. (As oxide particles from the electrode are dissolved into the slag, they do not agglomerate on the ingot surface.) Because ESR ingots do not have ingot shelf, they are inherently free of the formation of drop-in (discrete) white spots from this source, but drop-in electrode may still be a source of white spots in ESR. Solidification white spots have not been reported in ESR product. However, one consequence of the ingot slag skin is that heat extraction in ESR is less efficient than for VAR. This is shown schematically in Fig. 5 by the difference in pool shape between the two processes. ESR pools tend to be both deeper and more V shaped (compared to a U-shaped VAR pool). Deep pools favor freckle formation, which can only be counteracted by reducing ingot size. Consequently, the maximum size of ESR ingot produced (for any given alloy system) is smaller than one that can be produced by VAR.

Control of the ESR process is considered from two different aspects: control of pool depth and shape (control of solidification structure) and development of a satisfactory ingot skin. Pool depth and shape are controlled primarily by melt rate (power input). Electroslag remelting generally is run using melt rate control, with continuous amperage adjustments to maintain a uniform melt rate. Due to the high thermal inertia of the ESR process, the melt rate of ESR is more variable than in VAR. A secondary control of pool depth and shape is effected by maintaining uniform, shallow immersion of the electrode in the slag. The passage of molten metal droplets through the slag affects slag resistivity and thus causes variation in the operating voltage of the system. The operating voltage appears as a band of values due to this variation. The width of that band is called the volt swing. The electrode immersion is proportional to the volt swing, and the ram drive of the ESR advances the electrode to maintain the desired swing value.

Production of satisfactory ingot skin is not actively controlled during the melt, but is due to the choice of variables. The most important of these are melt rate, depth of the slag pool, and choice of slag composition. Higher melt rates produce better ingot surfaces. As higher melt rates also produce deeper molten pools and move the process closer to the conditions for freckle formation, selection of the correct balance of parameters is critical.

Slag compositions are based on  $\text{CaF}_2$ . Additions of  $\text{CaO}$ ,  $\text{MgO}$ , and  $\text{Al}_2\text{O}_3$  are made to modify both the resistance of the slag and its melting point. All commercial-purity  $\text{CaF}_2$  contains  $\text{SiO}_2$ . During melting of titanium bearing alloys, an exchange will take place between the titanium in the alloy and the silicon in the slag. The slag becomes enriched with  $\text{TiO}_2$  and the silicon content of the alloy increases until an equilibrium is established, usually within the first few hundred pounds of melting. To minimize this exchange some commercial slags are buffered with intentional additions of  $\text{TiO}_2$ .

**ESR-VAR Remelting Process.** Comparison of the VAR and ESR processes shows that the ESR process is inherently capable of producing cleaner metal but that the VAR process has the capability to produce larger ingots while retaining freedom from alloy-rich defects. The need to produce larger forging stock for gas turbine components has led to the

development of a hybrid process: VIM-ESR-VAR (triple melt). In this process, the ESR operation produces a clean, sound electrode for subsequent remelting. The improved (compared to VIM-VAR) electrode quality facilitates control in the VAR operation, producing material with a greater assurance of freedom from alloy-rich segregation (in very large ingot) and a reduced frequency of white spots for all ingot sizes.

In some advanced nickel-base superalloys with high volume fractions ( $V_f$ ) of  $\gamma'$ , even VIM-VAR or VIM-ESR does not provide a satisfactory ingot structure for subsequent hot working. Such superalloys have been processed by P/M techniques (see the section "Powder Processing" in this article).

**Other Melting Processes.** Electron-beam remelting/refining (EBR) has been evaluated as an alternative process for improving nickel- and iron-nickel-base superalloy properties and processability through a further lowering of impurity levels and drastic reductions in dross/inclusion content. This process can help produce improved feedstock for casting operations or provide more workable starting ingot for wrought processing. The expanded use of secondary melt processes such as EBR and argon-oxygen decarburization (AOD) will be governed by the extent to which they each provide an economical means for quality processing of nickel- and iron-nickel-base superalloys.

**Cobalt Alloy Melting.** Melting of cobalt-base superalloys generally does not require the sophistication of vacuum processing. An air induction melt (AIM) is commonly used, but VIM and ESR also have found application, the latter being used to produce stock for subsequent deformation processing. Alloys containing aluminum or titanium (J-1570) and tantalum or zirconium (MAR-M 302 and MAR-M 509) must be melted by VIM. Vacuum melting of other cobalt-base superalloys may enhance properties such as strength and ductility because of the improved cleanliness and compositional control associated with this process.

### ***Deformation Processing (Conversion)***

As noted in the preceding section, the structure of superalloy ingots consists of primary dendrites, which are solute lean, and interdendritic regions, which are solute rich. For those alloys with sufficient aluminum, titanium, or niobium to exhibit commercially useful age-hardening response, it is necessary to thermally treat the ingot prior to deformation processing. The thermal treatment is referred to as "homogenization" and consists of extended exposure (48 h is not uncommon) to temperatures approaching the incipient melting temperature of the alloy. The degree of segregation which must be removed by homogenization is a function of alloy composition and melt practice. While homogenization treatments are generally effective in producing a great leveling of microscale concentration differences in superalloys, some residual minor differences may remain in areas of large primary dendrite formation.

Consumably remelted superalloys generally are processed to either forged parts or to sheet/plate. Forged products are produced through an intermediate (billet) forging process, during which refinement of the cast structure is accomplished and a recrystallized grain size is established. Subsequent die forging of increments cut from the billet may further refine the structure or may simply shape the increment into the desired form while retaining the billet structure.

Similarly, ingots to be processed into sheet are often converted by cogging to the desired input size for the rolling mill. The large reductions of the subsequent sheet rolling process reduce the need for control of clogged structure compared to that required for forging stock. Thus, for some alloys utilizing ESR as the secondary melt process, the ingot may be "cast" into a slab for direct input into the rolling process.

Workability is affected primarily by composition and secondarily by microstructure. Optimum strain and temperature conditions for working of superalloys can be defined by "processing maps." In superalloys, high sulfur levels may constrict the favorable processing range, while additional elements such as magnesium may counteract the effect of sulfur and expand the process range. Unfavorable microstructure may be formed on grain boundaries at any stage in the processing. An example of carbide films developed on prior-grain boundaries is shown in Fig. 6. Such structures will restrict the range of processing conditions. Some superalloys and their nominal forging temperatures are given in Table 4. Superalloys such as IN 100 may have forging temperatures that vary depending on whether isothermal/superplastic forging is used. Grain refinement requirements also may affect the forging process.

**Table 4 Forgeability ratings of superalloys**

Alloy	Forging temperature		Forgeability
	°C	°F	
<b>A-286</b>	1065	1950	Excellent
<b>Inconel 901</b>	1095	2000	Good to excellent
<b>Hastelloy X</b>	1095	2000	Excellent
<b>Waspaloy</b>	1080	1975	Good
<b>Inconel 718</b>	1065	1950	Excellent
<b>Astroloy</b>	1095	2000	Fair to good

Source: Ref 2

To refine grain structure (to improve low-cycle fatigue resistance and/or stress-rupture resistance) in forgings, it is common to process precipitation-hardening superalloys within a more restricted temperature range than is given in Table 4. The temperature range is restricted so that not all the precipitating elements are in solution during forging, thus causing pinning of grain boundaries and restriction of grain growth. The forging conditions must be chosen and controlled so that sufficient strain and temperature are used to allow recrystallization while not allowing the temperature to exceed the solution temperature for the precipitate. The grain structure obtained by such processing must be retained during heat treatment of the forging by either direct aging of the forged structure or aging after a "pseudo" solution heat treatment that does not exceed the true solution temperature of all the precipitate.

A principal use of such processing is in the production of direct-aged IN 718. Figure 7 shows a time-temperature-transformation (TTT) diagram for the precipitates in IN 718. Note that the TTT diagram does not address the relative volume of each precipitate. In IN 718 the volumes of  $\gamma''$  and  $\delta$  greatly exceed the volume of  $\gamma'$ . At low temperatures, the metastable precipitates  $\gamma'$  and  $\gamma''$  predominate. At temperatures above 925 °C (1700 °F), the dominant phase is  $\delta$ . At temperatures around 925 °C (1700 °F), the  $\delta$  phase forms in a needlelike Widmanstätten structure. As the temperature is increased, the morphology of the  $\delta$  phase becomes more blocky. When  $\delta$  phase is subjected to strain at higher temperatures (980 to 1010 °C, or 1800 to 1850 °F), the  $\delta$  phase is spheroidized. As the temperature is increased, the volume of stable precipitate is decreased, with complete solution occurring at the  $\delta$  solvus temperature. Thus, hot working

in the range from 980 to 1010 °C (1800 to 1850 °F) causes the formation of a small volume of spheroidized  $\delta$  phase, which pins grain-boundary growth. The greater percentage of niobium is retained in solution and is available to form the strengthening  $\gamma''$  precipitate upon subsequent direct heat treatment (aging) of the forged part.

## Powder Processing

Powder techniques are being used extensively in superalloy production. Principally, high-strength gas turbine disk alloy compositions such as IN 100 or René 95, which are difficult or impractical to forge by conventional methods, have been powder processed. Inert atmospheres are used in the production of powders, often by gas atomization, and the powders are consolidated by extrusion or hot isostatic pressing (HIP). The latter process has been used either to produce shapes directly for final machining or to consolidate billets for subsequent forging. Extruded or HIP'ed billets often are isothermally forged to configurations for final machining. Minimal segregation, reduced inclusion sizes, ability to use very high  $V_f$   $\gamma'$  compositions, and ease of grain-size control are significant advantages of the powder process. Reduced costs, particularly through HIP formation of near-net-shape disks, may be possible with powder techniques but the extent of actual cost savings is a function of alloy and part complexity. An alternative powder processing technique, the Osprey process (or variants thereof), can create a built-up article by repetitive spraying of powder onto an appropriate mandrel.

Deformation processing of powder-produced articles generally is preferred from a mechanical property standpoint. Designers tend to have more confidence in parts that have been deformation processed to some extent. The deformation processing is thought to enhance the detectability of subsurface imperfections which would limit the fracture mechanics life of the article. It is claimed that Osprey-consolidated parts may be used with or without further deformation processing, but deformation processing would be desirable. Another facet of P/M is the importance of maintaining low gas content in powder products to minimize potential defects. Sources of excessive gas in P/M superalloys include hollow argon-atomized powder particles and container leakage or insufficient evacuation and purging of containers before consolidation.

Powder techniques also have been used to produce turbine blade/vane alloys of the ODS type. Mechanical alloying is the principal technique for introducing the requisite oxide/strain energy combination to achieve maximum properties. Rapid-solidification-rate (RSR) technology has been applied to produce highly alloyed (very high  $V_f$   $\gamma'$ ) superalloys and shows promise for advanced gas-turbine applications. Rapid-solidification-rate and ODS alloys can benefit from aligned crystal growth in the same manner as can directionally cast alloys. Directional recrystallization has been used in ODS alloys to produce favorable polycrystalline grain orientations with elongated (high-aspect-ratio) grains parallel to the major loading axis.

## Investment Casting

Cobalt-base, high  $V_f \gamma'$  nickel-base, and IN 718  $\gamma''$ -hardened superalloys are processed to complex final shapes by investment casting. Iron-nickel-base superalloys are not customarily investment cast. Investment casting permits intricate internal cooling passages and re-entrant angles to be achieved and produces a near-net shape of very precise dimensions. Most investment castings are small random-grain-oriented polycrystalline articles ranging in weight from less than a pound to a few pounds, but columnar-grain and single-crystal parts also are being cast, some as large as 4.5 to 9 kg (10 to 20 lb). In addition, large investment castings are being made in configurations up to several feet in diameter and hundreds of pounds in weight. A cast alloy commonly used to obtain the economic benefits of large sections is IN 718; a wide range of alloys are cast as smaller parts in polycrystalline, columnar-grain, or single-crystal form. Nickel-base and some cobalt-base superalloy remelting stock for investment casting is produced by VIM. Vacuum induction melted heats of superalloys intended for the investment casting process are much smaller in mass than the VIM heats used to produce stock for wrought alloy processing.

Cast articles are made by creating a pattern in wax or plastic. The pattern is duplicated as many times as necessary, typically using conventionally machined injection tooling. Hollow castings with complex internal features are produced by first creating a ceramic positive replica of the internal hollow passage through injection of a ceramic slurry into a die cavity to form a ceramic core. This core is then placed into the wax injection die and encapsulated with wax. An appropriate number of wax patterns are then attached to a "tree" complete with pourcup, sprue, risers, and so forth to channel metal from the pourcup into the part geometry.

The resulting tree is invested with ceramic of various sizes by dipping the assembled tree into a slurry, applying ceramic granules, and then drying the assembly under controlled conditions. The investing process is performed as many times as needed to build up a satisfactory ceramic coating. The invested tree is dried, and the wax is burned out. Then the investment is fired at a higher temperature to achieve maximum strength through sintering. The resulting mold is ready for use.

Many alloys are investment cast, including VIM superalloys, steels, and aluminum. These metals are melted and poured into the mold and solidified under conditions according to whether the product is to be large or small, and polycrystalline, columnar grained, or single crystal. Grain size in polycrystalline products is controlled by an appropriate primary dip coat in the investment along with mold-metal pour temperatures and selective mold insulation. An example is the Microcast-X method, which makes fine-grained (ASTM 5 to 3) superalloys by utilizing a very low superheat (low pour temperature) and a heated mold. Grain orientation in columnar-grain or single-crystal products is controlled by special furnaces that provide appropriate thermal gradients and by selective filters and/or starter nucleation sites.

After casting, the expendable ceramic shell is removed and the parts are cut from the tree. If the castings possess internal ceramic cores for internal feature fabrication, this core is removed using caustic chemicals. When removed, the positive core gives rise to the negative cavity possessing complex internal features. Most castings are typically heat treated to homogenize the metallurgical structure and precipitation strengthened to optimize mechanical properties. The castings then undergo x-ray inspection (internal defects), fluorescent penetrant inspection (external defects), chemical grain etch (crystal integrity), ultrasonic inspection (wall thickness for hollow parts), and dimensional inspection.

Inclusions, coarse grain size, surface attack in core leaching, core shift, and resulting undersized wall thickness are a few of the problems encountered in investment casting of superalloys. These problems reduce casting yield and cause potential property-level reductions if not properly controlled. Inclusions are controlled by melting technology and the use of filters to eliminate dross. Selective surface attack is controlled by modifying the autoclave leaching processes. In the past several decades, improved shell and core materials and casting mold design plus control of grain size and inclusions have led to improvements in casting yield and, occasionally, improvements in cast part strength. Casting porosity has been a problem in parts having large cross sections and in small parts made of some high  $V_f \gamma'$  alloys. Hot isostatic pressing techniques used for powder processing have been applied successfully in many instances to eliminate nonsurface-connected porosity, particularly in large castings of iron-nickel- and nickel-base superalloys. Improved fatigue and creep life generally result (Fig. 8), because casting quality is improved by HIP.

**Fig. 8 Beneficial effect of HIP on high-cycle fatigue resistance of René 80**

Directional-casting technology has become a commonly accepted production process for nickel-base superalloys. Columnar grain directionally solidified (CGDS) structures have been produced by promoting unidirectional heat flow within the furnace during the solidification cycle. Substantial property improvements have resulted for many alloys, Modulus parallel to the natural growth direction is lowered, leading to improvements in thermal fatigue life, ductility generally is increased, and creep-rupture strength (life) is improved through removal of transverse grain-boundary segments.

A logical extension of columnar-grain technology is the production of single crystals of hot-section aircraft gas turbine components. Removal of all grain boundaries and adjustments of alloy composition permitted by the absence of grain boundaries result in single-crystal (SC) article benefits similar to those described for the CGDS process, along with substantial improvements in strength capability. Directional casting to create a SC article provides composition flexibility and opens the possibility of additional alloy development for high-strength nickel-base superalloys. Although initially restricted to relatively small turbine airfoil components of aircraft gas turbines, CGDS, and SC processing has been extended to produce airfoils for large industrial gas turbines.

Directional solidification adds problems to those normally encountered in superalloy casting. Increased tendencies for inclusions (owing to the use of hafnium to enhance transverse ductility), separately nucleated grains, grain misorientation, and the tendency for freckle grains (grain nucleation caused by inverse segregation due to dendrite erosion) are causes for casting rejects in CGDS product. Freckles, slivers, low-angle boundaries (LAB), and spurious grains are casting problems in SC production. In both CGDS and SC alloys, surface recrystallization induced by surface strains and excess temperatures in postcast processing can be a cause for casting rejection.

Although cobalt-base superalloys can be directionally solidified in columnar grain structures, they are invariably cast as polycrystalline parts. Single-crystal manufacture of cobalt-base superalloys may be possible but has not been reported. It is doubtful that sufficiently significant property benefits would result from single-crystal or columnar-grain cobalt-base superalloys to warrant the expense of such processing.

A new technology known as rapid prototyping has enabled significant changes within the casting industry by eliminating the need for many of the investment casting process steps. This elimination has led to significant cost and lead-time reduction for development hardware. Processes such as stereolithography, selective laser sintering, and other three-dimensional printing technology can provide casting patterns without the use of costly conventional wax or ceramic injection dies. Special machines can take a three-dimensional computer-aided design (CAD), convert the design into cross-sectional layers, and build a three-dimensional representation of the CAD geometry in plastic, wax, or polymer. Some processes can directly build (from three-dimensional CAD geometry) three-dimensional ceramic shells into which metal can be poured. Other technologies focused on direct metal fabrication from three-dimensional CAD geometry are being developed. These technologies have revolutionized the industry in allowing faster development through low-cost iterative design so that design concepts can be transitioned to production rapidly.

## Joining

Cobalt-base superalloys are readily joined by gas metal-arc welding (GMAW) or gas tungsten-arc welding (GTAW) techniques. Cast alloys such as WI-52 and wrought alloys such as Haynes 188 have been extensively welded. Filler metals generally have been less highly alloyed cobalt-base alloy wire, although parent rod or wire (the same composition

as the alloy being welded) have been used. Cobalt-base superalloy sheet also is successfully welded by resistance techniques. Gas turbine vanes that crack in service have been repair welded using the above techniques (e.g., WI-52 vanes using L605 filler rod and 540 °C, or 1000 °F, preheat). Appropriate preheat techniques are needed in GMAW and GTAW to eliminate tendencies for hot cracking. Electron-beam welding (EBW) and plasma arc welding (PAW) can be used on cobalt-base superalloys, but usually are not required in most applications because alloys of this class are so readily weldable.

Nickel- and iron-nickel-base superalloys are considerably less weldable than cobalt-base superalloys. Because of the presence of the  $\gamma'$  strengthening phase, the alloys tend to be susceptible to hot cracking (weld cracking) and postweld heat treatment (PWHT) cracking (strain age or delay cracking). The susceptibility to hot cracking is directly related to the aluminum and titanium contents ( $\gamma'$  formers), as shown in Fig. 9. Hot cracking occurs in the weld heat-affected zone (HAZ), and the extent of cracking varies with alloy composition and weldment restraint.

**Fig. 9** Weldability diagram for some  $\gamma'$ -strengthened iron-nickel- and nickel-base superalloys, showing influence of total aluminum + titanium hardeners

Nickel- and iron-nickel-base superalloys have been welded by GMAW, GTAW, EBW, laser, and PAW techniques. Filler metals, when used, usually are weaker, more ductile austenitic alloys so as to minimize hot cracking. Occasionally, base-metal compositions are employed as fillers. Welding is restricted to the lower  $V_f \gamma'$  ( $\leq 0.35$ ) alloys, generally in the wrought condition. Cast alloys of high  $V_f \gamma'$  have not been consistently welded successfully when filler metal is required, as in weld repair of service parts. However, EBW can be used to make structural joints in such alloys. Friction or inertia welding also has been successfully applied to the lower  $V_f \gamma'$  alloys.

Because of their  $\gamma'$  strengthening mechanism and capability, many nickel- and iron-nickel-base superalloys are welded in the solution-heat-treated condition. Special preweld heat treatments have been used for some alloys. Nickel-niobium alloys, as typified by IN 718, have unique welding characteristics. The hardening phase,  $\gamma''$ , is precipitated more sluggishly at a lower temperature than is  $\gamma'$  so that the attendant welding-associated strains that must be redistributed are more readily accommodated in the weld metal and HAZ. The alloy is welded in the solution-treated condition and then given a postweld stress-relief-and-aging treatment that causes  $\gamma'$  precipitation. Some alloys, such as A-286, are inherently difficult to weld despite only moderate levels of  $\gamma'$  hardeners. There is some evidence that high-titanium alloys may be more difficult to weld than alloys of similar  $V_f \gamma'$  relying on high aluminum/titanium ratios for their strength capabilities.

Weld techniques for superalloys must address not only hot cracking but also PWHT cracking, particularly as it concerns microfissuring (microcracking), which can be subsurface and thus difficult to detect. Tensile and stress-rupture strengths may be hardly affected by microfissuring, but fatigue strengths can be drastically reduced.

In addition to being weldable by the usual fusion welding techniques discussed above, nickel- and iron-nickel-base alloys can be resistance welded when in sheet form; brazing, diffusion bonding, and transient liquid phase (TLP) bonding also have been employed to join these alloys. Brazed joints tend to be more ductility-limited than welds; diffusion bonding of superalloys has not found consistent application. Transient liquid phase bonding has been found to be very useful,

principally in turbine parts of aircraft gas turbine engines. The distinguishing characteristic of TLP bonding that produces its excellent integrity is that, although a lower-temperature bond is made as in brazing, subsequent diffusion occurs at the bonding temperature, leading to a fully solidified joint that has a composition similar to that of the base metal and a microstructure indistinguishable from it. Consequently, the resultant joint can have a melting temperature and properties very similar to those of the base metal.

## Properties and Microstructure

The principal microstructural variables of superalloys are the precipitate amount and its morphology, grain size and shape, and carbide distribution. Nickel and iron-nickel-base alloys of the titanium/aluminum type have their properties controlled by all three variables; nickel-niobium alloys have the additional variable of  $\delta$  phase distribution; cobalt-base superalloys are not affected by the first variable. Structure control is achieved through composition selection/modification and by processing. For a given nominal composition, there are property advantages and disadvantages of the structures produced by deformation processing and by casting. Cast superalloys generally have coarser grain sizes, more alloy segregation, and improved creep and rupture characteristics. Wrought superalloys generally have more uniform, and usually finer, grain sizes and improved tensile and fatigue properties.

Nickel- and iron-nickel-base superalloys of the Ni-Ti/Al type typically consist of  $\gamma'$  dispersed in a  $\gamma$  matrix, and the strength increases with increasing  $V_f \gamma'$ . The lowest  $V_f$  amounts of  $\gamma'$  are found in iron-nickel-base and first-generation nickel-base superalloys, where  $V_f \gamma'$  is generally less than about 0.25 (25 vol%). The  $\gamma'$  is commonly spheroidal in lower  $V_f \gamma'$  alloys but often cuboidal in higher  $V_f \gamma'$  ( $\geq 0.35$ ) nickel-base superalloys. The nickel-niobium-type superalloys typically consist of  $\gamma''$  dispersed in a  $\gamma$  matrix, with some  $\gamma'$  present as well. The inherent strength capability of the  $\gamma'$ - and  $\gamma''$ -hardened superalloys is controlled by the intragranular distribution of the hardening phases; however, the usable strength in polycrystalline alloys is determined by the condition of the grain boundaries, particularly as affected by the carbide-phase morphology and distribution, and in the case of nickel-niobium alloys, additionally by the distribution of the  $\delta$  phase.

Satisfactory properties in Ni-Ti/Al alloys are achieved by optimizing the  $\gamma'$   $V_f$  and morphology (not necessarily independent characteristics) in conjunction with securing a dispersion of discrete globular carbides along the grain boundaries (Fig. 10). Discontinuous (cellular) carbide or  $\gamma'$  at grain boundaries increases surface area and drastically reduces rupture life, even though tensile and creep strength may be relatively unaffected.

**Fig. 10** Carbide precipitation in Waspaloy. (a) Favorable discrete grain-boundary type (10,000 $\times$ ). (b) Less favorable zipperlike, discontinuous type (6800 $\times$ )

Wrought nickel- and iron-nickel-base superalloys generally are processed to have optimum tensile and fatigue properties. At one time, when wrought alloys were used for creep-limited applications, such as gas turbine high-pressure turbine blades, heat treatments different from those used for tensile-limited uses were applied to the same nominal alloy composition to maximize creep-rupture life. Occasionally, the nominal composition of an alloy such as IN 100 or U 700/Astroloy varies according to whether it is to be used in the cast or the wrought condition.

### ***Evolution of Microstructure***

Superalloys contain a variety of elements in a large number of combinations to produce desired effects. Some elements go into solid solution to provide one or more of the following: strength (molybdenum, tantalum, tungsten, rhenium); oxidation resistance (chromium, aluminum); phase stability (nickel); and increased volume fractions of favorable secondary precipitates (cobalt). Other elements are added to form hardening precipitates such as  $\gamma'$  (aluminum, titanium) and  $\gamma''$  (niobium). Minor elements (carbon, boron) are added to form carbides and borides; these and other elements (magnesium) are added for purposes of tramp-element control. Some elements (boron, zirconium, hafnium) also are added to promote grain-boundary effects other than precipitation or carbide formation. Lanthanum has been added to some alloys to promote oxidation resistance, and yttrium has been added to coatings to enhance oxidation resistance. A major addition to nickel-base superalloy chemistry in recent years has been the element rhenium, which has extended the temperature capability of the CGDS and SC alloys. Rhenium appears to produce these improvements by significantly reducing the coarsening rate for  $\gamma'$ . Many elements (cobalt, molybdenum, tungsten, rhenium, chromium, etc.), although added for their favorable alloying qualities, can participate, in some circumstances, in undesirable phase formation ( $\sigma$ ,  $\mu$ , Laves, etc.).

Some of these elements produce readily discernible changes in microstructure; others produce more subtle microstructural effects. The precise microstructural effects produced are functions of processing and heat treatment. The most obvious microstructural effects involve precipitation of geometrically close-packed (gcp) phases such as  $\gamma'$ , formation of carbides, and formation of topologically close-packed (tcp) phases such as  $\sigma$ . Even when the type of phase is specified, microstructure morphology can vary widely--for example, script versus blocky carbides, cuboidal versus spheroidal  $\gamma'$ , cellular versus uniform precipitation, acicular versus blocky  $\sigma$ , and discrete  $\gamma'$  versus  $\gamma'$  envelopes. Typical nickel-base superalloy microstructures as they evolved from spheroidal to cuboidal  $\gamma'$  are depicted in Fig. 11.

**Fig. 11** Qualitative description of the evolution of microstructure and chromium content of nickel-base superalloys. Source: Adapted from Ref 3. Original source: Ref 4

The  $\gamma'$  phase is an ordered ( $L1_2$ ) intermetallic fcc phase having the basic composition  $Ni_3(Al,Ti)$ . Alloying elements affect  $\gamma'$  mismatch with the matrix  $\gamma$  phase,  $\gamma'$  antiphase-domain-boundary (APB) energy,  $\gamma'$  morphology, and  $\gamma'$  stability. A related phase,  $\eta$ , is an ordered ( $D0_{24}$ ) hexagonal phase of composition  $Ni_3Ti$  that may exist in a metastable form as  $\gamma'$  before transforming to  $\eta$ . Other types of intermetallic phases, such as  $\delta$ , orthorhombic  $Ni_3Nb$ , or  $\gamma''$ , bct ordered ( $D0_{22}$ )  $Ni_3Nb$  strengthening precipitate, have been observed.

Carbides also are an important constituent of superalloys. They are particularly essential in the grain boundaries of cast polycrystalline alloys for production of desired strength and ductility characteristics. Carbide levels in wrought alloys always have been below those in cast alloys, but some carbide has been deemed desirable for achieving optimum strength properties. As cleanliness of superalloys has increased, the carbide levels in wrought alloys have been lowered. Carbides, at least large ones, become the limiting fracture mechanics criteria for modern wrought superalloy application.

Carbides may provide some degree of matrix strengthening, particularly in cobalt-base alloys, and are necessary for grain-size control in some wrought alloys. Some carbides are virtually unaffected by heat treatment, while others require such a step to be present. Various types of carbides are possible depending on alloy composition and processing. Some of the important types are MC,  $M_6C$ ,  $M_{23}C_6$ , and  $M_7C_3$ , where M stands for one or more types of metal atom. In many cases, the carbides exist jointly; however, they usually are formed by sequential reactions in the solid state following breakdown of the MC which normally is formed in the molten state. The common carbide-reaction sequence for many superalloys is MC to  $M_{23}C_6$ , and the important carbide-forming elements are chromium ( $M_{23}C_6$ ,  $M_7C_3$ ); titanium, tantalum, niobium, and hafnium (MC); and molybdenum and tungsten ( $M_6C$ ). Boron may participate somewhat interchangeably with carbon and produces such phases as  $MB_{12}$ ,  $M_3B_2$ , and others. One claim made for boron is that primary borides formed by adjustment of boron/carbon ratio are more amenable to morphological modification through heat treatment.

All superalloys contain some chromium plus other elements to promote resistance to environmental degradation. The role of chromium is to promote  $Cr_2O_3$  formation on the external surface of an alloy. When sufficient aluminum is present, formation of the more protective oxide  $Al_2O_3$  is promoted when oxidation occurs. A chromium content of 6 to 22 wt% generally is common in nickel-base superalloys, whereas a level of 20 to 30 wt% Cr is characteristic of cobalt-base superalloys, and a level of 15 to 25 wt% Cr is found in iron-nickel-base superalloys. Amounts of aluminum up to approximately 6 wt% can be present in nickel-base superalloys.

A discussion of the function of alloying elements in terms of microstructure would be incomplete without mention of the tramp elements. Elements such as silicon, phosphorus, sulfur, lead, bismuth, tellurium, selenium, and silver, often in amounts as low as the parts per million (ppm) level, have been associated with property-level reductions, but they are not

visible optically or with an electron microscope. Microprobe and Auger spectroscopic analyses have determined that grain boundaries can be decorated with tramp elements at high local concentrations. Elements such as magnesium tend to tie up some detrimental elements such as sulfur in the form of a compound, and titanium tends to tie up the element nitrogen as TiN. In such cases, these and other similar compounds often are visible in the microstructure.

### Function of Processing

Processing is considered to be the art/science of rendering the superalloy material into its final form. Processing and alloying elements are interdependent. The general microstructural changes brought about by processing result from the overall alloy composition plus the processing sequence. The role of heat treatment on phases will be referred to when prior microstructural effects are considered; the role of composition on phases has been discussed above. Tables 5 and 6 provide information pertaining to typical heat treatment cycles for a variety of common superalloys.

Note: Alternate treatments may be used to improve specific properties.

- (a) If furnace size/load prohibits fast heat up to initial age temperature, a controlled ramp up from 590 to 730 °C (1100 to 1350 °F) is recommended.
- (b) To provide adequate quenching after solution treating, it is necessary to cool below about 540 °C (1000 °F) rapidly enough to prevent precipitation in the intermediate temperature range. For sheet metal parts of most alloys, rapid air cooling will suffice. Oil or water quenching is frequently required for heavier sections that are not subject to cracking.
- (c) Heat treatment of Inconel 706 to enhance tensile properties instead of creep resistance for tensile-limited applications

The three most significant process-related microstructural variables other than those resulting from composition/heat treatment interactions are the size, shape, and orientation (in anisotropic structures) of the grains. Grain size varies considerably from cast to wrought structure, generally being significantly smaller for the latter. Special processing--for example, directional solidification or directional recrystallization--can effect changes not only in grain size but also in grain shape and orientation, which significantly alter mechanical and physical properties. Corrosion reactions, however, are primarily functions of composition.

### ***Effects of Prior Microstructure on Properties***

Nickel- and iron-nickel-base superalloys may be hardened by  $\gamma'$  or  $\gamma''$  precipitation (in an fcc  $\gamma$  matrix). The  $\gamma'$  in iron-nickel-base and first-generation nickel-base alloys generally is spheroidal, whereas the  $\gamma'$  in later-generation nickel-base alloys generally is cuboidal (Fig. 12). The  $\gamma''$  phase is disk shaped. The  $V_f$  of  $\gamma'$  is generally approximately 0.2 or less in wrought iron-nickel-base superalloys but may exceed 0.6 in nickel-base superalloys. There are insufficient alloy compositions to provide knowledge of a range for  $V_f$   $\gamma''$  in  $\gamma''$ -hardened alloys.

**Fig. 12** Wrought nickel-base superalloys showing spheroidal nature of early (low  $V_f$   $\gamma'$ ) alloys (Waspaloy, left) and cuboidal nature of later (higher  $V_f$   $\gamma'$ ) alloys (U 700, right). Note secondary (cooling)  $\gamma'$  between primary cuboidal  $\gamma'$  particles in U 700. Original magnification, 6800 $\times$

**$\gamma'$  Precipitation.** Strengthening by precipitate particles is related to many factors; in the case of  $\gamma'$ , the most direct correlations can be made with  $V_f$  of  $\gamma'$  and with  $\gamma'$  particle size. However, the correlation between strength and  $\gamma'$  size may be difficult to prove in commercial alloys over the range of particle sizes available. Before the age-hardening peak is reached during precipitation, the operative strengthening mechanism involves cutting of  $\gamma'$  particles by dislocations, and strength increases with increasing  $\gamma'$  size (Fig. 13) at constant  $V_f$  of  $\gamma'$ . After the age-hardening peak is reached, strength decreases with continuing particle growth because dislocations no longer cut  $\gamma'$  particles but rather bypass them. This effect can be demonstrated for tensile or hardness behavior in low  $V_f$   $\gamma'$  alloys (A-286, Incoloy 901, Waspaloy), but is not as readily apparent in high  $V_f$   $\gamma'$  alloys such as MAR-M 246, IN 100, and so forth. For creep rupture, the effects are less well defined; however, uniform fine-to-moderate  $\gamma'$  sizes (0.25 to 0.5  $\mu\text{m}$ ) are preferred to coarse or hyperfine  $\gamma'$  for optimum properties.

**Fig. 13** Strength (hardness) versus particle diameter in a nickel-base superalloy. Cutting occurs at low particle sizes, bypassing at larger sizes. Note that aging temperature also affects strength in conjunction with particle size.

Alloy strength in titanium/aluminum hardened alloys clearly depends on  $V_f \gamma'$ . The  $V_f \gamma'$  and thus strength can be increased to a point by adding more hardener elements (aluminum, titanium). Alloy strengths increase as aluminum + titanium content increases (Fig. 14), and also as the aluminum-to-titanium ratio increases. In wrought alloys, the  $\gamma'$  usually exists as a bimodal (duplex) distribution of fine  $\gamma'$ , and all of the aluminum + titanium contributes effectively to the hardening process. In cast alloys, the character of the  $\gamma'$  precipitate developed can be extremely variable because of the effects of segregation and cooling rate. Large amounts of  $\gamma$ - $\gamma'$  eutectic and coarse  $\gamma'$  may be developed during solidification. Subsequent heat treatment can modify these structures. Bimodal and trimodal  $\gamma'$  distributions plus  $\gamma$ - $\gamma'$  eutectic can be found in cast alloys after heat treatment. Solution heat treatments at temperatures sufficiently high to homogenize the alloy and dissolve coarse  $\gamma'$  and the eutectic  $\gamma$ - $\gamma'$  constituents for subsequent reprecipitation as a uniform fine  $\gamma'$  have improved creep capability. However, incipient melting temperatures limit the homogenization possible in many polycrystalline or CGDS super-alloys. For a columnar-grain nickel-base superalloy, a direct correlation has been found to exist between creep-rupture life at 980 °C (1800 °F) and the  $V_f$  of fine  $\gamma'$  (Fig. 15).

**Fig. 14** Effect of aluminum + titanium content on strength of wrought and cast nickel-base superalloys at 870 °C (1600 °F)

**Fig. 15** Increase in creep-rupture life with increase in  $V_f$  of fine  $\gamma'$ , demonstrated in a columnar-grain, directionally solidified nickel-base superalloy, PWA 1422 (variant of MarM-200, with hafnium addition)

In general, to achieve the greatest hardening in  $\gamma'$ -hardened alloys it is necessary to solution heat treat the alloys above the  $\gamma'$  solvus. One or more aging treatments are used to optimize the  $\gamma'$  distribution and to promote transitions in other phases such as carbides. In some alloys, several intermediate and several lower-temperature aging treatments are used; in cast alloys or in very high  $V_f$   $\gamma'$  wrought alloys, a coating cycle or high-temperature aging treatment may precede the intermediate-temperature aging cycle. When multiple aging treatments are used, a superalloy may show the bimodal or trimodal  $\gamma'$  distribution described above. An essential feature of  $\gamma'$  hardening in nickel-base superalloys is that a temperature fluctuation that dissolves some  $\gamma'$  does not necessarily produce permanent property damage, because subsequent cooling to normal operating conditions reprecipitates  $\gamma'$  in a useful form.

In the final analysis, it is not possible to judge alloy performance by considering just the  $\gamma'$  phase. The strength of  $\gamma'$ -hardened grains must be balanced by grain-boundary strength. If the  $\gamma'$ -hardened matrix becomes much stronger relative to grain boundaries, then premature failure occurs because stress relaxation at the grain boundaries becomes difficult.

**$\gamma''$  Precipitation.** The  $\gamma''$  phase relationship to properties has not been studied extensively. Strength will be a function of  $V_f$  of  $\gamma''$ ; however, any quantitative relationships established for  $\gamma'$ -hardened alloys will not hold for  $\gamma''$ -hardened alloys because of a difference in precipitate morphology (the  $\gamma'$ -hardened alloys use initial precipitates which are cuboids or spheres, while the  $\gamma''$  precipitates are disks). The nickel-niobium alloys tend to have reversion or dissolution of the strengthening phase at relatively low temperatures. Bimodal  $\gamma''$  distributions are not necessarily found, but  $\gamma''$  coupled with  $\gamma'$  distributions form.

Heat treatments for the nickel-niobium alloys attempt to optimize the distribution of the  $\gamma''$  phase as well as to control grain size. Although for many years, a sequence of solution treatment followed by two-step aging was the preferred route to an appropriate  $\gamma''$  distribution after an article was forged, this is no longer the case. This sequence has been replaced in most instances by a direct-age process after cooling of the nickel-niobium alloy article from the forging temperature. Uniform  $\gamma''$  distributions with attendant  $\gamma'$  precipitate are formed. See the following discussion and the prior discussion of direct aging in IN 718 in the "Deformation Processing" section.

The practical use of  $\gamma''$  precipitation is restricted to nickel-base alloys with niobium additions in excess of 4 wt%. IN 718 is the outstanding example of an alloy in which  $\gamma''$  formation has been commercially exploited. The  $V_f$  of  $\gamma''$  in IN 718 is substantially in excess of that of  $\gamma'$ . Both  $\gamma''$  and  $\gamma'$  will be found in alloys where  $\gamma''$  is present, but  $\gamma''$  will be the predominant strengthening agent. Although the strengthening behavior of  $\gamma''$  phase has not been studied, similar considerations to  $\gamma'$  behavior as described earlier probably pertain; that is, there will be an optimum  $\gamma''$  size and  $V_f$  for strength. The most significant feature of  $\gamma''$  is probably the ease with which it forms at moderate temperatures after prior solutioning by heat treatment or joining processes. Because of this behavior, a  $\gamma''$ -hardened alloy can be aged, after welding, to produce a fully strengthened structure with exceptional ductility.

The  $\gamma''$  phase, not normally a stable phase, can convert to  $\gamma'$  and  $\delta\text{Ni}_3\text{Nb}$  on longtime exposure. The strength of  $\gamma'$  is additive to that of  $\gamma''$  phase. A lack of notch ductility in IN 718 has been associated with a  $\gamma''$  precipitate-free zone (PFZ); the  $\gamma''$  PFZ can be eliminated and ductility restored by appropriate heat treatment. Alloys hardened with  $\gamma''$  phase achieve high tensile strengths and very good creep-rupture properties at lower temperatures, but the conversion of  $\gamma''$  to  $\gamma$  and  $\delta$  above approximately 675 °C (1250 °F) causes a sharp reduction in strength.

**Carbide Precipitation: Grain-Boundary Hardening.** Carbides exert a profound influence on properties by their precipitation on grain boundaries. In most superalloys,  $\text{M}_{23}\text{C}_6$  forms at the grain boundaries after a postcasting or postsolution treatment thermal cycle such as aging. Chains of discrete globular  $\text{M}_{23}\text{C}_6$  carbides were found to optimize creep-rupture life by preventing grain-boundary sliding in creep rupture while concurrently providing sufficient ductility in the surrounding grain for stress relaxation to occur without premature failure.

In contrast, if carbides precipitate as a continuous grain-boundary film, properties can be severely degraded.  $\text{M}_{23}\text{C}_6$  films were reported to reduce impact resistance of M252, and MC films were blamed for lowered rupture lives and ductility in forged Waspaloy. At the other extreme, when no grain-boundary carbide precipitate is present, premature failure will also occur because grain-boundary movement essentially is unrestricted, leading to subsequent cracking at grain-boundary triple points.

The role of carbides at grain boundaries in iron-nickel-base superalloys is less well documented than for nickel-base alloys, although detrimental effects of carbide films have been reported. Studies of specific effects of grain-boundary carbides in cobalt-base alloys are even more sparse, because the carbide distribution in cobalt-base alloys arises from the original casting or on cooling after mill annealing for wrought cobalt-base alloys. The significantly greater carbon content of cobalt-base alloys leads to much more extensive grain-boundary carbide precipitation than in nickel- and iron-nickel-base alloys. Carbides at grain boundaries in cast cobalt-base alloys appear as eutectic aggregates of  $\text{M}_6\text{C}$ ,  $\text{M}_{23}\text{C}_6$ , and fcc  $\gamma$  cobalt-base solid solution. No definitive study of the effects of varied carbide forms in grain boundaries on the mechanical behavior of cobalt-base superalloys has been reported.

The lamellar eutectic (carbides- $\gamma$  Co) nature of carbides ( $\text{M}_{23}\text{C}_6$ - $\text{M}_6\text{C}$ ) in cast cobalt-base superalloys is interesting. A somewhat similar morphology of  $\text{M}_{23}\text{C}_6$ , occurring when it is precipitated in cellular form in nickel- and iron-nickel-base alloys, leads to mechanical-property loss in such alloys, but lamellar eutectic does not seem to degrade cast cobalt-base alloy properties. Cellular growth in nickel-base alloys was found to occur when a high supersaturation of carbon produced by solution heat treatment was not relieved by an intermediate precipitation treatment prior to aging at 705 to 760 °C (1300 to 1400 °F). The ductility of a nickel-base superalloy also was impaired by a different type of precipitation--namely, Widmanstätten  $\text{M}_6\text{C}$  at grain and twin boundaries. However, formation of intragranular Widmanstätten  $\text{M}_6\text{C}$  after exposure of B-1900 nickel-base alloy did not appear to reduce properties.

Another effect produced by grain-boundary  $\text{M}_{23}\text{C}_6$  carbide precipitation is the occasional formation, on either side of the boundary, of a zone depleted in  $\gamma'$  precipitate. These PFZs may have significant effects on rupture life of nickel- and iron-nickel-base superalloys. If such zones should become wide or much weaker than the matrix, deformation would concentrate there, resulting in early failure. The more complex (higher  $V_f$   $\gamma'$ ) alloys do not show significant PFZ effects, probably because of their higher saturation with regard to  $\gamma'$ -forming elements. An effect seen concurrently with PFZ and not clearly separated from it is the  $\gamma'$  envelope produced by breakdown of TiC and consequent formation of  $\text{M}_{23}\text{C}_6$  or  $\text{M}_6\text{C} + \gamma'$  (from the excess titanium). Not only is the role of the  $\gamma'$  envelope insufficiently established, but there is also the remote possibility that the excess titanium-rich area is really either  $\eta$  or a metastable  $\gamma'$  that could transform to  $\eta$  in use.

**Carbide Precipitation: Matrix or General Hardening.** Carbides affect the creep-rupture strengths of cobalt-base superalloys and some nickel- and iron-nickel base superalloys by formation within grains. In cobalt-base cast superalloys, script MC carbides are liberally interspersed within grains, causing a form of dispersion hardening that is not of a large magnitude owing to its relative coarseness. The distribution of carbides in cast alloys can be modified by heat treatment, but strength levels attained at all but the highest temperatures are substantially less than those of the  $\gamma'$ -hardened alloys. Consequently, cast cobalt-base alloys generally are not heat treated except in a secondary sense through the coating diffusion heat treatment of 4 h at 1065 to 1120 °C (1950 to 2050 °F) sometimes applied.

Wrought cobalt-base superalloys have carbide modifications produced during the fabrication sequence. Carbide distributions in wrought alloys result from the mill anneal after final working. Properties are largely a result of grain size, refractory-metal content, and carbon level, which indicates the  $V_f$  of carbides available for hardening.

True solutioning, in which all minor constituents are dissolved, is not possible in most cobalt-base superalloys, because melting often occurs before all the carbides are solutioned. Some enhancement of creep rupture behavior has been achieved by heat treatment. Rupture-time improvements can be gained by aging a modified Vitallium alloy (Fig. 16); larger increases have been produced by increasing the carbon content of the alloy. Solution treating and aging is not suitable for producing stable cobalt-base superalloys for use above 815 °C (1500 °F) because of carbide dissolution or overaging.

**Fig. 16** Effect of heat treatment on a cobalt-base superalloy (HS-31, also known as X-40), showing increase in strength resulting from carbide precipitation

Matrix carbides in nickel- and iron-nickel-base superalloys also may be partially solutioned. MC carbides will not totally dissolve, however, without incipient melting of the alloy and tend to be unstable, decomposing to  $M_{23}C_6$  at temperatures below about 815 to 870 °C (1500 to 1600 °F) or possibly converting to  $M_6C$  at temperatures of 980 to 1040 °C (1800 to 1900 °F) if the alloy has a sufficiently high molybdenum + tungsten content. Matrix carbides generally contribute very small increments of strengthening to nickel- and iron-nickel-base superalloys.

An interesting microstructural trend has taken place with the advent of single crystals of nickel-base superalloys. Because no grain boundaries exist, there is little need for the normal grain-boundary strengtheners such as carbon. Consequently, very few matrix or subboundary carbides exist in first-generation SC alloys. Although the initial trend was to remove carbon completely from SC nickel-base superalloys, the subsequent realization that subboundaries in single crystals could benefit from carbides has led to a relaxation of carbon restrictions, and low amounts of carbon are now permitted in many single-crystal alloys. (Hafnium, boron, and zirconium in limited amounts also may be permitted.) As noted above, the trend in wrought nickel-base superalloys continues to be toward reduced carbon and reduced carbide size.

Perhaps the most common other role of matrix carbides (also shared by grain-boundary carbides) is a negative one: They may participate in the fatigue cracking process by premature cracking or by oxidizing at the surface of uncoated alloys to cause a notch effect. Oxidized carbides or precracked carbides from machining or thermal stresses can initiate fatigue cracks. Precracked carbides can be related to prior casting processes. Carbide size is important, and reduced carbide volumes and sizes in nickel-base alloys result in a reduction in precracked carbides. The longer solidification times and lower gradients of early directional solidification processes often resulted in moderately large carbides. However, improved gradients and the reduced carbon contents of SC alloys (few or no carbides) have resulted in substantial improvements in fatigue resistance, particularly over similarly oriented CGDS alloys with normal carbon levels. This effect is most noticeable in low-cycle fatigue (LCF) and thermomechanical fatigue (TMF). No evidence is available to interpret the effect of the absence of carbides on high-cycle fatigue (HCF), but beneficial effects could be anticipated.

Oxidized carbides can be minimized or prevented by several methods. Casting procedures and/or chemical composition may be modified to produce smaller primary carbides. Powder processing may be used to produce the same result. Carbon content may be reduced if it is not specifically required to enable the alloy to attain the desired strength levels. Reduced carbon is the rule in SC and powdered superalloys. Of course, the alloy may be coated with an appropriate protective coating that leaves the carbides in a subsurface location.

Although there is limited documentation, it frequently is assumed that noncarbide-forming elements do influence the formation of carbides. Cobalt, for example, has been claimed to modify the carbides in nickel-base alloys, and phosphorus has produced a more general, more finely dispersed, and smaller carbide precipitation than carbon alone in a heat-resisting iron-base alloy. The modifying effect on carbides may be intragranular or intergranular depending on the modifier and the base-alloy system.

**Boron, Zirconium, and Hafnium.** Within limits, significant improvements in mechanical properties can be achieved by additions of boron, zirconium, and hafnium. However, only limited microstructural correlations can be made. The presence of these elements may modify the initial grain-boundary carbides or tie up deleterious elements such as sulfur and lead. Reduced grain-boundary diffusion rates may be obtained, with consequent suppression of carbide agglomeration and creep cracking. Hafnium contributes to the formation of more  $\gamma$ - $\gamma'$  eutectic in cast alloys; the eutectic at grain boundaries is thought (in modest quantities) to contribute to alloy ductility. The effects of these elements are limited to nickel- and iron-nickel-base alloys; virtually no cobalt-base alloys contain them. Hafnium in particular contributes strongly to improved ductility in transverse boundaries in CGDS alloys.

**Processing.** Three major processing techniques are used for controlling superalloy properties. Thermomechanical working is used for wrought nickel- and iron-nickel-base alloys to store energy by producing a fine grain size and controlling dislocation density/configuration. Improvements in tensile properties and LCF have resulted.

A second processing route involves the use of powder metallurgy to produce reduced carbide size and greater homogeneity in materials with a resultant improvement in fatigue resistance and fracture mechanics life limits. Furthermore, in conjunction with isothermal processing, alloy grain sizes of ASTM 8 to 12 are being routinely produced in very-high-strength alloys, resulting in additional fatigue-life benefits. (Major benefits result from the ability to form alloys such as IN 100, which are unforgeable by some standard procedures.)

The third area is casting control of grain size and morphology, especially by controlled solidification. Cast-alloy grain sizes have been made more uniform and, in some cases, have been reduced to enhance fatigue or tensile properties. Directional grain structures have improved strength (Fig. 17). Improved creep-rupture and fatigue resistance have resulted from the elimination of transverse grain boundaries and the favorable orientation of a low modulus direction to reduce strains. In the extreme, grains have been eliminated in SC alloys with additional gains in creep-rupture behavior (Fig. 17).

**Fig. 17** Comparison of creep properties of MAR-M 200 alloy, polycrystalline conventionally cast (C), columnar-grain directionally solidified (D), and single-crystal directionally solidified (M)

Porosity in superalloys has led to fatigue and creep-rupture failure. Reduced porosity owing to HIP has resulted in improved properties. Efforts to date have centered on nickel-base cast alloys, but the process should enhance properties of any cast alloy with nonsurface-connected casting porosity. (In the biomedical field, use of HIP has provided significant improvements in fatigue life of cast Vitallium alloy hip replacements.)

### ***Effects of Thermal Exposure on Mechanical Properties***

Superalloys generally behave much like other alloy systems on thermal exposure during testing or in service, but with some differences due to the nature of the  $\gamma'$  precipitates. Most alloys with secondary hardening phases undergo property degradation due to coalescence of the secondary phases, a process that reduces their effectiveness. This behavior occurs in superalloys and is manifested by such phenomena as  $\gamma'$  agglomeration and coarsening; carbide precipitation and  $\gamma'$  envelope formation also occur. In addition, the superalloys may show a tendency to form less-desirable secondary phases such as  $\sigma$ .

These detrimental phases generally reduce property levels of the superalloys in which they form because of their inherent properties and/or the consumption of elements intended for  $\gamma$  and  $\gamma'$ . Some of these phases can be prevented from forming by application of compositional control guided by the concept of the electron-vacancy number,  $N_v$ . Formation of tcp phases such as  $\sigma$ , Laves, and  $\mu$  is found to be related to excess electron vacancies in the transition-element base metals (iron, nickel, and cobalt). By ascribing  $N_v$  values to the alloying elements of the  $\gamma$  matrix, a weighted  $N_v$  can be calculated for  $\gamma$ , and, by experiment, upper limits for  $N_v$  can be set for a given alloy composition to ensure the absence of tcp phases in reasonable exposure times. Unfortunately, simple calculations of this type have not been found applicable to  $\delta$  or  $\eta$  formation, which can be detrimental in certain morphologies and/or in excess amounts. Trial-and-error adjustments of composition and processing generally are required to ensure that  $\delta$  and  $\eta$  precipitation do not occur and cause a significant loss of properties.

In addition to the formation of a singular detrimental phase, a more complex microstructure can appear under coatings. A specific secondary reaction zone (SRZ) was reported for alloys of the N4 and N5 type. This zone produced a transformation front which often occurred as a cellular reaction in which  $\gamma$  and P phase (about 50% Re) formed in a matrix of  $\gamma'$  phase. Strength was dramatically reduced, especially when SRZ formed in dendritic areas. Modified alloys have negated the formation of this complex structure, just as  $N_v$  control minimizes formation of detrimental tcp phases.

**Transformation of Hardening Phase.** In iron-nickel-base superalloys, the strengthening precipitate usually degrades in a moderate temperature regime, 650 to 760 °C (1200 to 1400 °F), forming structures and precipitate morphologies that are less effective in strengthening the alloy. In alloys hardened by large amounts of titanium,  $\eta$  phase replaces  $\gamma'$ . The precipitation of  $\eta$  may occur in two forms: at the grain boundaries as cellular product or intragranularly as Widmanstätten plates. The cellular precipitation is often associated with loss of mechanical properties, particularly notch stress rupture (NSR). Intragranular plates also may cause some property loss, but data are not available. In some nickel-base superalloys with higher titanium/aluminum ratios (e.g., IN 738, IN 792, and IN 939),  $\eta$  has been reported, but no information on property degradation is available.

In a nickel-niobium alloy such as IN 718, plates of orthorhombic  $\delta$  phase will form on exposure after sufficiently long times at elevated temperatures. Because of its relatively coarse morphology, properties deteriorate when excess amounts of platelike or acicular  $\delta$  form.

**Formation of Transition-Element Phases.** Of great concern in all superalloys has been the formation of detrimental secondary phases not directly associated with the primary hardening precipitate phases,  $\gamma'$  and  $\gamma''$ . Laves phases have been found in the iron-nickel-base superalloys IN 718, Incoloy 901, and A-286. Room-temperature yield strength and ductility of IN 718 are reduced by Laves formation, whereas Laves in A-286 does not affect properties. Laves in the cobalt-base alloy L605 severely degrades room-temperature ductility.

Phases such as Laves,  $\sigma$ , and  $\mu$  in acicular form generally are detrimental owing to their morphology, lack of ductility, and the tying up of some hardening elements. Sigma-phase formation in several nickel-base alloys has been shown to reduce stress-rupture life (Fig. 18). Sigma generally forms with exposure and is controlled by establishing composition limits (phase control electron vacancy number,  $N_v$ ) or by preventing an alloy from operating in the  $\sigma$ -forming temperature range. The extent of the effect that tcp and other secondary phases have on properties varies with the type of alloy (cast versus wrought), property being measured, initial microstructure, and environmental effects (coated versus uncoated, test atmosphere).

Fig. 18 Stress-rupture behavior of U 700, showing reduction in strength that occurs when  $\sigma$  phase forms. Source: Ref 5 (original source: Ref 6)

**Morphological Changes in  $\gamma'$ .** Changes in  $\gamma'$  during testing produce effects on properties that may not be readily observed because of the simultaneous occurrence of other microstructural changes. Most commonly,  $\gamma'$  coarsens following well-established kinetics and agglomerates in a creep-rupture test (Fig. 19), tending to form platelets of  $\gamma'$  on the [001] planes perpendicular to the applied stress. The coarsening of  $\gamma'$  can cause reduced rupture life (Fig. 20). Overheating can cause accelerated coarsening as well as solutioning of some fine  $\gamma'$ . Properties may be reduced, but reprecipitation of fine  $\gamma'$  occurs in the case of mild overheating excursions.

Fig. 19 Agglomeration of  $\gamma'$  in Udimet 700 resulting from creep testing. Left, as heat treated. Right, after 91.2 h at 252.3 MPa (36.6 ksi) and 893 °C (1640 °F). 4000 $\times$

Fig. 20 Stress-rupture behavior of B-1900 nickel-base superalloy, showing break in slope believed to be caused

by  $\gamma'$  coarsening

**Carbide Morphology/Type Changes.** As exposure time increases, there is a tendency for further reduction in the primary MC carbide amounts and for further morphological changes together with a tendency to form increased amounts of the secondary carbides  $M_{23}C_6$  and  $M_6C$ . If carbide films form and/or acicular carbides of the  $M_6C$  type form, alloy ductility and strength can be reduced. Agglomeration of carbides, however, can lead to increased ductility accompanied by strength reduction.

In cast cobalt-base superalloys, precipitation of additional intragranular carbides during service has led to sharply increased rupture strength and reduced rupture ductility. The precipitation of an intragranular acicular Widmanstätten carbide brought about by aging in another cobalt-base alloy degraded both rupture life and ductility.

**Property Recovery after Thermal Exposure.** As noted, changes in  $\gamma'$  occur with exposure to elevated temperatures. Most commonly,  $\gamma'$  coarsens and agglomerates, particularly under stress. Overheating can cause accelerated coarsening as well as solutioning of some fine  $\gamma'$ . Properties may be reduced in such circumstances, but when the overheating has been mild, reprecipitation of fine  $\gamma'$  occurs with a return to normal temperatures, and some property recovery occurs. Property recovery, however, does not occur in the case of additional thermal exposure of  $\text{tcp}$ ,  $\delta$ , or  $\eta$  phases in superalloys. Nor is recovery achieved by thermal exposure after excessive carbide precipitation (as may occur in cobalt-base superalloys) or after extensive  $\gamma'$  coarsening (as in nickel- and iron-nickel-base superalloys).

Recovery of properties is desired as a means of prolonging component life. If, as above, additional thermal exposure fails to promote better properties, then re-solution heat treatment and aging is required to restore property levels. While this process may be satisfactory in alloys degraded only by thermal exposure, service exposure under stress generally produces property losses (due in part to cavitation or wedge creep cracking), which cannot be recovered by simple heat treatment alone—at least for the more complex commercial superalloys. The use of HIP plus re-solution and aging treatment of exposed superalloys has suggested that some improvements can be achieved under suitable circumstances, but the extent to which such salvage processing is economically viable is uncertain.

### Typical Mechanical Properties of Superalloys

In this discussion, "typical" means the most likely value to be reached for a given property in a standard test if one were to conduct random testing. Typical properties are merely a guide for comparison. Exact chemistry, section size, heat treatment, and other processing steps must be known to generate property for design. Tables 7 and 8 summarize property behavior for wrought alloys; Tables 9 and 10 provide similar information for cast alloys.

**Table 7 Effect of temperature on the mechanical properties of wrought nickel-, iron-, and cobalt-base superalloys**

## Environmental Effects

### General Oxidation

Superalloys generally react with oxygen, and oxidation is the prime environmental effect on these alloys. At moderate temperatures--approximately 870 °C (1600 °F) and below--general uniform oxidation is not a major problem. At higher temperatures, commercial nickel- and cobalt-base superalloys are attacked by oxygen. The level of oxidation resistance at temperatures below approximately 980 °C (1800 °F) is a function of chromium content (Cr<sub>2</sub>O<sub>3</sub> forms as a protective oxide); at temperatures above approximately 980 °C (1800 °F), aluminum content becomes more important in oxidation resistance (Al<sub>2</sub>O<sub>3</sub> forms as a protective oxide). Chromium and aluminum can contribute in an interactive fashion to oxidation protection. The higher the chromium level, the less aluminum may be required to form a highly protective Al<sub>2</sub>O<sub>3</sub> layer. However, the aluminum contents of many superalloys are insufficient to provide long-term Al<sub>2</sub>O<sub>3</sub> protection,

and so protective coatings are applied (see below). These coatings also prevent selective attack that occurs along grain boundaries and at surface carbides (Fig. 21) and inhibit internal oxidation or subsurface interaction of  $O_2/N_2$  with  $\gamma'$  envelopes, a process believed to occur in nickel-base superalloys.

**Fig. 21** Effects of oxidation on superalloys. (a) Accelerated oxidation of MC carbide (arrow) at surface of MAR-M 200 at 925 °C (1700 °F). (b) Accelerated oxidation of grain boundary in Udimet 700 at 760 °C (1400 °F). 1000×

### **Hot Corrosion**

In lower temperature operating conditions,  $\leq 870$  °C ( $\leq 1600$  °F), accelerated oxidation in a gas path may occur in superalloys through the operation of selective fluxing agents. One of the better-documented accelerated oxidation processes is hot corrosion (sometimes known as sulfidation). The hot corrosion process is separated into two regimes: low temperature and high temperature. The principal method for combating hot corrosion is the use of a high chromium content ( $\geq 20$  wt%) in the base alloy. Although cobalt-base superalloys and many iron-nickel-base alloys have chromium levels in this range, most nickel-base alloys--especially those with high creep-rupture strengths--do not, because a high chromium content is not compatible with the high  $V_f \gamma'$  required.

Higher titanium/aluminum ratios also seem to reduce attack on uncoated superalloys, and alloys with improved resistance to hot corrosion, based on slightly increased chromium contents and appropriate titanium/aluminum modifications, have been produced. For maximum uncoated hot-corrosion resistance, however, chromium contents in excess of 20 wt% appear to be required. Such alloys are not capable of achieving the strengths of the high  $V_f \gamma'$  alloys such as MAR-M 247. Consequently, coatings that protect the base metal (overlay coatings seem to provide the best surface protection), or sometimes environmental inhibitors, are used to suppress hot-corrosion attack in high-strength (high  $V_f \gamma'$ ) nickel-base superalloys.

### **Coatings**

Development of increased strength (increased  $V_f \gamma'$ ) in nickel-base superalloys led to reductions in chromium content and to greater oxidation attack and susceptibility to hot corrosion. Although aluminum contents of some alloys were increased in order to enhance resistance to oxidation, intergranular and carbide attack worsened as operating temperatures escalated. Furthermore, some of the more oxidation-resistant alloys were found to be very poor in hot-corrosion resistance. To protect against local oxidation, and later, against hot corrosion and similar fluxing reactions, coatings were applied to superalloys. In recent years, thermal barrier coatings (TBCs) have been developed to provide substantial reductions in temperatures on superalloy surfaces. These coatings are commonly used in conjunction with corrosion protective coatings.

Coatings are of two types: aluminide (diffusion) coatings and overlay coatings. Use of coatings is a preferred method of protecting superalloy surfaces from environmental attack because:

- Coatings (at least overlay coatings) can be tailored to the hostile environment anticipated.
- Development of base alloys for strength is less inhibited, because significant protection (but not all of the protection) is provided by the coating.
- Coatings provide an opportunity to refurbish worn surfaces after exposure and environmental attack without causing significant degradation of the base metal.

**Aluminide (Diffusion) Coatings.** The most common type of coating for environmental protection of superalloys is the aluminide diffusion coating, which develops an aluminide (CoAl or NiAl) outer layer with enhanced oxidation resistance. This outer layer is developed by the reaction of aluminum with the nickel or cobalt in the base metal.

Some use has been made of aluminides containing chromium or silicon, and in recent years noble metals such as platinum have been used to enhance the oxidation resistance of aluminides. The oxidation resistance of aluminide coatings is derived from formation of protective  $\text{Al}_2\text{O}_3$  scales. Aluminide diffusion coatings generally are thin--about 50 to 75  $\mu\text{m}$  (2 to 3 mils). They consume some base metal in their formation and, although deposited at lower temperatures, are invariably diffused at temperatures from approximately 1040 to 1120 °C (1900 to 2050 °F) prior to being placed in service.

**Overlay coatings** generally are referred to as MCrAl or MCrAlY coatings, and are derived directly from the deposition process. They do not require diffusion for their formation. The constituent denoted "M" in these designations has at various times been iron, cobalt, nickel, or combinations of nickel and cobalt. A high-temperature heat treatment (at 1040 to 1120 °C, or 1900 to 2050 °F) is performed to homogenize the coating and to ensure its adherence to the substrate.

MCrAl coatings are approximately twice as thick as aluminide coatings, and, through incorporation of yttrium, overlay coatings can be made to have improved corrosion resistance. An advantage of MCrAlY coatings is that their compositions can be tailored to produce greater or lesser amounts of chromium or aluminum within the coating, and thus the protectivity and mechanical properties of the coating can be balanced for optimum performance.

**Thermal barrier coatings** have provided enough insulation for superalloys to operate in temperature environments as much as 165 °C (300 °F) above their customary operating range. The TBCs are ceramics, most notably plasma-sprayed partially stabilized zirconia (PSZ). These ceramic coatings use an underlay of a corrosion-protective layer--typically an overlay coating such as an MCrAlY that provides for oxidation resistance and the necessary roughness for top-coat adherence. Thermal barrier coatings do not provide oxidation protection for superalloys.

**Effects of Coatings on Mechanical Behavior.** Coatings seem to have little deleterious effect on tensile and creep-rupture properties. In fact, creep-rupture life may be enhanced by protection of the superalloy surface from oxidation or fluxing-agent attack. Thermomechanical fatigue can be greatly affected by a coating because the ductilities of coatings tend to be low at low temperatures. Ductilities of aluminide coatings generally are lower than those of overlay coatings at lower temperatures ( $\leq 540$  °C, or 1000 °F). However, ductilities of both overlay and diffusion coatings increase sharply at higher temperatures ( $\geq 650$  °C, or 1200 °F). When TMF cycles have peak tensile strains at lower temperatures, coatings may crack within the first few cycles, and TMF response is related to the crack-propagation rate in the base metal. Some adjustment of ductility is possible, particularly in the overlay coatings. However, because aluminum--the protective element--is a principal cause of reduced ductility, a balance must be achieved between protectivity and resistance to TMF.

**Coating Processes.** Aluminide diffusion coatings generally are applied by pack processes, but slurry, electrophoretic, and other techniques also have been used. Customarily, deposition is done at an intermediate temperature, followed by diffusion in a controlled-atmosphere furnace at approximately 1040 to 1120 °C (1900 to 2050 °F).

Overlay coatings are applied by physical vapor deposition (PVD) in vacuum chambers. They also may be applied by plasma spray techniques. Low-pressure plasma spray (LPPS) techniques produce coatings with properties comparable to or better than those of PVD vacuum-produced coatings. (Argon is used in LPPS, in opposition to the air plasma-spray process originally used.) Low-pressure plasma spray has been one of the primary methods of applying TBCs.

Overlay coatings tend to be line-of-sight coatings, whereas pack-diffusion coatings are not. Plasma spray techniques afford more flexibility in application of overlay coatings than do PVD processes, because the angular relationship between the plasma and the part may be varied more or less in a large envelope in order to direct the coating to desired areas. Plasma spray also provides more opportunity for compositional flexibility than does PVD.

**General Requirements of a Corrosion Protective Coating.** Coating selection will be based on knowledge of oxidation/corrosion behavior in laboratory, pilot-plant, and field tests. Attributes that probably will be required for successful coating selection include:

- High resistance to oxidation and/or hot corrosion
- Ductility sufficient to provide adequate resistance to TMF
- Compatibility with the base alloys
- Low rate of interdiffusion with the base alloy
- Ease of application and low cost relative to improvement in component life
- Ability to be stripped and reapplied without significant reduction of base-metal dimensions or degradation of base-metal properties

### ***Other Environmental Effects***

Stress-corrosion cracking can occur in nickel-and iron-nickel-base superalloys at lower temperatures. Hydrogen embrittlement at cryogenic temperatures has been reported for such alloys. Furthermore, so-called inert environments--vacuum, for example, or gases such as helium or argon--may produce mechanical behavior substantially different from baseline uncoated properties, which usually are determined in static-air tests.

# **Introduction to Aluminum and Aluminum Alloys**

## **Introduction**

THE UNIQUE COMBINATIONS of properties provided by aluminum and its alloys make aluminum one of the most versatile, economical, and attractive metallic materials for a broad range of uses--from soft, highly ductile wrapping foil to the most demanding engineering applications. Aluminum alloys are second in use only to steels as structural metals.

Aluminum has a density of only 2.7 g/cm<sup>3</sup>, approximately one-third as much as steel (7.83 g/cm<sup>3</sup>). One cubic foot of steel weighs about 490 lb; a cubic foot of aluminum, only about 170 lb. Such light weight, coupled with the high strength of some aluminum alloys (exceeding that of structural steel), permits design and construction of strong, lightweight structures that are particularly advantageous for anything that moves--space vehicles and aircraft as well as all types of land- and water-borne vehicles.

Aluminum resists the kind of progressive oxidization that causes steel to rust away. The exposed surface of aluminum combines with oxygen to form an inert aluminum oxide film only a few ten-millionths of an inch thick, which blocks further oxidation. And, unlike iron rust, the aluminum oxide film does not flake off to expose a fresh surface to further oxidation. If the protective layer of aluminum is scratched, it will instantly reseal itself.

The thin oxide layer itself clings tightly to the metal and is colorless and transparent--invisible to the naked eye. The discoloration and flaking of iron and steel rust do not occur on aluminum.

Appropriately alloyed and treated, aluminum can resist corrosion by water, salt, and other environmental factors, and by a wide range of other chemical and physical agents. The corrosion characteristics of aluminum are examined in detail in the article "Corrosion Resistance of Aluminum and Aluminum Alloys" in this Section.

Aluminum surfaces can be highly reflective. Radiant energy, visible light, radiant heat, and electromagnetic waves are efficiently reflected, while anodized and dark anodized surfaces can be reflective or absorbent. The reflectance of

polished aluminum, over a broad range of wave lengths, leads to its selection for a variety of decorative and functional uses.

Aluminum typically displays excellent electrical and thermal conductivity, but specific alloys have been developed with high degrees of electrical resistivity. These alloys are useful, for example, in high-torque electric motors. Aluminum is often selected for its electrical conductivity, which is nearly twice that of copper on an equivalent weight basis. The requirements of high conductivity and mechanical strength can be met by use of long-line, high-voltage, aluminum steel-cored reinforced transmission cable. The thermal conductivity of aluminum alloys, about 50 to 60% that of copper, is advantageous in heat exchangers, evaporators, electrically heated appliances and utensils, and automotive cylinder heads and radiators.

Aluminum is nonferromagnetic, a property of importance in the electrical and electronics industries. It is nonpyrophoric, which is important in applications involving inflammable or explosive-materials handling or exposure. Aluminum is also non-toxic and is routinely used in containers for food and beverages. It has an attractive appearance in its natural finish, which can be soft and lustrous or bright and shiny. It can be virtually any color or texture.

The ease with which aluminum may be fabricated into any form is one of its most important assets. Often it can compete successfully with cheaper materials having a lower degree of workability. The metal can be cast by any method known to foundrymen. It can be rolled to any desired thickness down to foil thinner than paper. Aluminum sheet can be stamped, drawn, spun, or roll formed. The metal also may be hammered or forged. Aluminum wire, drawn from rolled rod, may be stranded into cable of any desired size and type. There is almost no limit to the different profiles (shapes) in which the metal can be extruded.

## The Aluminum Industry

**Primary Production.** All aluminum production is based on the Hall-Héroult process. Alumina refined from bauxite is dissolved in a cryolite bath with various fluoride salt additions made to control bath temperature, density, resistivity, and alumina solubility. An electrical current is then passed through the bath to electrolyze the dissolved alumina with oxygen forming at and reacting with the carbon anode, and aluminum collecting as a metal pad at the cathode. The separated metal is periodically removed by siphon or vacuum methods into crucibles, which are then transferred to casting facilities where remelt or fabricating ingots are produced.

The major impurities of smelted aluminum are iron and silicon, but zinc, gallium, titanium, and vanadium are typically present as minor contaminants. Internationally, minimum aluminum purity is the primary criterion for defining composition and value. In the United States, a convention for considering the relative concentrations of iron and silicon as the more important criteria has evolved. Reference to grades of unalloyed metal may therefore be by purity alone, for example, 99.70% aluminum, or by the method sanctioned by the Aluminum Association in which standardized Pxxx grades have been established. In the latter case, the digits following the letter P refer to the maximum decimal percentages of silicon and iron, respectively. For example, P1020 is unalloyed smelter-produced metal containing no more than 0.10% Si and no more than 0.20% Fe. P0506 is a grade that contains no more than 0.05% Si and no more than 0.06% Fe. Common P grades range from P0202 to P1535, each of which incorporates additional impurity limits for control purposes.

Refining steps are available to attain much higher levels of purity. Purities of 99.99% are achieved through fractional crystallization or Hoopes cell operation. The latter process is a three-layer electrolytic process which employs molten salt of greater density than pure molten aluminum. Combinations of these purification techniques result in 99.999% purity for highly specialized applications.

**Secondary Aluminum.** Aluminum recovered from scrap (secondary aluminum) has been an important contributor to the total metal supply for many years. New scrap is defined as that generated by plants making end products, whereas old scrap is that recovered from metal that has been previously used by consumers. In addition, considerable amounts of scrap generated at various stages of mill processing are recycled. The increased concern with and economic implications of energy supply in recent years have focused even more attention on recycling of aluminum because of its energy-intensive nature. The energy required to remelt secondary aluminum preparatory to fabrication for reuse is only 5% of that required to produce new aluminum. Consequently, recycling is increasing. In particular, recovery of used aluminum beverage containers has multiplied many times in the last 20 years. In 1996, some 893 thousand metric tons of used beverage cans were collected in the United States. This constitutes 63.5% of can shipments. In some countries, for example Sweden, recycling rates exceeding 80% are achieved.

For some uses, secondary aluminum alloys may be treated to remove certain impurities or alloying elements. Chief among the alloying elements removed is magnesium, which is frequently present in greater amounts in secondary metal than in the alloys to be produced from it. Magnesium is usually removed by fluxing with chlorine gas or halide salts. More detailed information on secondary recovery of aluminum is included in the Section "Recycling and Life-Cycle Analysis" in this Handbook.

**Production and Markets.** World production of primary aluminum totaled 20,670 thousand metric tons in 1996. Over the decade 1986-1996, world production increased at an annual growth rate of 2.1%. The United States accounted for 17.3% of the world's 1996 production while the European Union accounted for 10.7%. Other European countries, including former members of the Union of Soviet Socialist Republics, accounted for 20.7%. The remaining production includes Asia (17.5%), Canada (11%), Latin America (9.8%), Oceania (8%), and Africa (5%).

The total United States supply in 1996 was 9,434 thousand metric tons. Since 1986, the total supply has expanded at an average of 3.6% a year. In 1996, primary production accounted for 37.9% of the total supply, imports 27.3%, and secondary recovery 34.8%.

Sheet, plate, and foil constitute the major share of total U.S. aluminum product shipments, followed by ingot for castings, export, and other uses. A percentage distribution of major aluminum products is presented below:

Product form	Distribution, %
<b>Sheet, plate, and foil</b>	51.3
<b>Ingot</b>	26.4
<b>Extrusions and tube</b>	14.9
<b>Other<sup>(a)</sup></b>	7.4

Source: The Aluminum Association Inc.

(a) Includes conductor (3.0%); rod, bar, and wire (2.7%); forgings and impacts (1.1%); and powder (0.6%).

In decreasing order of current market size, the major application categories are transportation (27.6%), containers and packaging (22.8%), building and construction (13.7%), exports (13.5%), electrical (7.0%), consumer durables (6.6%), machinery and equipment (5.9%), and others (2.9%).

## Aluminum Alloys

The mechanical, physical, and chemical properties of aluminum alloys depend upon composition and microstructure. The addition of selected elements to pure aluminum greatly enhances its properties and usefulness. Because of this, most applications for aluminum utilize alloys having one or more elemental additions. The major alloying additions used with aluminum are copper, manganese, silicon, magnesium, and zinc. The total amount of these elements can constitute up to 10% of the alloy composition (all percentages given in weight percent unless otherwise noted). Impurity elements are also present, but their total percentage is usually less than 0.15% in aluminum alloys.

It is convenient to divide aluminum alloys into two major categories: wrought compositions and cast compositions. A further differentiation for each category is based on the primary mechanism of property development. Many alloys

respond to thermal treatment based on phase solubilities. These treatments include solution heat treatment, quenching, and precipitation, or age, hardening. For either casting or wrought alloys, such alloys are described as heat treatable. A large number of other wrought compositions rely instead on work hardening through mechanical reduction, usually in combination with various annealing procedures for property development. These alloys are referred to as work hardening. Some casting alloys are essentially not heat treatable and are used only in as-cast or in thermally modified conditions unrelated to solution or precipitation effects.

Cast and wrought alloy nomenclatures have been developed. The Aluminum Association system is most widely recognized in the United States. Their alloy identification system employs different nomenclatures for wrought and cast alloys, but divides alloys into families for simplification (see the article "Alloy and Temper Designation Systems for Aluminum" in this Section for details). For wrought alloys a four-digit system is used to produce a list of wrought composition families as follows:

- 1xxx: Controlled unalloyed (pure) composition, used primarily in the electrical and chemical industries
- 2xxx: Alloys in which copper is the principal alloying element, although other elements, notably magnesium, may be specified. 2xxx-series alloys are widely used in aircraft where their high strength (yield strengths as high as 455 MPa, or 66 ksi) are valued.
- 3xxx: Alloys in which manganese is the principal alloying element, used as general-purpose alloys for architectural applications and various products
- 4xxx: Alloys in which silicon is the principal alloying element, used in welding rods and brazing sheet
- 5xxx: Alloys in which magnesium is the principal alloying element, used in boat hulls, gangplanks, and other products exposed to marine environments
- 6xxx: Alloys in which magnesium and silicon are the principal alloying elements, commonly used for architectural extrusions
- 7xxx: Alloys in which zinc is the principal alloying element (although other elements, such as copper, magnesium, chromium, and zirconium, may be specified), used in aircraft structural components and other high-strength applications. The 7xxx series are the strongest aluminum alloys, with yield strengths  $\geq 500$  MPa ( $\geq 73$  ksi) possible.
- 8xxx: Alloys characterizing miscellaneous compositions. The 8xxx series alloys may contain appreciable amounts of tin, lithium, and/or iron.
- 9xxx: Reserved for future use

Wrought alloys that constitute heat-treatable (precipitation-hardenable) aluminum alloys include the 2xxx, 6xxx, 7xxx, and some of the 8xxx alloys. The various combinations of alloying additions and strengthening mechanisms used for wrought aluminum alloys are shown in Table 1. The strength ranges achievable with various classes of wrought alloys are given in Table 2. More detailed information on the strengthening mechanisms associated with aluminum alloys can be found in the article "Physical Metallurgy of Aluminum Alloys" in this Section.

**Table 1 Classification of wrought aluminum alloys according to their strengthening mechanism**

Alloy system	Aluminum series
Work-hardenable alloys	
Pure Al	1xxx
Al-Mn	3xxx
Al-Si	4xxx

Al-Mg	5xxx
Al-Fe	8xxx
Al-Fe-Ni	8xxx
Precipitation-hardenable alloys	
Al-Cu	2xxx
Al-Cu-Mg	2xxx
Al-Cu-Li	2xxx
Al-Mg-Si	6xxx
Al-Zn	7xxx
Al-Zn-Mg	7xxx
Al-Zn-Mg-Cu	7xxx
Al-Li-Cu-Mg	8xxx

**Table 2 Strength ranges of various wrought aluminum alloys**

Aluminum Association series	Type alloy composition	of Strengthening method	Tensile strength range	
			MPa	ksi
1xxx	Al	Cold work	70-175	10-25
2xxx	Al-Cu-Mg (1-2.5% Cu)	Heat treat	170-310	25-45
2xxx	Al-Cu-Mg-Si (3-6% Cu)	Heat treat	380-520	55-75
3xxx	Al-Mn-Mg	Cold work	140-280	20-40
4xxx	Al-Si	Cold work (some heat treat)	105-350	15-50
5xxx	Al-Mg (1-2.5% Mg)	Cold work	140-280	20-40

<b>5xxx</b>	Al-Mg-Mn (3-6% Mg)	Cold work	280-380	40-55
<b>6xxx</b>	Al-Mg-Si	Heat treat	150-380	22-55
<b>7xxx</b>	Al-Zn-Mg	Heat treat	380-520	55-75
<b>7xxx</b>	Al-Zn-Mg-Cu	Heat treat	520-620	75-90
<b>8xxx</b>	Al-Li-Cu-Mg	Heat treat	280-560	40-80

Casting compositions are described by a three-digit system followed by a decimal value. The decimal .0 in all cases pertains to casting alloy limits. Decimals .1, and .2 concern ingot compositions, which after melting and processing should result in chemistries conforming to casting specification requirements. Alloy families for casting compositions include the following:

- 1xx.x: Controlled unalloyed (pure) compositions, especially for rotor manufacture
- 2xx.x: Alloys in which copper is the principal alloying element. Other alloying elements may be specified.
- 3xx.x: Alloys in which silicon is the principal alloying element. The other alloying elements such as copper and magnesium are specified. The 3xx.x series comprises nearly 90% of all shaped castings produced.
- 4xx.x: Alloys in which silicon is the principal alloying element.
- 5xx.x: Alloys in which magnesium is the principal alloying element.
- 6xx.x: Unused
- 7xx.x: Alloys in which zinc is the principal alloying element. Other alloying elements such as copper and magnesium may be specified.
- 8xx.x: Alloys in which tin is the principal alloying element.
- 9xx.x: Unused

Heat-treatable casting alloys include the 2xx, 3xx, and 7xx series.

## Manufactured Forms

**Commercial wrought aluminum products** are divided into five major categories based on production method as well as geometric configuration. These categories are (a) flat rolled products (sheet, plate and foil); (b) rod, bar and wire; (c) tubular products; (d) shapes; and (e) forgings. In the aluminum industry, rod, bar, wire, and tubular products and shapes are termed "mill" products, as they are in the steel industry, even though they often are produced by extrusion rather than by rolling. Aluminum forgings usually are not classified as "mill products" but as "engineered products." Engineered products are those designed for one specific application in contrast to "off-the-shelf" products such as standard sizes of sheet, plate, rod, bar, wire, tube, pipe, and standard structural shapes. These standard items may be available from distributors. Engineered wrought products include special extruded shapes, die forgings, hand forgings, impacts, and special sizes of standard products. More detailed information on aluminum mill and engineered wrought products can be found in the article "Aluminum Wrought Products" in this Section.

**Aluminum alloy engineered castings**, designed for specific purposes, are produced in a great variety of shapes and sizes by pressure-die, permanent-mold, green- and dry-sand, investment, and plaster casting. Process variations include vacuum, low-pressure, centrifugal, and pattern-related processes such as lost foam (each of the aforementioned foundry methods are described in the Section "Casting" in this Handbook). Table 3 provides shipment statistics for aluminum castings. Transportation is the leading market, and the trend toward increasing use in automotive applications is increasing the importance of castings in the total industry picture.

**Table 3 Shipments of aluminum castings by type in 1996**

Type of casting	Shipments <sup>(a)</sup> , 10 <sup>6</sup> kg (10 <sup>6</sup> lb)	Percentage of total
<b>Die castings</b>	1076.1 (2372.3)	57.7
<b>Permanent mold and semipermanent mold castings</b>	548.4 (1209.1)	29.4
<b>Sand castings</b>	153.9 (339.4)	8.2
<b>Others</b>	87.9 (193.9)	4.7
<b>Total</b>	<b>1866.4 (4114.6)</b>	<b>100</b>

Source: The Aluminum Association Inc.

(a) Rounded values may not add up to the totals shown.

Die castings generally are not heat treated. Those produced by the other processes may or may not be heat treated, depending on their intended applications, and alloy selection is affected by both the casting process and whether or not heat treatment is to be applied. The most popular alloys differ from those used in producing wrought products chiefly in their higher silicon contents.

The choice of castings over other product forms is often based on net shape considerations. Reinforcing ribs, internal passageways, and complex design features, which would be costly to machine in a part made from a wrought product, can often be cast by appropriate pattern and mold or die design. Premium engineered castings display extreme integrity, close dimensional tolerances, and consistently controlled mechanical properties in the upper range of existing high-strength capabilities for selected alloys and tempers. More detailed information on aluminum castings is included in the article "Aluminum Foundry Products" in this Section.

**Powder metallurgy (P/M) parts** are formed by various processes. For less demanding applications, metal powder is compressed in a shaped die to produce green compacts, and then the compacts are sintered (diffusion bonded) at elevated temperature under protective atmosphere. During sintering, the compacts consolidate and strengthen. The density of sintered compacts may be increased by re-pressing the P/M compact. Re-pressing may be followed by resintering, which relieves stresses induced by cold work and may further consolidate the structure. By pressing and sintering only, parts having densities of greater than 80% theoretical density can be produced. By re-pressing, with or without resintering, parts of 90% theoretical density or more can be produced.

For more demanding applications, such as aerospace parts or components requiring enhanced resistance to stress-corrosion cracking, rapidly solidified or mechanically attrited aluminum powders are consolidated by more advanced techniques that result in close to 100% of theoretical density. These consolidation methods include hot isostatic pressing, forging, rolling, extrusion, ultra-high strain rate (dynamic) compaction, and spray deposition techniques. Using advanced P/M processing methods, alloys that cannot be produced through conventional ingot metallurgy methods are routinely manufactured. More detailed information on aluminum P/M processing is included in the article "Aluminum Powder Metallurgy Products" in this Section.

**Metal-matrix composites (MMCs)** basically consist of a nonmetallic reinforcement incorporated into a metallic matrix. The combination of light weight, corrosion resistance, and useful mechanical properties, which has made aluminum alloys so popular, lends itself well to aluminum MMCs. The melting point of aluminum is high enough to satisfy many application requirements, yet is low enough to render composite processing reasonably convenient. Aluminum can also accommodate a variety of reinforcing agents. Reinforcements, characterized as either continuous or

discontinuous fibers, typically constitute 20 vol% or more of the composite. The family of aluminum MMC reinforcements includes continuous boron; aluminum oxide; silicon carbide and graphite fibers; and various particles, short fibers, and whiskers. The processing and properties of MMCs are described in the Section "Special-Purpose Materials" in this Handbook.

Fabrication Characteristics

This section briefly reviews importance considerations in the machining, forming, forging, and joining of aluminum alloys. Additional information is included in the Sections in this Handbook that deal with specific fabrication processes. Table 4 summarizes the fabrication characteristics of commonly used wrought grades or alloys.

Table 4 Comparative fabrication characteristics of wrought aluminum alloys

- (a) Ratings A through D for workability (cold), and A through E for machinability, are relative ratings in decreasing order of merit.
- (b) Ratings A through D for weldability and brazeability are relative ratings defined as follows: A = Generally weldable by all commercial procedures and methods. B = Weldable with special techniques or for specific applications; requires preliminary trials or testing to develop welding procedure and weld performance. C = Limited weldability because of crack sensitivity or loss in resistance to corrosion and mechanical properties. D = No commonly used welding methods have been developed.
- (c) Ratings A through D and NA for solderability are relative ratings defined as follows: A = Excellent. B = Good. C = Fair. D = Poor. NA = Not applicable

**Machinability.** The ease and speed with which aluminum may be machined is one of the most important factors contributing to the low cost of finished aluminum parts. The metal may be turned, milled, bored, or machined in other manners at the maximum speeds of which the majority of machines are capable. Another advantage of its flexible machining characteristics is that aluminum rod and bar may readily be employed in the high speed manufacture of parts by automatic screw machines.

Among the various wrought and cast aluminum alloys and among the tempers in which they are produced, there is considerable variation in machining characteristics (see Table 4), which may require special tooling or techniques (for example, the use of polycrystalline diamond tooling for machining hard (>100 HB) high-silicon-content casting alloys.) Hardness and yield strengths are variously used as approximations of machinability.

**Chemical milling**, the removal of metal by chemical attack in an alkaline or acid solution, is routine for specialized reductions in thickness. For complex large surface areas in which uniform metal removal is required, chemical milling is often the most economical method. The process is used extensively to etch preformed aerospace parts to obtain maximum strength-to-weight ratios. Integrally stiffened aluminum wing and fuselage sections are chemically milled to produce an optimum cross section and minimum skin thickness. Spars, stringers, floor beams, and frames are frequent applications as well.

**Formability** is among the more important characteristics of aluminum and many of its alloys. Specific tensile and yield strengths, ductility, and respective rates of work hardening control differences in the amount of permissible deformation.

Ratings of comparable formability of the commercially available alloys in various tempers depend on the forming process. Such ratings provide generally reliable comparisons of the working characteristics of metals, but serve as an approximate guide rather than as quantitative formability limits.

Choice of temper may depend on the severity and nature of forming operations. The annealed temper may be required for severe forming operations, such as deep drawing, or for roll forming or bending on small radii. Usually, the strongest temper than can be formed consistently is selected. For less severe forming operations, intermediate tempers or even fully hardened conditions may be acceptable.

Heat-treatable alloys can be formed in applications for which a high strength-to-weight ratio is required. The annealed temper of these alloys is the most workable condition, but the effects of dimensional change and distortion caused by subsequent heat treatment for property development, and the straightening or other dimensional control steps that may be required, are important considerations. Alloys that are formed immediately following solution heat treatment and quench (T3, T4, or W temper) are nearly as formable as when annealed and can be subsequently hardened by natural or artificial aging. Parts can be stored at low temperatures (approximately -30 to -35 °C, or -20 to -30 °F, or lower) in the W temper for prolonged periods as a means of inhibiting natural aging and preserving an acceptable level of formability. Material that has been solution heat treated and quenched but not artificially aged (T3, T4, or W temper) is generally suitable only for mild forming operations such as bending, mild drawing, or moderate stretch forming if these operations cannot be

performed immediately after quenching. Solution heat-treated and artificially aged (T6 temper) alloys are in general unsuitable for forming operations.

**Forgeability.** Aluminum alloys can be forged into a variety of shapes and types of forgings with a broad range of final part forging design criteria based on the intended application. Aluminum alloy forgings, particularly closed-die forgings, are usually produced to more highly refined final forging configurations than hot-forged carbon and/or alloy steels. For a given aluminum alloy forging shape, the pressure requirements in forging vary widely, depending primarily on the chemical composition of the alloy being forged, the forging process being employed, the forging strain rate, the type of forging being manufactured, the lubrication conditions, and the forging and die temperatures.

As a class of alloys, aluminum alloys are generally considered to be more difficult to forge than carbon steels and many alloy steels. Compared to the nickel/cobalt-base alloys and titanium alloys, however, aluminum alloys are considerably more forgeable, particularly in conventional forging process technology, in which dies are heated to 540 °C (1000 °F) or less.

**Joining.** Aluminum can be joined by a wide variety of methods, including fusion and resistance welding, brazing, soldering, adhesive bonding, and mechanical methods such as riveting and bolting. Factors that affect the welding of aluminum include:

- Aluminum oxide coating
- Thermal conductivity
- Thermal expansion coefficient
- Melting characteristics
- Electrical conductivity

**Aluminum oxide** immediately forms on aluminum surfaces exposed to air. Before aluminum can be welded by fusion methods, the oxide layer must be removed mechanically by machining, filing, wire brushing, scraping, or chemical cleaning. If oxides are not removed, oxide fragments may be entrapped in the weld and will cause a reduction in ductility, a lack of fusion, and possibly weld cracking. During welding, the oxide must be prevented from re-forming by shielding the joint area with a nonoxidizing gas such as argon, helium, or hydrogen, or chemically by use of fluxes.

**Thermal conductivity** is a property that most affects weldability. The thermal conductivity of aluminum alloys is about one-half that of copper and four times that of low-carbon steel. This means that heat must be supplied four times as fast to aluminum alloys as to steel to raise the temperature locally by the same amount. However, the high thermal conductivity of aluminum alloys helps to solidify the molten weld pool of aluminum and, consequently, facilitates out-of-position welding.

**The coefficient of linear expansion**, which is a measure of the change in length of a material with a change in its temperature, is another physical property of importance when considering weldability. The coefficient of linear thermal expansion for aluminum is twice that for steel. This means that extra care must be taken in welding aluminum to ensure that the joint space remains uniform. This may necessitate preliminary joining of the parts of the assembly by tack welding prior to the main welding operation.

The combination of high coefficient of thermal expansion and high thermal conductivity would cause considerable distortion of aluminum during welding were it not for the high welding speed possible.

**Melt Characteristics.** The melting ranges for aluminum alloys are considerably lower than those for copper or steel. Melting temperatures and the volumetric specific heats and heats of fusion of aluminum alloys determine that the amount of heat required to enter the welding temperature range is much lower for aluminum alloys.

**Electrical conductivity** has little influence on fusion welding but is a very important property for materials that are to be resistance welded. In resistance welding, resistance of the metal to the flow of welding current produces heat, which causes the portion of the metal through which the current flows to approach or reach its melting point. Aluminum has higher conductivity than steel, which means that much higher currents are required to produce the same heating effect. Consequently, resistance welding machines for aluminum must have much higher output capabilities than those normally

used for steel, for welding comparable sections. Table 4 lists welding, brazing, and soldering characteristics of selected wrought aluminum alloys.

## Finishes

The natural metallic surface of aluminum is aesthetically pleasing in many product designs even without further finishing. Its natural protective oxide film is transparent and can be thickened by anodizing, for extra protection, without affecting the metal's appearance.

But aluminum also accepts a great variety of finishes that can alter its appearance or enhance its surface characteristics as required. Surface textures can be created from rough to matte to mirror-smooth. The metallic hue can be colored by appropriate chemical or anodizing processes. Surface coatings such as paint, lacquer, enamel, electroplating or laminates can be applied.

## Applications

Aluminum alloys are economical in many applications. They are used in the automotive industry, aerospace industry, in construction of machines, appliances, and structures, as cooking utensils, as covers for housings for electronic equipment, as pressure vessels for cryogenic applications, and in innumerable other areas. Tables 5 and 6 list typical applications for some of the more commonly used wrought and cast alloys, respectively.

**Table 5 Selected applications for wrought aluminum alloys**

Alloy	Description and selected applications
<b>1100</b>	Commercially pure aluminum highly resistant to chemical attack and weathering. Low cost, ductile for deep drawing, and easy to weld. Used for high-purity applications such as chemical processing equipment. Also for nameplates, fan blades, flue lining, sheet metal work, spun holloware, and fin stock
<b>1350</b>	Electrical conductors
<b>2011</b>	Screw machine products. Appliance parts and trim, ordnance, automotive, electronic, fasteners, hardware, machine parts
<b>2014</b>	Truck frames, aircraft structures, automotive, cylinders and pistons, machine parts, structurals
<b>2017</b>	Screw machine products, fittings, fasteners, machine parts
<b>2024</b>	For high-strength structural applications. Excellent machinability in the T-temper. Fair workability and fair corrosion resistance. Alclad 2024 combines the high strength of 2024 with the corrosion resistance of the commercially pure cladding. Used for truck wheels, many structural aircraft applications, gears for machinery, screw machine products, automotive parts, cylinders and pistons, fasteners, machine parts, ordnance, recreation equipment, screws and rivets
<b>2219</b>	Structural uses at high temperature (to 315 °C, or 600 °F). High-strength weldments
<b>3003</b>	Most popular general-purpose alloy. Stronger than 1100 with same good formability and weldability. For general use including sheet metal work, stampings, fuel tanks, chemical equipment, containers, cabinets, freezer liners, cooking utensils, pressure vessels, builder's hardware, storage tanks, agricultural applications, appliance parts and trim, architectural applications, electronics, fin stock, fan equipment, name plates, recreation vehicles, trucks and trailers. Used in drawing and spinning.
<b>3004</b>	Sheet metal work, storage tanks, agricultural applications, building products, containers, electronics, furniture, kitchen equipment, recreation vehicles, trucks and trailers

<b>3105</b>	Residential siding, mobile homes, rain-carrying goods, sheet metal work, appliance parts and trim, automotive parts, building products, electronics, fin stock, furniture, hospital and medical equipment, kitchen equipment, recreation vehicles, trucks and trailers
<b>5005</b>	Specified for applications requiring anodizing; anodized coating is cleaner and lighter in color than 3003. Uses include appliances, utensils, architectural, applications requiring good electrical conductivity, automotive parts, containers, general sheet metal, hardware, hospital and medical equipment, kitchen equipment, name plates, and marine applications
<b>5052</b>	Stronger than 3003 yet readily formable in the intermediate tempers. Good weldability and resistance to corrosion. Uses include pressure vessels, fan blades, tanks, electronic panels, electronic chassis, medium-strength sheet metal parts, hydraulic tube, appliances, agricultural applications, architectural uses, automotive parts, building products, chemical equipment, containers, cooking utensils, fasteners, hardware, highway signs, hospital and medical equipment, kitchen equipment, marine applications, railroad cars, recreation vehicles, trucks and trailers
<b>5056</b>	Cable sheathing, rivets for magnesium, screen wire, zippers, automotive applications, fence wire, fasteners
<b>5083</b>	For all types of welded assemblies, marine components, and tanks requiring high weld efficiency and maximum joint strength. Used in pressure vessels up to 65 °C (150 °F) and in many cryogenic applications, bridges, freight cars, marine components, TV towers, drilling rigs, transportation equipment, missile components, and dump truck bodies. Good corrosion resistance
<b>5086</b>	Used in generally the same types of applications as 5083, particularly where resistance to either stress corrosion or atmospheric corrosion is important
<b>5454</b>	For all types of welded assemblies, tanks, pressure vessels. ASME code approved to 205 °C (400 °F). Also used in trucking for hot asphalt road tankers and dump bodies; also, for hydrogen peroxide and chemical storage vessels
<b>5456</b>	For all types of welded assemblies, storage tanks, pressure vessels, and marine components. Used where best weld efficiency and joint strength are required. Restricted to temperatures below 65 °C (150 °F)
<b>5657</b>	For anodized auto and appliance trim and nameplates
<b>6061</b>	Good formability, weldability, corrosion resistance, and strength in the T-tempers. Good general-purpose alloy used for a broad range of structural applications and welded assemblies including truck components, railroad cars, pipelines, marine applications, furniture, agricultural applications, aircrafts, architectural applications, automotive parts, building products, chemical equipment, dump bodies, electrical and electronic applications, fasteners, fence wire, fan blades, general sheet metal, highway signs, hospital and medical equipment, kitchen equipment, machine parts, ordnance, recreation equipment, recreation vehicles, and storage tanks
<b>6063</b>	Used in pipe railing, furniture, architectural extrusions, appliance parts and trim, automotive parts, building products, electrical and electronic parts, highway signs, hospital and medical equipment, kitchen equipment, marine applications, machine parts, pipe, railroad cars, recreation equipment, recreation vehicles, trucks and trailers
<b>7050</b>	High-strength alloy in aircraft and other structures. Also used in ordnance and recreation equipment
<b>7075</b>	For aircraft and other applications requiring highest strengths. Alclad 7075 combines the strength advantages of 7075 with the corrosion-resisting properties of commercially pure aluminum-clad surface. Also used in machine parts and ordnance

**Table 6 Selected applications for aluminum casting alloys**

Alloy	Representative applications
-------	-----------------------------

<b>100.0</b>	Electrical rotors larger than 152 mm (6 in.) in diameter
<b>201.0</b>	Structural members; cylinder heads and pistons; gear, pump, and aerospace housings
<b>208.0</b>	General-purpose castings; valve bodies, manifolds, and other pressure-tight parts
<b>222.0</b>	Bushings; meter parts; bearings; bearing caps; automotive pistons; cylinder heads
<b>238.0</b>	Sole plates for electric hand irons
<b>242.0</b>	Heavy-duty pistons; air-cooled cylinder heads; aircraft generator housings
<b>A242.0</b>	Diesel and aircraft pistons; air-cooled cylinder heads; aircraft generator housings
<b>B295.0</b>	Gear housings; aircraft fittings; compressor connecting rods; railway car seat frames
<b>308.0</b>	General-purpose permanent mold castings; ornamental grilles and reflectors
<b>319.0</b>	Engine crankcases; gasoline and oil tanks; oil pans; typewriter frames; engine parts
<b>332.0</b>	Automotive and heavy-duty pistons; pulleys, sheaves
<b>333.0</b>	Gas meter and regulator parts; gear blocks; pistons; general automotive castings
<b>354.0</b>	Premium-strength castings for the aerospace industry
<b>355.0</b>	Sand: air compressor pistons; printing press bedplates; water jackets; crankcases. Permanent: impellers; aircraft fittings; timing gears; jet engine compressor cases
<b>356.0</b>	Sand: flywheel castings; automotive transmission cases; oil pans; pump bodies. Permanent: machine tool parts; aircraft wheels; airframe castings; bridge railings
<b>A356.0</b>	Structural parts requiring high strength; machine parts; truck chassis parts
<b>357.0</b>	Corrosion-resistant and pressure-tight applications
<b>359.0</b>	High-strength castings for the aerospace industry
<b>360.0</b>	Outboard motor parts; instrument cases; cover plates; marine and aircraft castings
<b>A360.0</b>	Cover plates; instrument cases; irrigation system parts; outboard motor parts; hinges

<b>380.0</b>	Housings for lawn mowers and radio transmitters; air brake castings; gear cases
<b>A380.0</b>	Applications requiring strength at elevated temperature
<b>384.0</b>	Pistons and other severe service applications; automatic transmissions
<b>390.0</b>	Internal combustion engine pistons, blocks, manifolds, and cylinder heads
<b>413.0</b>	Architectural, ornamental, marine, and food and dairy equipment applications
<b>A413.0</b>	Outboard motor pistons; dental equipment; typewriter frames; street lamp housings
<b>443.0</b>	Cookware; pipe fittings; marine fittings; tire molds; carburetor bodies
<b>514.0</b>	Fittings for chemical and sewage use; dairy and food handling equipment; tire molds
<b>A514.0</b>	Permanent mold casting of architectural fittings and ornamental hardware
<b>518.0</b>	Architectural and ornamental castings; conveyor parts; aircraft and marine castings
<b>520.0</b>	Aircraft fittings; railway passenger car frames; truck and bus frame sections
<b>535.0</b>	Instrument parts and other applications where dimensional stability is important
<b>A712.0</b>	General-purpose castings that require subsequent brazing
<b>713.0</b>	Automotive parts; pumps; trailer parts; mining equipment
<b>850.0</b>	Bushings and journal bearings for railroads
<b>A850.0</b>	Rolling mill bearings and similar applications

# Alloy and Temper Designation Systems for Aluminum

## Introduction

SYSTEMS FOR DESIGNATING aluminum and aluminum alloys that incorporate the product form (wrought, casting, or foundry ingot), and its respective temper (with the exception of foundry ingots, which have no temper classification) are covered by American National Standards Institute (ANSI) standard H35.1. The Aluminum Association is the registrar under ANSI H35.1 with respect to the designation and composition of aluminum alloys and tempers registered in the United States.

## Wrought Aluminum and Aluminum Alloy Designation System

A four-digit numerical designation system is used to identify wrought aluminum and aluminum alloys. As shown below, the first digit of the four-digit designation indicates the group:

Aluminum, $\geq 99.00\%$	1xxx
Aluminum alloys grouped by major alloying element(s):	
Copper	2xxx
Manganese	3xxx
Silicon	4xxx
Magnesium	5xxx
Magnesium and silicon	6xxx
Zinc	7xxx
Other elements	8xxx
Unused series	9xxx

For the 2xxx through 7xxx series, the alloy group is determined by the alloying element present in the greatest mean percentage. An exception is the 6xxx series alloys in which the proportions of magnesium and silicon available to form magnesium silicide ( $\text{Mg}_2\text{Si}$ ) are predominant. Another exception is made in those cases in which the alloy qualifies as a modification of a previously registered alloy. If the greatest mean percentage is the same for more than one element, the

choice of group is in order of group sequence: copper, manganese, silicon, magnesium, magnesium silicide, zinc, or others.

**Aluminum.** In the 1xxx group, the series 10xx is used to designate unalloyed compositions that have natural impurity limits. The last two of the four digits in the designation indicate the minimum aluminum percentage. These digits are the same as the two digits to the right of the decimal point in the minimum aluminum percentage when expressed to the nearest 0.01%. Designations having second digits other than zero (integers 1 through 9, assigned consecutively as needed) indicate special control of one or more individual impurities.

**Aluminum Alloys.** In the 2xxx through 8xxx alloy groups, the second digit in the designation indicates alloy modification. If the second digit is zero, it indicates the original alloy; integers 1 through 9, assigned consecutively, indicate modifications of the original alloy. Explicit rules have been established for determining whether a proposed composition is merely a modification of a previously registered alloy or if it is an entirely new alloy. The last two of the four digits in the 2xxx through 8xxx groups have no special significance, but serve only to identify the different aluminum alloys in the group.

### Cast Aluminum and Aluminum Alloy Designation System

A system of four-digit numerical designations incorporating a decimal point is used to identify aluminum and aluminum alloys in the form of castings and foundry ingot. The first digit indicates the alloy group:

Aluminum, $\geq 99.00\%$	1xx.x
Aluminum alloys grouped by major alloying element(s):	
Copper	2xx.x
Silicon, with added copper and/or magnesium	3xx.x
Silicon	4xx.x
Magnesium	5xx.x
Zinc	7xx.x
Tin	8xx.x
Other elements	9xx.x
Unused series	6xx.x

For 2xx.x through 9xx.x (excluding 6xx.x alloys), the alloy group is determined by the alloying element present in the greatest mean percentage, except in cases in which the composition being registered qualifies as a modification of a previously registered alloy. If the greatest mean percentage is common to more than one alloying element, the alloy group is determined by the element that comes first in the sequence.

The second two digits identify the specific aluminum alloy or, for the aluminum (1xx.x) series, indicate purity. The last digit, which is separated from the others by a decimal point, indicates the product form, whether casting or ingot. A modification of an original alloy, or of the impurity limits for unalloyed aluminum, is indicated by a serial letter preceding the numerical designation. The serial letters are assigned in alphabetical sequence starting with A but omitting I, O, Q, and X, the X being reserved for experimental alloys. Explicit rules have been established for determining whether a proposed composition is a modification of an existing alloy or if it is a new alloy.

**Aluminum Castings and Ingot.** For the 1xx.x group, the second two of the four digits in the designation indicate the minimum aluminum percentage. These digits are the same as the two digits to the right of the decimal point in the minimum aluminum percentage when expressed to the nearest 0.01%. The last digit indicates the product form: 1xx.0 indicates castings, and 1xx.1 indicates ingot.

**Aluminum Alloy Castings and Ingot.** For the 2xx.x through 9xx.x alloy groups, the second two of the four digits in the designation have no special significance but serve only to identify the different alloys in the group. The last digit, which is to the right of the decimal point, indicates the produce form: xxx.0 indicates castings, and xxx.1 indicates ingot having limits for alloying elements the same as those for the alloy in the form of castings, except for those listed in Table 1.

**Table 1 Alloying element and impurity specifications for ingots that will be remelted into sand, permanent mold, and die castings**

Alloying element	Composition, wt%			
	Casting			Ingot
	Sand and permanent mold	Die	All	
Iron	≤0.15	...	...	Casting -0.03
	>0.15-0.25	...	...	Casting -0.05
	>0.25-0.6	...	...	Casting -0.10
	>0.6-1.0	...	...	Casting -0.2
	>1.0	...	...	Casting -0.3
	...	≤1.3	...	Casting -0.3
	...	>1.3	...	≤1.1
Magnesium	...	...	<0.50	Casting +0.05 <sup>(a)</sup>
	...	...	≥0.50	Casting +0.1 <sup>(a)</sup>
Zinc	...	>0.25-0.60	...	Casting -0.10

...	>0.60	...	Casting -0.1
-----	-------	-----	--------------

Source: ANSI H35.1-1997

(a) Applicable only when the specified range for castings is >0.15% Mg.

## Designations for Experimental Alloys

Experimental alloys also are designated in accordance with the systems for wrought and cast alloys, but they are indicated by the prefix X. The prefix is dropped when the alloy is no longer experimental. During development and before they are designated as experimental, new alloys may be identified by serial numbers assigned by their originators. Use of the serial number is discontinued when the ANSI H35.1 designation is assigned.

## Temper Designation System for Aluminum and Aluminum Alloys

The temper designation system used in the United States for aluminum and aluminum alloys is used for all product forms (both wrought and cast), with the exception of ingot. The system is based on the sequences of mechanical or thermal treatments, or both, used to produce the various tempers. The temper designation follows the alloy designation and is separated from it by a hyphen. Basic temper designations consist of individual capital letters. Major subdivisions of basic tempers, where required, are indicated by one or more digits following the letter. These digits designate specific sequences of treatments that produce specific combinations of characteristics in the product. Variations in treatment conditions within major subdivisions are identified by additional digits. The conditions during heat treatment (such as time, temperature, and quenching rate) used to produce a given temper in one alloy may differ from those employed to produce the same temper in another alloy.

### *Basic Temper Designations*

**F, As-Fabricated.** This is applied to products shaped by cold working, hot working, or casting processes in which no special control over thermal conditions or strain hardening is employed. For wrought products, there are no mechanical property limits.

**O, Annealed.** O applies to wrought products that are annealed to obtain lowest-strength temper and to cast products that are annealed to improve ductility and dimensional stability. The O may be followed by a digit other than zero.

**H, Strain-Hardened (Wrought Products Only).** This indicates products that have been strengthened by strain hardening, with or without supplementary thermal treatment to produce some reduction in strength. The H is always followed by two or more digits, as discussed in the section "System for Strain-Hardened Products" in this article.

**W, Solution Heat-Treated.** This is an unstable temper applicable only to alloys whose strength naturally (spontaneously) changes at room temperature over a duration of months or even years after solution heat treatment. The designation is specific only when the period of natural aging is indicated (for example, W  $\frac{1}{2}$  h). See also the discussion of the Tx51, Tx52, and Tx54 tempers in the section "System for Heat-Treatable Alloys" in this article.

**T, Solution Heat-Treated.** This applies to alloys whose strength is stable within a few weeks of solution heat treatment. The T is always followed by one or more digits, as discussed in the section "System for Heat-Treatable Alloys" in this article.

### *System for Strain-Hardened Products*

Temper designations for wrought products that are strengthened by strain hardening consist of an H followed by two or more digits. The first digit following the H indicates the specific sequence of basic operations.

**H1, Strain-Hardened Only.** This applies to products that are strain hardened to obtain the desired strength without supplementary thermal treatment. The digit following the H1 indicates the degree of strain hardening.

**H2, Strain-Hardened and Partially Annealed.** This pertains to products that are strain-hardened more than the desired final amount and then reduced in strength to the desired level by partial annealing. For alloys that age soften at room temperature, each H2x temper has the same minimum ultimate tensile strength as the H3x temper with the same second digit. For other alloys, each H2x temper has the same minimum ultimate tensile strength as the H1x with the same second digit, and slightly higher elongation. The digit following the H2 indicates the degree of strain hardening remaining after the product has been partially annealed.

**H3, Strain-Hardened and Stabilized.** This applies to products that are strain-hardened and whose mechanical properties are stabilized by a low-temperature thermal treatment or as a result of heat introduced during fabrication. Stabilization usually improves ductility. This designation applies only to those alloys that, unless stabilized, gradually age soften at room temperature. The digit following the H3 indicates the degree of strain hardening remaining after stabilization.

**H4, Strain-Hardened and Lacquered or Painted.** This applies to products that are strain-hardened and that are also subjected to some thermal operation during subsequent painting or lacquering. The number following this designation indicates the degree of strain-hardening remaining after the product has been thermally treated as part of the painting/lacquering cure operation. The corresponding H2x or H3x mechanical property limits apply.

**Additional Temper Designations.** The digit following the designation H1, H2, H3, and H4 indicates the degree of strain-hardening as identified by the *minimum* value of the ultimate tensile strength. The numeral 8 has been assigned to the hardest tempers normally produced. The minimum tensile strength of tempers Hx8 can be determined from Table 2 and is based on the minimum tensile strength of the alloy (given in ksi units) in the annealed temper. However, temper registrations prior to 1992 that do not conform to the requirements of Table 2 shall not be revised and registrations of intermediate or modified tempers for such alloy/temper systems shall conform to the registration requirements that existed prior to 1992.

**Table 2 Minimum tensile requirements for the Hx8 tempers**

Minimum tensile strength in annealed temper, ksi	Increase in tensile strength to Hx8 temper, ksi
$\leq 6$	8
7-9	9
10-12	10
13-15	11
16-18	12
19-24	13
25-30	14
31-36	15

<b>37-42</b>	16
<b>≥43</b>	17

Source: ANSI H35.1-1997

Temper between O (annealed) and Hx8 are designated by numerals 1 through 7 as follows:

- Numeral 4 designates tempers whose ultimate tensile strength is approximately midway between that of the O temper and that of the Hx8 tempers.
- Numeral 2 designates tempers whose ultimate tensile strength is approximately midway between that of the O temper and that of the Hx4 tempers.
- Numeral 6 designates tempers whose ultimate tensile strength is approximately midway between that of the Hx4 tempers and that of the Hx8 tempers.
- Numerals 1, 3, 5, and 7 designate, similarly, tempers intermediate between those defined above.
- Numeral 9 designates tempers whose minimum ultimate tensile strength exceeds that of the Hx8 tempers by 2 ksi or more.

The ultimate tensile strength of intermediate tempers, determined as described above, when not ending in 0 or 5, shall be rounded to the next higher 0 or 5.

When it is desirable to identify a variation of a two-digit H temper, a third digit (from 1 to 9) may be assigned. The third digit is used when the degree of control of temper or the mechanical properties are different from but close to those for the two-digit H temper designation to which it is added, or when some other characteristic is significantly affected. The minimum ultimate tensile strength of a three-digit H temper is at least as close to that of the corresponding two-digit H temper as it is to either of the adjacent two-digit H tempers. Products in H tempers whose mechanical properties are below those of Hx1 tempers are assigned variations of Hx1. Some three-digit H temper designations have already been assigned for wrought products in all alloys:

- Hx11 applies to products that incur sufficient strain hardening after final annealing to fail to qualify as O temper, but not so much or so consistent an amount of strain hardening to qualify as Hx1 temper.
- H112 pertains to products that may acquire some strain hardening during working at elevated temperature and for which there are mechanical property limits.
- H temper designations assigned to patterned or embossed sheet are listed in Table 3.

**Table 3 H temper designations for aluminum and aluminum alloy patterned or embossed sheet**

Patterned or embossed sheet	Temper of sheet from which textured sheet was fabricated
<b>H114</b>	O
<b>H124</b>	H11

### ***System for Heat-Treatable Alloys***

The temper designation system for wrought and cast products that are strengthened by heat treatment employs the W and T designations described in the section "Basic Temper Designations" in this article. The W designation denotes an unstable temper, whereas the T designation denotes a stable temper other than F, O, or H. The T is followed by a number from 1 to 10, each number indicating a specific sequence of basic treatments.

**T1, Cooled from an Elevated-Temperature Shaping Process and Naturally Aged to a Substantially Stable Condition.** This designation applies to products that are not cold worked after an elevated-temperature shaping process such as casting or extrusion and for which mechanical properties have been stabilized by room-temperature aging. It also applies to products that are flattened or straightened after cooling from the shaping process, for which the effects of the cold work imparted by flattening or straightening are not accounted for in specified property limits.

**T2, Cooled from an Elevated-Temperature Shaping Process, Cold Worked, and Naturally Aged to a Substantially Stable Condition.** This variation refers to products that are cold worked specifically to improve strength after cooling from a hot-working process such as rolling or extrusion and for which mechanical properties have been stabilized by room-temperature aging. It also applies to products in which the effects of cold work, imparted by flattening or straightening, are accounted for in specified property limits.

**T3, Solution Heat Treated, Cold Worked, and Naturally Aged to a Substantially Stable Condition.** T3 applies to products that are cold worked specifically to improve strength after solution heat treatment and for which mechanical properties have been stabilized by room-temperature aging. It also applies to products in which the effects of cold work, imparted by flattening or straightening, are accounted for in specified property limits.

**T4, Solution Heat Treated and Naturally Aged to a Substantially Stable Condition.** This signifies products that are not cold worked after solution heat treatment and for which mechanical properties have been stabilized by room-temperature aging. If the products are flattened or straightened, the effects of the cold work imparted by flattening or straightening are not accounted for in specified property limits.

**T5, Cooled from an Elevated-Temperature Shaping Process and Artificially Aged.** T5 includes products that are not cold worked after an elevated-temperature shaping process such as casting or extrusion and for which mechanical properties have been substantially improved by precipitation heat treatment. If the products are flattened or straightened after cooling from the shaping process, the effects of the cold work imparted by flattening or straightening are not accounted for in specified property limits.

**T6, Solution Heat Treated and Artificially Aged.** This group encompasses products that are not cold worked after solution heat treatment and for which mechanical properties or dimensional stability, or both, have been substantially improved by precipitation heat treatment. If the products are flattened or straightened, the effects of the cold work imparted by flattening or straightening are not accounted for in specified property limits.

**T7, Solution Heat Treated and Overaged or Stabilized.** T7 applies to wrought products that have been precipitation heat treated beyond the point of maximum strength to provide some special characteristic, such as enhanced resistance to stress-corrosion cracking or exfoliation corrosion. It applies to cast products that are artificially aged after solution heat treatment to provide dimensional and strength stability.

**T8, Solution Heat Treated, Cold Worked, and Artificially Aged.** This designation applies to products that are cold worked specifically to improve strength after solution heat treatment and for which mechanical properties or

dimensional stability, or both, have been substantially improved by precipitation heat treatment. The effects of cold work, including any cold work imparted by flattening or straightening, are accounted for in specified property limits.

**T9, Solution Heat Treated, Artificially Aged, and Cold Worked.** This grouping is comprised of products that are cold worked specifically to improve strength after they have been precipitation heat treated.

**T10, Cooled from an Elevated-Temperature Shaping Process, Cold Worked, and Artificially Aged.** T10 identifies products that are cold worked specifically to improved strength after cooling from a hot-working process such as rolling or extrusion and for which mechanical properties have been substantially improved by precipitation heat treatment. The effects of cold work, including any cold work imparted by flattening or straightening, are accounted for in specified property limits.

**Additional T Temper Variations.** When it is desirable to identify a variation of one of the ten major T tempers described above, additional digits, the first of which cannot be zero, may be added to the designation. Specific sets of additional digits have been assigned to the following wrought products that have been stress relieved by stretching, compressing, or a combination of stretching and compressing:

Product form	Permanent set, %
<b>Plate</b>	$1\frac{1}{2}$ -3
<b>Rolled or cold-finished rod and bar</b>	1-3
<b>Extruded rod, bar, profiles (shapes), and tube</b>	1-3
<b>Drawn tube</b>	$\frac{1}{2}$ -3
<b>Die or ring forgings and rolled rings</b>	1-5

***Stress relieved by stretching*** includes the following.

Tx51 applies specifically to plate, to rolled or cold-finished road and bar, to die or ring forgings, and to rolled rings when stretched to the indicated amounts after solution heat treatment or after cooling from an elevated-temperature shaping process. These products receive no further straightening after stretching.

Tx510 applies to extruded rod, bar, shapes and tubing, and to drawn tubing when stretched to the indicated amounts after solution heat treatment or after cooling from an elevated-temperature shaping process. Products in this temper receive no further straightening after stretching.

Tx511 applies to extruded rod, bar, profiles (shapes) and tube and to drawn tube when stretched to the indicated amounts after solution heat treatment or after cooling from an elevated temperature shaping process. These products may receive minor straightening after stretching to comply with standard tolerances.

***Stress relieved by compressing*** includes the following.

Tx52 applies to products that are stress relieved by compressing after solution heat treatment or after cooling from a hot-working process to produce a permanent set of 1 to 5%.

***Stress relieved by combined stretching and compressing*** includes the following.

Tx54 applies to die forgings that are stress relieved by restriking cold in the finish die.

***The same digits (51, 52, and 54)*** can be added to the designation W to indicate unstable solution-heat-treated and stress-relieved tempers.

Temper designations have been assigned to wrought products heat treated from the O or the F temper to demonstrate response to heat treatment.

T42 means solution heat treated from the O or the F temper to demonstrate response to heat treatment and naturally aged to a substantially stable condition.

T62 means solution heat treated from the O or the F temper to demonstrate response to heat treatment and artificially aged.

T7x2 means solution heat treated from the O or F temper and artificially overaged to meet the mechanical properties and corrosion resistance limits of the T7<sub>x</sub> temper.

Temper designations T42 and T62 also may be applied to wrought products heat treated from any temper by the user when such heat treatment results in the mechanical properties applicable to these tempers.

### ***System for Annealed Products***

A digit following the "O" indicates a product in annealed condition having special characteristics. For example, for heat-treatable alloys, O1 indicates a product that has been heat treated at approximately the same time and temperature required for solution heat treatment and then air cooled to room temperature; this designation applies to products that are to be machined prior to solution heat treatment by the user. Mechanical property limits are not applicable.

### ***Designation of Unregistered Tempers***

The letter P has been assigned to denote H, T, and O temper variations that are negotiated between manufacturer and purchaser. The letter P follows the temper designation that most nearly pertains. The use of this type of designation includes the following situations:

- The use of the temper is sufficiently limited to preclude its registration.
- The test conditions are different from those required for registration with the Aluminum Association.
- The mechanical property limits are not established on the same basis as required for registration with the Aluminum Association.
- It is used for products such as aluminum metal-matrix composites, which are not included in any registration records. (A proposed nomenclature system for aluminum metal-matrix composites is described in the Section "Special-Purpose Materials" in this Handbook.)

# Chemical Compositions and International Designations for Aluminum Alloys

## Introduction

MORE THAN 450 ALLOY designations/compositions have been registered by the Aluminum Association Inc. for aluminum and aluminum alloys. Table 1 lists the designations and composition limits of wrought unalloyed aluminum and wrought aluminum alloys. Table 2 lists designations and composition limits for aluminum alloys in the form of castings and ingot.

Table 1 Composition limits for wrought aluminum and aluminum alloys

Source: Aluminum Association Inc.

- (a) D, die casting. P, permanent mold. S, sand. Other products may pertain to the composition shown even though not listed.
- (b) 0.025% max Mg +Cr + Ti + V.
- (c) Fe/Si ratio 2.5 min.
- (d) Fe/Si ratio 2.0 min.
- (e) Fe/Si ratio 1.5 min.
- (f) 0.40-1.0% Ag.
- (g) 0.50-1.0% Ag.
- (h) 0.50% max Ti + Zr.
- (i) 0.20-0.30%Sb, 0.20-0.30% Co, 0.10-0.30% Zr.
- (j) Primarily used for making metal-matrix composite.
- (k) If Fe exceeds 0.45%, Mg content will not be less than one-half Fe content.

- (l) 0.04-0.07% Be.
- (m) 0.10-0.30% Be.
- (n) 0.15-0.30% Be.
- (o) A360.1, A380.1, and A413.1 ingot is used to produce 360.0 and A360.0; 380.0 and A380.0; 413.0 and A413.0 castings, respectively.
- (p) 0.8% max Mg +Cr.
- (q) 0.25% max Pb.
- (r) 0.02-0.04% Be.
- (s) The number of decimal places to which Mg percent is expressed differs from the norm.
- (t) 0.08-0.15% V.
- (u) 408.2, 409.2, 411.2, and 445.2 are used to coat steel.
- (v) Used with Zn to coat steel.
- (w) 0.10% max Pb.
- (x) 0.003-0.007% Be, 0.005% max B.

(y) 0.003-0.007% Be, 0.002 max B.

# Chemical Compositions and International Designations for Aluminum Alloys

## Cross Referencing Aluminum Alloy Designations

### *Unified Numbering System (UNS)*

The UNS numbers correlate many nationally used numbering systems currently administered by societies, trade associations, and individual users and producers of metals and alloys. Table 3cross references AA (Aluminum Association) numbers to UNS numbers.

**Table 3 Unified Numbering System (UNS) numbers corresponding to Aluminum Association(AA) numbers for aluminum and aluminum alloys**

### ***International Alloy Designations***

Historically, all major industrialized countries developed their own standard designations for aluminum and aluminum alloys. These are now being grouped under systems of the American National Standards Institute (ANSI), the International Organization for Standardization (ISO), and the European Committee for Standardization (Comité de Normalization, CEN).

**The International Organization for Standardization** has developed its own alphanumeric designation system for wrought aluminum and its alloys (ISO R209) based on the systems that have been used by certain European countries. The main addition element is distinguished by specifying the required content (middle of range) rounded off to the nearest 0.5:

5052 = Al Mg2.5  
5251 = Al Mg2

If required, the secondary addition elements are distinguished by specifying the required content rounded off to the nearest 0.1, for two elements at most:

6181 = Al Si1Mg0.8

The chemical symbols for addition elements should be limited to four:

If an alloy cannot otherwise be distinguished, a suffix in parentheses is used:

Note that suffixes (A),(B), and so on should not be confused with suffixes of the Aluminum Association.

Table 4 cross references ISO designations with equivalent or similar AA alloy designations. Also included in this table are cross-referenced alloys listed in Austrian, Canadian, French, German, British, Italian, Spanish, and Swiss standards. Additional information is included in the "Registration Record of International Alloy Designations and Chemical Composition Limits for Wrought Aluminum and Wrought Aluminum Alloys" (commonly referred to as the blue sheets) published by the Aluminum Association.

#### Table 4 International alloy designations cross referenced to wrought Aluminum Association (AA) alloys

The table includes only those alloys that are essentially equivalent in composition to the corresponding AA alloys, but whose composition limits are not necessarily exactly the same as their AA counterparts.

# Physical Metallurgy of Aluminum Alloys

## Introduction

THE PRINCIPAL CONCERNS in the physical metallurgy of aluminum alloys include the effects of composition, mechanical working, and/or heat treatment on mechanical and physical properties. In terms of properties, strength improvement is a major objective in the design of aluminum alloys because the low strength of pure aluminum limits its commercial usefulness. The two most common methods for increasing the strength of aluminum alloys follow:

- To disperse second-phase constituents or elements in solid solution and cold work the alloy (non-heat-treatable alloys)
- To dissolve the alloying elements into solid solution and precipitate them as coherent submicroscopic particles (heat-treatable or precipitation-hardening alloys)

The factors affecting these strengthening mechanisms are reviewed in the first half of this article. The use of phase diagrams to better understand the effects of solid-state thermal processing is discussed in the second half of this article.

## Alloying and Strengthening Mechanisms

The predominant reason for alloying is to increase strength, hardness, and resistance to wear, creep, stress relaxation or fatigue. Effects on these properties are specific to the different alloying elements and combinations of them, and are related to their alloy phase diagrams and to the microstructures and substructures that they form as a result of solidification, thermomechanical history, heat treatment and/or cold working.

The tensile yield strength of super-purity aluminum in its annealed (softest) state is approximately 10 MPa (1.5 ksi), whereas those of some heat treated commercial high-strength alloys exceed 550 MPa (80 ksi). When the magnitude of this difference (an increase of over 5000%) is considered, this practical, everyday accomplishment, which is just one aspect of the physical metallurgy of aluminum, is truly remarkable. Higher strengths, up to a yield strength of 690 MPa (100 ksi) and over, may be readily produced, but the fracture toughness of such alloys does not meet levels considered essential for aircraft or other critical-structure applications.

The elements that are most commonly present in commercial alloys to provide increased strength--particularly when coupled with strain hardening by cold working or with heat treatment, or both--are copper, magnesium, manganese, silicon, and zinc (Fig. 1). These elements all have significant solid solubility in aluminum, and in all cases the solubility increases with increasing temperature (see Fig. 2).

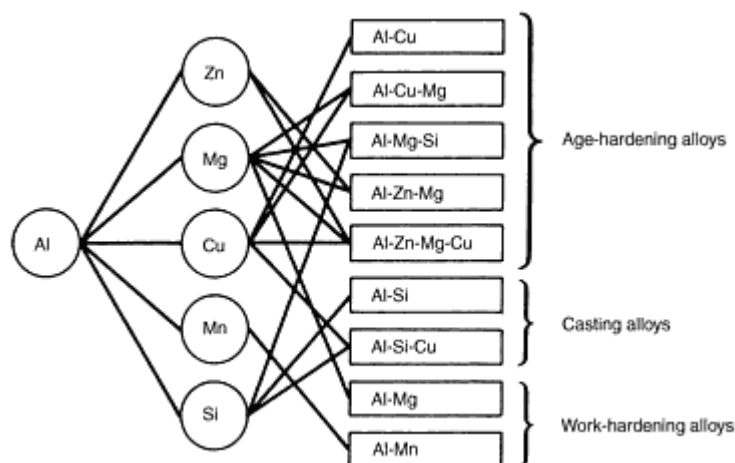

Fig. 1 The principal aluminum alloys

**Fig. 2** Equilibrium binary solid solubility as a function of temperature for alloying elements most frequently added to aluminum

For those elements that form solid solutions, the strengthening effect when the element is in solution tends to increase with increasing difference in the atomic radii of the solvent (Al) and solute (alloying element) atoms. This factor is evident in data obtained from super-purity binary solid-solution alloys in the annealed state, presented in Table 1, but it is evident that other effects are involved, chief among which is an electronic bonding factor. The effects of multiple solutes in solid solution are somewhat less than additive and are nearly the same when one solute has a larger and the other a smaller atomic radius than that of aluminum as when both are either smaller or larger. Manganese in solid solution is highly effective in strengthening binary alloys. Its contribution to the strength of commercial alloys is less, because in these compositions, as a result of commercial mill fabricating operations, the manganese is largely precipitated.

**Table 1** Solid-solution effects on strength of principal solute elements in super-purity aluminum

Element	Difference in atomic radii, $r_x - r_{Al}$ , % <sup>(a)</sup>	Strength/addition values <sup>(b)</sup>							
		Yield strength/% addition <sup>(c)</sup>				Tensile strength/% addition <sup>(d)</sup>			
		MPa/at.%	ksi/at.%	MPa/wt%	ksi/wt%	MPa/at.%	ksi/at.%	MPa/wt%	ksi/wt%
<b>Si</b>	-3.8	9.3	1.35	9.2	1.33	40.0	5.8	39.6	5.75
<b>Zn</b>	-6.0	6.6	0.95	2.9	0.42	20.7	3.0	15.2	2.2
<b>Cu</b>	-10.7	16.2	2.35	13.8	2.0	88.3	12.8	43.1	6.25
<b>Mn</b>	-11.3	(e)	(e)	30.3	4.4	(e)	(e)	53.8	7.8

(a) Listed in order of increasing percent difference in atomic radii.

(b) Some property to percent addition relationships are nonlinear. Generally, the unit effects of smaller additions are greater.

(c) Increase in yield strength (0.2% offset) for 1% (atomic or weight basis) alloy addition.

(d) Increase in ultimate tensile strength for 1% (atomic or weight basis) alloy addition.

(e) 1 at.% of manganese is not soluble.

The principal alloys that are strengthened by alloying elements in solid solution (often coupled with cold work) are those in the aluminum-magnesium series, ranging from 0.5 to 6 wt% Mg. These alloys often contain small additions of transition elements, such as chromium or manganese, and less frequently zirconium, to control the grain or subgrain structure, and iron and silicon impurities that usually are present in the form of intermetallic particles. Figure 3 illustrates the effect of magnesium in solid solution on the yield strength and tensile elongation for most of the common aluminum-magnesium commercial alloys.

**Fig. 3** Correlation between tensile yield, strength elongation, and magnesium content for some commercial aluminum alloys

Elements and combinations that form predominantly second-phase constituents with relatively low solid solubility include iron, nickel, titanium, manganese and chromium, and combinations thereof. The presence of increasing volume fractions of the intermetallic-compound phases formed by these elements and the elemental silicon constituent formed by silicon during solidification or by precipitation in the solid state during postsolidification heating also increases strength and hardness. The rates of increase per unit weight of alloying element added are frequently similar to but usually lower than those resulting from solid solution. This "second-phase" hardening occurs even though the constituent particles are of sizes readily resolved by optical microscopy. These irregularly shaped particles form during solidification and occur mostly along grain boundaries and between dendrite arms.

Manganese and chromium are included in the group of elements that form predominantly second phase constituents, because in commercial alloys they have very low equilibrium solid solubilities. In the case of many compositions containing manganese, this is because iron and silicon are also present and form the quaternary phase  $Al_{12}(Fe,Mn)_3Si$ . In alloys containing copper and manganese, the ternary phase  $Al_{20}Cu_2Mn_3$  is formed. Most of the alloys in which chromium is present also contain magnesium, so that during solid-state heating they form  $Al_{12}Mg_2Cr$ , which also has very low equilibrium solid solubility. The concentrations of manganese and/or chromium held in solid solution in as-cast ingot that has been rapidly solidified and cooled from the molten state greatly exceed the equilibrium solubility. The solid solution is thus supersaturated and metastable. Ingot preheating for wrought commercial alloys containing these elements is designed to cause solid-state precipitation of the complex phase containing one or the other of these elements that is appropriate to the alloy composition. This precipitation does not cause appreciable hardening, nor is it intended that it should. Its purpose is to produce finely divided and dispersed particles that retard or inhibit recrystallization and grain growth in the alloy during subsequent heatings. The precipitate particles of  $Al_{12}(Fe,Mn)_3Si$ ,  $Al_{20}Cu_2Mn_3$ , or  $Al_{12}Mg_2Cr$

are incoherent with the matrix, and concurrent with their precipitation the original solid solution becomes less concentrated. These conditions do not provide appreciable precipitation hardening. Changes in electrical conductivity constitute an effective measure of the completeness of these precipitation reactions that occur in preheating.

For alloys that are composed of both solid-solution and second-phase constituents and/or dispersoid precipitates, all of these components of microstructure contribute to strength, in a roughly additive manner. This is shown in Fig. 4 for Al-Mg-Mn alloys in the annealed condition.

Fig. 4 Tensile properties in Al-Mg-Mn alloys in the form of annealed (O temper) plate 13 mm (0.5 in.) thick

Non-Heat-Treatable Alloys

By definition, the group of commercial alloys that are classed as non-heat-treatable are those that are not appreciably strengthened by heat treatment--that is, show no effective precipitation hardening. The strengthening mechanisms discussed so far (solid-solution formation, second-phase microstructural constituents and dispersoid precipitates) are those that provide the basis for the non-heat-treatable alloys. Wrought alloys of this type are mainly those of the 3xxx and 5xxx groups containing magnesium, manganese, and/or chromium, and the 1xxx aluminum group and some alloys of the 4xxx group that contain only silicon. Non-heat-treatable casting alloys are of the 4xx.x and 5xx.x groups, containing silicon or magnesium, respectively, and the 1xx.x aluminum group.

**Strain Hardening.** Strain hardening by cold rolling, drawing, or stretching is a highly effective means of increasing the strength of non-heat-treatable alloys. Work- or strain-hardening curves for several typical non-heat-treatable commercial alloys (Fig. 5) illustrate the increases in strength that accompany increasing reduction by cold rolling of initially annealed temper sheet. This increase is obtained at the expense of ductility as measured by percent elongation in a tensile test and by reduced formability in operations such as bending and drawing. It is frequently advantageous to employ material in a partially annealed (H2x) or stabilized (H3x) temper when bending, forming, or drawing is required, since materials in these tempers has greater forming capability for the same strength levels than does strain-hardened-only (H1x) material (see Table 2 for example).

Table 2 Tensile-property data illustrating typical relationship between strength and elongation for non-heat-treatable alloys in H1x versus H2x tempers

Alloy and temper	Tensile strength		Yield strength		Elongation, %
	MPa	ksi	MPa	ksi

<b>3105-H16</b>	193	28	172	25	4

Fig. 5 Strain-hardening curves for aluminum (1100), Al-Mn (3003) alloys, and Al-Mg (5050 and 5052) alloys

All mill products can be supplied in the strain-hardened condition although there are limitations on the amounts of strain that can be applied to products such as die forgings and impacts. Even aluminum castings have been strengthened by cold pressing for certain applications.

## Heat-Treatable Alloys and Precipitation Hardening

Again by definition, heat-treatable alloys are those that can be strengthened by suitable thermal treatment and include compositions used for wrought products as well as alloys for producing castings. Temperature-dependent solid solubility of the type shown for individual solutes in Fig. 1, the solubility increasing with increasing temperature, is a prerequisite. However, this feature alone does not make an alloy capable of precipitation hardening (or heat-treatable). The strengths of most binary alloys containing Mg, Si, Zn, Cr, or Mn alone exhibit little change from thermal treatments regardless of whether the solute is completely in solid solution, partially precipitated, or completely precipitated.

In contrast, alloys of the binary Al-Cu system having 3% Cu or more exhibit *natural aging* (hardening with time at ambient temperatures) after being solution heat treated and quenched. The amounts by which strength and hardness increase become larger with time of natural aging and with the copper content of the alloy from about 3% to the limit of solid solubility (5.65%). Natural aging curves for slowly quenched, high-purity Al-Cu alloys with 1 to 4.5% Cu are shown in Fig. 6. The rates and amounts of the changes in strength and hardness can be increased by holding the alloys at moderately elevated temperatures (for alloys of all types, the useful range is about 120 to 230 °C, or 250 to 450 °F). This treatment is called precipitation heat treating or *artificial aging*. In the Al-Cu system, alloys with as little as 1% Cu, again slowly quenched, start to harden after about 20 days at a temperature of 150 °C or 300 °F (see Fig. 7). The alloys of this system having less than  $\sim 3\%$  Cu show little or no natural aging after low-cooling-rate quenching, which introduces little stress.

Fig. 6 Natural aging curves for binary Al-Cu alloys quenched in water at 100 °C (212 °F)

**Fig. 7** Precipitation hardening curves for binary Al-Cu alloys quenched in water at 100 °C (212 °F) and aged at 150 °C (300 °F)

The characteristic that distinguishes between the systems having the required temperature to solid solubility relationship that does or does not exhibit precipitation hardening is the type or types of precipitate structures formed. Precipitation hardening is caused by a sequence of submicroscopic structure changes resulting from precipitation reactions that are responsible for the strength changes and can be revealed and analyzed only by such methods as x-ray diffraction and transmission electron microscopy. Room-temperature age hardening (natural aging) is a result of spontaneous formation of Guinier-Preston (G-P) zone structure. Solute atoms either cluster or segregate to selected atomic lattice planes, depending on the alloy system, to form the G-P zones, and this structure is more resistant to movement of dislocations through the lattice and, hence, is stronger.

Curves showing the changes in tensile yield strength with time at room temperature (natural aging curves) for three wrought commercial heat-treatable alloys of different alloy systems are shown in Fig. 8. The magnitudes of increase in this property are considerably different for the three alloys, and the differences in rate of change with time are of practical importance. Because 7075 and similar alloys never become completely stable under these conditions, they are rarely used in the naturally aged temper. On the other hand, 2024 is widely used in this condition.

**Fig. 8 Natural aging curves for three solution heat-treated wrought aluminum alloys**

Precipitation heat treating (or artificial aging) at higher temperatures produces transition, metastable forms of the equilibrium precipitate of the of the particular alloy system. These transition precipitates are still coherent with the solid-solution matrix. The characteristic that determines whether a precipitate phase is coherent or noncoherent is the closeness of match or degree of disregistry between the atomic spacings on the lattice of the matrix and on that of the precipitate. The presence of the precipitate particles, and, even more importantly in most cases, the strain fields in the matrix surrounding the coherent particles, obstruct and retard the movement of dislocations, thus providing increased resistance to deformation--in other words, higher strength. These particles, at the maximum-strength stage, are extremely fine, are resolvable only by transmission electron microscopy (TEM), and constitute a relatively large volume fraction, particularly when the strain fields are considered.

With further heating at temperatures that cause strengthening or at higher temperatures, the precipitate particles grow, but even more importantly convert to the equilibrium phases, which generally are not coherent. These changes soften the material and, carried further, produce the softest or annealed condition. Even at this stage, the precipitate particles are still too small to be clearly resolved by optical microscopy, although etching effects are readily observed--particularly in alloys containing copper.

Precipitation heat treatment or artificial aging curves for the Al-Mg-Si wrought alloy 6061 are shown in Fig. 9. This is a typical family of curves showing the changes in tensile yield strength that accrue with increasing time at each of a series of temperatures. In all cases, the material has been given a solution heat treatment followed by a quench just prior to the start of the precipitation heat treatment. For detailed presentation of heat treating operations, parameters, and practices see the Section "Heat Treating" in this Handbook.

**Fig. 9 Precipitation heat treatment or artificial aging curves for solution heat-treated aluminum alloy 6061**

The above description of the precipitation process and its effects on strength and metallurgical structures applies not only to heat treatable binary compositions, none of which is used commercially, but also to the commercial alloys, having generally much greater complexity of composition. As noted before, not only do the mechanical properties change with these heat treatments, and with natural aging, but also physical properties (density and electrical and thermal conductivities) and electrochemical properties (solution potential). On the microstructural and submicroscopic scales, the electrochemical properties develop point-to-point nonuniformities that account for changes in corrosion resistance.

Measurements of changes in physical and electrochemical properties have played an important role in completely describing precipitation reactions and are very useful in analyzing or diagnosing whether heat treatable products have been properly or improperly heat treated. Although they may indicate the strength levels of products, they cannot be relied on to determine whether or not the product meets specified mechanical-property limits. Because elements in solid solution are always more harmful to electrical conductivity than the same elements combined with others as intermetallic compounds, thermal treatments are applied to ingots used for fabrication of electrical conductor products. These thermal treatments are intended to precipitate as much as possible of the dissolved impurities. Iron is the principal element involved, and, although the amount precipitated is only a few hundredths of a percent, the effect on electrical conductivity of the wire, cable, or other product made from the ingot is of considerable practical importance. These alloys may or may not be heat treatable with respect to mechanical properties. Electrical conductor alloys 6101 and 6201 are heat treatable.

These alloys are used in tempers in which their strengthening precipitate, the transition form of  $\text{Mg}_2\text{Si}$ , is largely out of solid solution to optimize both strength and conductivity.

The commercial heat treatable alloys are, with few exceptions, based on ternary or quaternary systems with respect to the solutes involved in developing strength by precipitation. The most prominent systems are: Al-Cu-Mg, Al-Cu-Si, and Al-Cu-Mg-Si, which are in the 2xxx and 2xx.x groups (wrought and casting alloys, respectively); Al-Mg-Si (6xxx wrought alloys); Al-Si-Mg, Al-Si-Cu, and Al-Si-Mg-Cu (3xx.x casting alloys); Al-Zn-Mg and Al-Zn-Mg-Cu (7xxx wrought and 7xx.x casting alloys); and Al-Li-Cu-Mg (8xxx wrought alloys). In each case, the solubility of the multiple solute elements decreases with decreasing temperatures, as shown in the solvus diagrams in *Alloy Phase Diagrams*, Volume 3, *ASM Handbook*. These diagrams show the equilibrium phase (or phases) that precipitates in a particular system. They do not show whether a transition phase occurs, nor do they provide its composition.

These multiple alloying additions of both major solute elements and supplementary elements employed in commercial alloys are strictly functional and serve with different heat treatments to provide the many different combinations of properties--physical, mechanical, and electrochemical--that are required for different applications. Some alloys, particularly those for foundry production of castings, contain amounts of silicon far in excess of the amount that is soluble or needed for strengthening alone. The function here is chiefly to improve casting soundness and freedom from cracking, but the excess silicon also serves to increase wear resistance, as do other microstructural constituents formed by manganese, nickel, and iron. Parts made of such alloys are commonly used in gasoline and diesel engines (pistons, cylinder blocks, etc.).

Alloys containing the elements silver and lithium are also capable of providing high strength with heat treatment and, in the case of lithium, both increased elastic modulus and lower density, which are highly advantageous--particularly for aerospace applications. Commercial use of alloys containing these elements has been restricted either by cost or by difficulties encountered in producing them.

In the case of alloys having copper as the principal alloying ingredient and no magnesium, strengthening by precipitation can be greatly increased by adding small fractional percentages of tin, cadmium, or indium, or combinations of these elements. Alloys based on these effects have been produced commercially but not in large volumes because of costly special practices and limitations required in processing and, in the case of cadmium, the need for special facilities to avoid health hazards from formation and release of cadmium vapor during alloying.

Strength at elevated temperatures is improved mainly by solid-solution and second-phase hardening, because, at least for temperatures exceeding those of the precipitation-hardening range-- $\geq 230^\circ\text{C}$  ( $450^\circ\text{F}$ )--the precipitation reactions continue into the softening regime. For supersonic aircraft and space vehicle applications subject to aerodynamic heating, the heat treatable alloys of the 2xxx group can be used for temperatures up to  $\sim 150^\circ\text{C}$  ( $300^\circ\text{F}$ ). Aged rapidly solidified powder metallurgy alloys (Al-Fe-V-Si alloys) maintain usable strengths at temperatures as high as  $315^\circ\text{C}$  ( $600^\circ\text{F}$ ).

**Effects of Strengthening on Other Mechanical Properties.** Resistance to fatigue (from application of dynamic stresses into the tensile range) increases generally with increasing strength whether from alloying effects alone, from strain hardening, or from heat treatment. This improvement, in terms of either time to initiate cracks or cycles to failure, is generally less than the improvement in static strength, and the highest resistance to fatigue for a given alloy is sometimes provided by a temper having static strength levels lower than the highest strength possible--e.g., 2024-T3x or 2024-T4x versus 2024-T6x or 2024-T8x. This occurs mainly because the resistance to fatigue-crack growth at high levels of stress-intensity factor requires good fracture toughness, and this property decreases generally with increasing strength at high levels.

As strength, defined as resistance to deformation, increases, the properties of ductility, malleability, ease of forming, and fracture toughness tend to decrease. This inverse relationship between these properties and strength, however, is not universal. As indicated previously, for the non-heat-treatable alloys, the H2x or H3x tempers have advantages over those of the H1x series in the ductility/strength relationship. It is also true that, in the relationship of fracture toughness to yield strength, alloys of the 7xxx group (Al-Zn-Mg-Cu types) are superior to those of the 2xxx and 6xxx groups.

All of these properties must be carefully considered in application of alloys to critical engineering structures such as aircraft as well as to products such as truck wheels and other automotive and truck components. Good design, avoiding stress-concentrating features and any features that promote localized corrosion, is in most cases at least as important as good alloy and temper selection.

**Other Considerations Involved in Alloy Development.** The engineering properties and characteristics that have immediate effects on the functional behavior of end products is only a partial list of the features that must be considered in alloy design. One of the foremost considerations is that, to be economically viable, an alloy must be capable of being cast and fabricated to the form desired with reasonable freedom from scrap losses resulting from cracking or other in-process damage. Many alloys and specialty products, including those for extremely large-tonnage items such as beverage cans as well as Alclad products and brazing composites, are tailored to very specific uses, and cost-effective principles apply to the commercial viability of these also. All of these products must compete for markets with other metallic materials as well as polymeric materials, glasses, and ceramics.

## Use of Aluminum Alloy Phase Diagrams

Although few products are sold and used in their equilibrium condition, equilibrium phase diagrams are an essential tool in understanding effects of composition and both solidification and solid-state thermal processing on microstructure. For aluminum alloys, phase diagrams are used to determine solidification and melting temperatures, the solidification path, and the equilibrium phases that form and their dissolution temperatures. In addition to determining appropriate temperatures for casting and thermal treatments, phase diagrams are used to determine the maximum levels for ancillary element additions of certain elements to prevent the crystallization of coarse primary particles. The most important liquid-to-solid transformations for aluminum alloys are the eutectic and the peritectic. Examples of phase diagrams illustrating eutectic and peritectic reactions are discussed in the following paragraphs, and phase diagrams for aluminum alloys are included in the Section "Structure and Properties of Metals" in this Handbook and in Volume 3 of the *ASM Handbook*.

The eutectic reaction is illustrated by the aluminum-copper system (Fig. 10). When the liquidus temperature of aluminum-rich alloys is reached during solidification, the liquid begins to solidify into a solid solution of copper in aluminum ( $\alpha$ -aluminum). As temperature approaches the solidus, the  $\alpha$ -aluminum becomes more enriched with copper. When the temperature falls below the solidus temperature in alloys containing less than the maximum solubility, 5.7% Cu, solidification is complete. At temperatures below the solvus,  $\text{Al}_2\text{Cu}$  particles precipitate, depleting the  $\alpha$ -aluminum of copper. When cooled to room temperature under near-equilibrium conditions, the  $\alpha$ -aluminum contains little copper, so strength is low. To increase strength, the material must be solution heat treated, quenched, and aged to develop metastable precipitates as described earlier in this article. In alloys containing more than 5.7% Cu, some liquid remains when the eutectic temperature is reached. This liquid solidifies at this temperature by a eutectic reaction to  $\alpha$ -aluminum and  $\text{Al}_2\text{Cu}$  intermetallic particles. On cooling below the eutectic temperature, the  $\alpha$ -aluminum rejects copper as  $\text{Al}_2\text{Cu}$  precipitates. It is important to realize that the eutectic reaction can occur in alloys containing less than the maximum solid solubility under commercial casting conditions, even though the equilibrium phase diagram does not predict that. Consequently,  $\text{Al}_2\text{Cu}$  particles form during solidification of most aluminum alloy ingots and shaped castings. Therefore, they are "preheated" or homogenized to dissolve the intermetallic particles.

Fig. 10 Aluminum-copper phase diagram illustrating the eutectic reaction

The peritectic reaction in aluminum alloys is typified by the aluminum-chromium system (Fig. 11). During equilibrium solidification of alloys containing more than the peritectic composition, 0.41% Cr, but less than the maximum solid solubility of 0.77%, an intermetallic compound,  $\text{Al}_7\text{Cr}$ , forms when the liquidus temperature is reached. When the temperature falls to the peritectic temperature,  $661^\circ\text{C}$  ( $1222^\circ\text{F}$ ), the remaining liquid along with the  $\text{Al}_7\text{Cr}$  transforms to  $\alpha$ -aluminum. Under commercial solidification conditions, however, the primary particles of  $\text{Al}_7\text{Cr}$  would not have the opportunity to transform to  $\alpha$ -aluminum, so they would remain. Consequently, maximum chromium limits are established so that all of the chromium remains in supersaturated solid solution in the ingot. It precipitates as chromium-bearing dispersoids during ingot preheat.

Fig. 11 Aluminum-chromium phase diagram illustrating the peritectic reaction

### Alloying Effects on Phase Formation

All commercial aluminum alloys contain iron and silicon as well as two or more elements intentionally added to enhance properties. The phases formed and the function of the alloying elements are described below. Figure 1 summarizes the most common alloying additions in aluminum alloys.

**Iron.** Virtually all aluminum alloys contain some iron that is an impurity remaining after refining bauxite and smelting. The phase diagram predicts that during solidification of an aluminum-iron alloy containing a few tenths of a percent of iron, most of the iron remains in the liquid phase until a eutectic of solid solution plus  $\text{Al}_3\text{Fe}$  intermetallic constituent particles having a monoclinic crystal structure freezes. Depending on solidification rate and on the presence of other elements such as manganese, constituent particles of the metastable orthorhombic  $\text{Al}_6\text{Fe}$  phase can form instead of the equilibrium  $\text{Al}_3\text{Fe}$ . The maximum solid solubility of iron in aluminum is 0.05%, but the solubility is much lower in most structural alloys.

**Silicon.** This element is also a ubiquitous impurity in commercial aluminum alloys. Two ternary phases, cubic  $\alpha$ - $\text{Al}_{12}\text{Fe}_3\text{Si}$  and monoclinic  $\beta$ - $\text{Al}_9\text{Fe}_2\text{Si}_2$ , form by a eutectic reaction. At low silicon contents, almost all of the iron is present as  $\text{Al}_3\text{Fe}$ . With increasing silicon contents, first the  $\alpha$ - then the  $\beta$ -Al-Fe-Si phases appear. Phases in commercial products may not be those predicted by the equilibrium phase diagrams because of the long times at high temperatures required to approach equilibrium. In large amounts, silicon improves castability and fluidity. Consequently, it is used in 4xx brazing sheet and in 3xx.x and 4xx.x casting alloys. Silicon ranges from about 5 to 20% in casting alloys.

Hypereutectic alloys (those containing >12.6% Si, the eutectic composition) are used for engine blocks because the primary silicon particles are wear resistant. Some 3xx.x casting alloys contain small additions of magnesium to render them capable of being age hardened.

Silicon is deliberately added to some alloys containing magnesium to provide precipitation hardening. The Al-Mg-Si system is the basis for the 6xxx alloys. At low magnesium contents, elemental silicon may be present as second-phase particles. As magnesium increases, both silicon particles and equilibrium hexagonal  $\text{Mg}_2\text{Si}$  constituents may be present. At higher magnesium contents, only  $\text{Mg}_2\text{Si}$  is present. Ternary alloys are strengthened by precipitation of metastable precursors to  $\text{Mg}_2\text{Si}$ . With the addition of copper, a complex quaternary  $\text{Al}_4\text{CuMg}_5\text{Si}_4$  phase can form. A precursor to this quaternary phase strengthens Al-Cu-Mg-Si alloys.

**Manganese.** The aluminum-manganese system is the basis for the oldest aluminum alloys. Such alloys, known as 3xxx, are the most widely used wrought alloys because of their excellent formability and resistance to corrosion. Commercial aluminum-manganese alloys contain both iron and silicon. During solidification of commercial size ingots, some of the manganese forms  $\text{Al}_6(\text{Mn,Fe})$  and cubic  $\text{Al}_{12}(\text{Fe,Mn})\text{Si}$  by eutectic reactions. The remaining manganese remains in solution and is precipitated during the ingot preheat as  $\text{Al}_{12}(\text{Mn,Fe})\text{Si}$  and  $\text{Al}_6(\text{Mn,Fe})$  dispersoids. These dispersoids strengthen the material and control recrystallized grain size. In alloys containing copper, manganese precipitates as  $\text{Al}_{20}\text{Cu}_2\text{Mn}_3$  dispersoid particles. Effects on strength are minor, but the dispersoids aid in grain size control after solution heat treatment.

**Magnesium.** The aluminum-magnesium system is the basis for the wrought 5xxx and cast 5xx.x non-heat-treatable aluminum alloys, which provide excellent combinations of strength and corrosion resistance by solid-solution strengthening and work hardening. Although in principle this phase diagram exhibits a positively sloping solvus, a necessary condition for a precipitation-hardening system, difficulty in nucleating the face-centered cubic (fcc)  $\text{Al}_3\text{Mg}_2$  precipitates has precluded commercialization of heat-treatable aluminum-magnesium alloys, unless they contain enough silicon, copper, or zinc to form  $\text{Mg}_2\text{Si}$ , Al-Cu-Mg, or Al-Zn-Mg precipitates.

**Copper.** The aluminum-copper system is the basis for the wrought 2xxx and cast 2xx.x alloys, and many other heat-treatable alloys contain copper. In commercial aluminum-copper alloys, some of the copper chemically combines with aluminum and iron to form either tetragonal  $\text{Al}_7\text{Cu}_2\text{Fe}$  or orthorhombic  $\alpha(\text{Al,Cu,Fe})$  constituent particles during solidification. These constituents cannot be dissolved during subsequent thermal treatments, but one can transform to the other during thermal treatments of ingots or castings. During heat treatment of aluminum-copper alloys containing little magnesium,  $\text{Al}_2\text{Cu}$  precipitates as the strengthening phase.

Adding magnesium to aluminum-rich aluminum-copper alloys results in the formation of the  $\text{Al}_2\text{CuMg}$  phase by eutectic decomposition. Metastable precursors to face-centered orthorhombic  $\text{Al}_2\text{CuMg}$  precipitates are used to strengthen several structural alloys used in the aerospace industry because they confer a desirable combination of strength, fracture toughness, and resistance to the growth of fatigue cracks.

**Zinc.** This element confers little solid-solution strengthening or work hardening to aluminum, but Al-Zn-Mg precipitates provide the basis for the 7xxx wrought alloys and the 7xx.x cast alloys. Two phases can form by eutectic decomposition in commercial Al-Zn-Mg alloys: hexagonal  $\text{MgZn}_2$  and body-centered cubic (bcc)  $\text{Al}_2\text{Mg}_3\text{Zn}_3$ . Depending on the zinc/magnesium ratio, copper-free alloys are strengthened by metastable precursors to either  $\text{MgZn}_2$  or  $\text{Al}_2\text{Mg}_3\text{Zn}_3$ . In Al-Zn-Mg-Cu alloys, copper and aluminum substitute for zinc in  $\text{MgZn}_2$  to form  $\text{Mg}(\text{Zn,Cu,Al})_2$ .  $\text{Al}_2\text{CuMg}$  particles can also form in these alloys by eutectic decomposition and solid-state precipitation.

**Chromium.** In commercial alloys, the solubility can be reduced to such an extent that  $\text{Al}_7\text{Cr}$  primary particles can form by a peritectic reaction at chromium contents lower than that indicated by the binary aluminum-chromium phase diagram. Because coarse primary particles are harmful to ductility, fatigue, and fracture toughness, the upper limits of chromium depend on the amount and nature of the other alloying and impurity elements. In 5xxx alloys, fcc cubic  $\text{Al}_{18}\text{Mg}_3\text{Cr}_2$  dispersoids precipitate during ingot preheating. In 7xxx alloys, the composition of the dispersoids is closer to  $\text{Al}_{12}\text{Mg}_2\text{Cr}$ . Chromium dispersoids contribute to strength in non-heat-treatable alloys and control grain size and degree of recrystallization in heat-treatable alloy products.

**Zirconium.** This element also forms a peritectic with aluminum. The phase diagram predicts that the equilibrium  $\text{Al}_3\text{Zr}$  phase is tetragonal, but fine dispersoids of metastable cubic  $\text{Al}_3\text{Zr}$  form during ingot preheating treatments. Most 7xxx and some 6xxx and 5xxx alloys developed since the 1960s contain small amounts of zirconium, usually less than 0.15%, to form  $\text{Al}_3\text{Zr}$  dispersoids for recrystallization control.

**Lithium.** This element reduces the density and increases the modulus of aluminum alloys. In binary alloys it forms metastable  $\text{Al}_3\text{Li}$  precipitates and combines with aluminum and copper in Al-Cu-Li alloys to form a large number of Al-Cu-Li phases. Because of its high cost relative to other alloying elements, lithium alloys have been found to be cost effective thus far only in space and military applications.

# Aluminum Wrought Products

## Introduction

COMMERCIAL WROUGHT ALUMINUM PRODUCTS can be divided into two groups. *Standardized* wrought products include sheet, plate, foil, rod, bar, wire, tube, pipe, and structural forms. *Engineered* wrought products are those designed for specific applications and include extruded shapes, forgings, and impacts. Typical examples of wrought products include plate or sheet, which is subsequently formed or machined into products such as aircraft or building components, household foil, and extruded shapes such as storm window frames.

## Alloys Used for Wrought Products

Aluminum alloys are commonly grouped into an alloy designation series, as described in the article "Alloy and Temper Designations for Aluminum" in this Section. The general characteristics of the alloy groups are described below.

**1xxx Series.** Aluminum of 99.00% or higher purity has many applications, especially in the electrical and chemical fields. These grades of aluminum are characterized by excellent corrosion resistance, high thermal and electrical conductivities, low mechanical properties, and excellent workability. Moderate increases in strength may be obtained by strain hardening. Iron and silicon are the major impurities.

**2xxx Series.** Copper is the principal alloying element in 2xxx series alloys, often with magnesium as a secondary addition. These alloys require solution heat treatment to obtain optimum properties; in the solution heat-treated condition, mechanical properties are similar to, and sometimes exceed, those of low-carbon steel. In some instances, precipitation heat treatment (aging) is employed to further increase mechanical properties. This treatment increases yield strength, with attendant loss in elongation; its effect on tensile strength is not as great.

The alloys in the 2xxx series do not have as good corrosion resistance as most other aluminum alloys, and under certain conditions they may be subject to intergranular corrosion. Therefore, these alloys in the form of sheet usually are clad with a high-purity aluminum, a magnesium-silicon alloy of the 6xxx series, or an alloy containing 1% Zn. The coating, usually from  $2\frac{1}{2}$  to 5% of the total thickness on each side, provides galvanic protection of the core material and thus greatly increases resistance to corrosion.

Alloys in the 2xxx series are particularly well suited for parts and structures requiring high strength-to-weight ratios and are commonly used to make truck and aircraft wheels, truck suspension parts, aircraft fuselage and wing skins, structural parts, and those parts requiring good strength at temperatures up to 150 °C (300 °F).

**3xxx Series.** Manganese is the major alloying element of 3xxx series alloys. These alloys generally are non-heat-treatable but have about 20% more strength than 1xxx series alloys. Because only a limited percentage of manganese (up to about 1.5%) can be effectively added to aluminum, manganese is used as a major element in only a few alloys. However, one of these, the popular 3003 alloy, is widely used as a general-purpose alloy for moderate-strength applications requiring good workability.

**4xxx Series.** The major alloying element in 4xxx series alloys is silicon, which can be added in sufficient quantities (up to 12%) to cause substantial lowering of the melting range without producing brittleness. For this reason, aluminum-silicon alloys are used in welding wire and as brazing alloys for joining aluminum, where a lower melting range than that of the base metal is required. Most alloys in this series are non-heat treatable, but when used in welding heat-treatable alloys, they pick up some of the alloying constituents of the latter and so respond to heat treatment to a limited extent. The alloys containing appreciable amounts of silicon become dark gray to charcoal when anodic oxide finishes are applied and hence are in demand for architectural applications. Alloy 4032 has a low coefficient of thermal expansion and high wear resistance; thus it is well suited to production of forged engine pistons.

**5xxx Series.** The major alloying element in 5xxx series alloys is magnesium. When it is used as a major alloying element or with manganese, the result is a moderate-to-high-strength work-hardenable alloy. Magnesium is considerably more effective than manganese as a hardener, about 0.8% Mg being equal to 1.25% Mn, and it can be added in considerably higher quantities. Alloys in this series possess good welding characteristics and good resistance to corrosion in marine atmospheres. However, certain limitations should be placed on the amount of cold work and the safe operating temperatures permissible for the higher-magnesium alloys (over  $\sim 3.5\%$  for operating temperatures above  $\sim 65^\circ\text{C}$ , or  $150^\circ\text{F}$ ) to avoid susceptibility to stress-corrosion cracking.

**6xxx Series.** Alloys in the 6xxx series contain silicon and magnesium approximately in the proportions required for formation of magnesium silicide ( $\text{Mg}_2\text{Si}$ ), thus making them heat treatable. Although not as strong as most 2xxx and 7xxx alloys, 6xxx series alloys have good formability, weldability, machinability, and corrosion resistance, with medium strength. Alloys in this heat-treatable group may be formed in the T4 temper (solution heat treated but not precipitation heat treated) and strengthened after forming to full T6 properties by precipitation heat treatment.

**7xxx Series.** Zinc, in amounts of 1 to 8%, is the major alloying element in 7xxx series alloys, and when coupled with a smaller percentage of magnesium results in heat-treatable alloys of moderate to very high strength. Usually other elements, such as copper and chromium, are added in small quantities. Dilute additions of scandium also improve properties. 7xxx series alloys are used in airframe structures, mobile equipment, and other highly stressed parts.

Higher strength 7xxx alloys exhibit reduced resistance to stress corrosion cracking and are often utilized in a slightly overaged temper to provide better combinations of strength, corrosion resistance, and fracture toughness.

**8xxx series** alloys constitute a wide range of chemical compositions. For example, improved elevated-temperature performance is achieved through the use of dispersion-strengthened Al-Fe-Ce alloys (e.g., 8019) or Al-Fe-V-Si alloys (e.g., 8009) made by powder metallurgy processing. Lower density and higher stiffness can be achieved in lithium-containing alloys (e.g., 8090). The latter alloy, which is precipitation hardenable, has replaced medium-to-high strength 2xxx and 7xxx alloys in some aircraft/aerospace applications (e.g., helicopter components).

## General Characteristics of Wrought Products

Wrought products are those that have been shaped by plastic deformation. This deformation, which is done by hot and cold working processes such as rolling, extruding, forging, and drawing, either singly or in combination, transforms the cast ingot into the desired product form. As the deformation proceeds, the metallurgical structure also changes from a cast structure to a fully wrought structure. In this process, grain size and shape may be radically changed, the final configuration depending on the entire thermomechanical history (including any final annealing stages or heat treatments). During deformation, the second-phase microconstituents present in irregular forms in the ingot are fragmented into more equiaxed particles, which tend to align in the direction of greatest extension. The grains are usually also elongated in this direction and thinned or flattened in flat rolled products, in thin extruded products, and in the flash-plane areas of die forgings. Thus, the wrought metallurgical structure has directionality, the degree of which depends on the directionality of the deformation imposed during shaping of the product.

These changes in metallurgical structure are accompanied by changes in properties, particularly mechanical properties, which are generally higher in the wrought products than in the cast ingot from which they originate. The wrought products generally exhibit some pronounced directionality of mechanical properties (i.e., anisotropy), which is negligible in the ingot from which they are produced. The directionality in sheet is not pronounced with respect to tensile properties but can be quite significant with respect to performance in deep drawing or cupping operations. Nonuniformity in different directions in the plane of the sheet causes formation of protuberances called "ears" in circular cups. These are primarily the result of crystallographic texture in the sheet, a nonrandom or preferred orientation of the grains (see the following discussion on "Crystallographic Texture"). For deep drawing and cupping operations such as those employed in making beverage and food cans, special "non-earring quality" sheet is supplied.

Thicker products that can be stressed or tested in three orthogonal directions generally exhibit differences in tensile and compressive properties as well as in resistance to fatigue stresses and stress-corrosion cracking in the three directions. With respect to these characteristics, the longitudinal direction (that in which the product was lengthened or extended most in working, as shown in Fig. 1) generally is superior. In the long-transverse direction (which may be either an extension or compression direction, as shown in Fig. 1, but with less extension or less compression than either of the other two directions), the properties and resistance are intermediate to those of the other directions. In the short transverse direction (direction of greatest compression in working, as shown in Fig. 1), the properties and resistance are generally

lower than in the other directions. In most cases the longitudinal, long-transverse, and short-transverse directions correspond to the greatest, intermediate, and smallest dimensions of product having a rectangular cross section. For products of axisymmetric cross section (round, square, hexagonal, etc.), there is no long- and short-transverse distinction; any direction in the cross-sectional plane is regarded as transverse (Fig. 2).

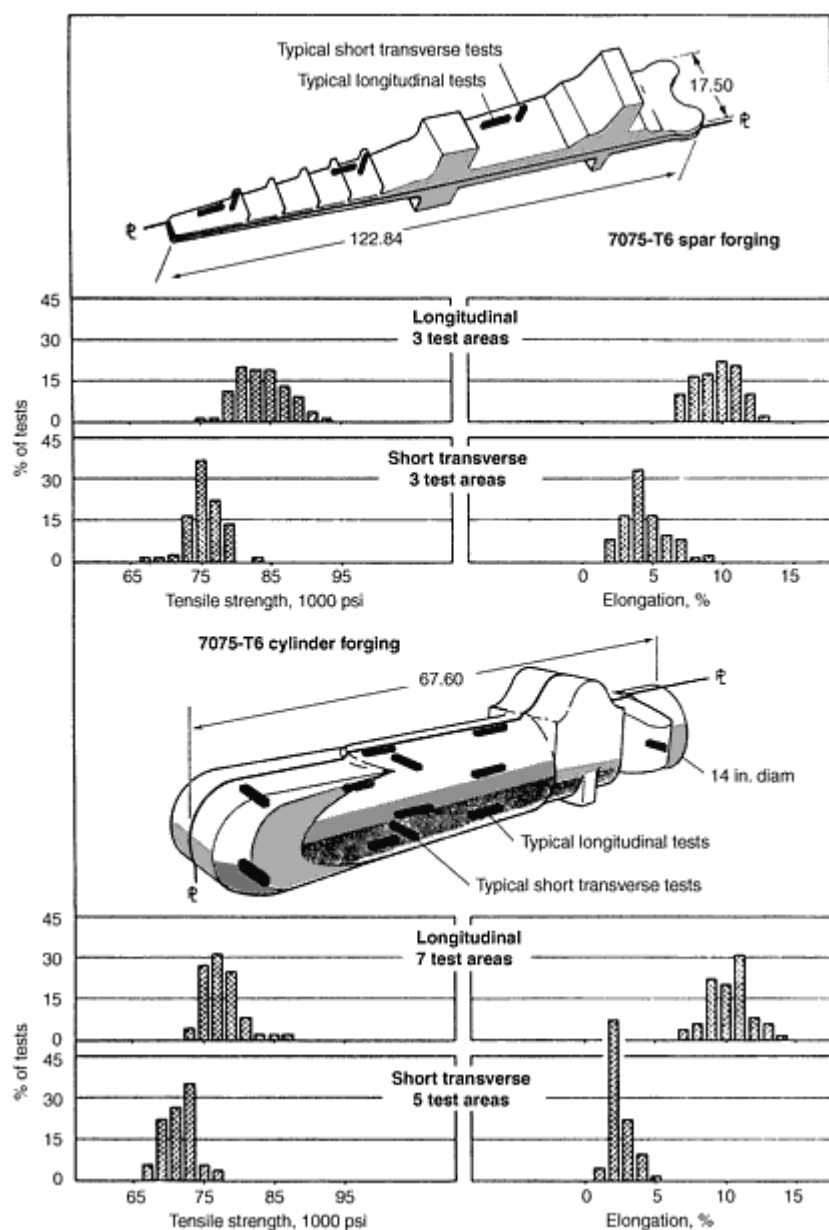

**Fig. 1** Composite of micrographs of flat-rolled 7075-T6 illustrating metallurgical structure directionality. 40×

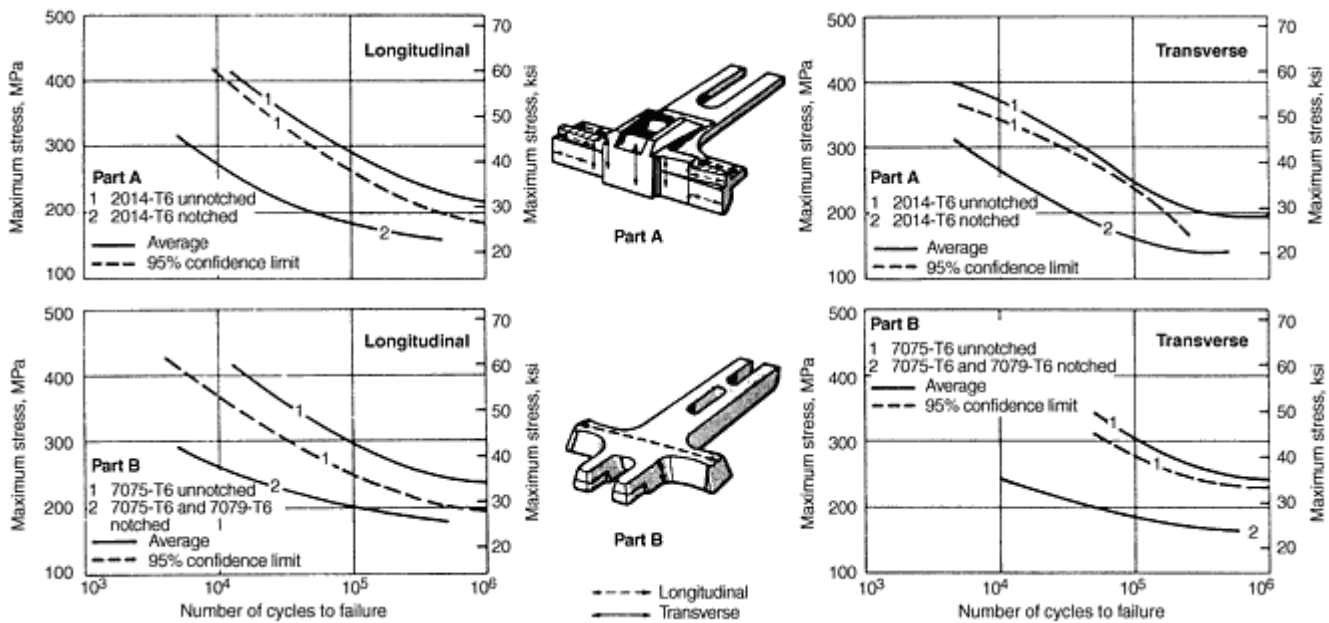

**Fig. 2** Composite of micrographs of 7075-T6 rod illustrating metallurgical structure directionality. 40×

The influence of directionality on mechanical properties is shown in Fig. 3 for two closed-die forgings. Variation in properties is obtained because of the variations in thickness, variations in reduction during forging, and variation in angle between the axis of the test specimen and the direction of grain flow. Both die forgings show markedly lower properties in the short transverse direction than in the longitudinal direction.

**Fig. 3** Variation in mechanical properties for two different 7075-T6 aluminum alloy forgings. Both were forged on a 35,000 ton press, solution treated at 470 °C (880 °F) for 3 h, quenched in water at 60 °C (140 °F), and aged at 120 °C (250 °F) for 24 h. Spar forging (shown at top): Cast ingots were received in 17 lots from three sources. Two lots were in 480 mm (19 in.) rounds, and 15 lots were in 250 to 300 mm (10 to 20 in.) squares. Twenty-eight forgings were tested at the locations indicated. Cylinder forging (shown at bottom): All cylinders were forged from 480 mm (19 in.) rounds. Six of the forgings were tested at locations shown.

Fatigue strength of bars cut from forgings is affected in the same manner as tensile strength, yield strength, and elongation. Figure 4 shows the results of fatigue tests of specimens cut from two sample forgings in directions both parallel and transverse to the forging flow lines. Once again, properties are superior in the longitudinal direction.

**Fig. 4** Effect of alloy, design, and directionality on the axial fatigue strength of aluminum alloy forgings. Data apply to parts A and B, as shown. Sheet-type fatigue specimens, 3.2 mm (0.125 in.) thick and 6.4 mm (0.250 in.) wide, were cut both parallel and transverse to the forging flow lines. Locations from which specimens were taken are shown on the drawings. Mean stress was 91.7 MPa (13.3 ksi); notch was 1.2 mm (0.047 in.) in diameter hole in center of specimen.  $K_t = 2.5$ .

Directionality is considerably affected by whether the grain structure is recrystallized or unrecrystallized, the latter condition generally being more highly directional (see the following discussion on "Grain Structure"). In the case of heat treated extruded shapes, there is usually a very thin surface or peripheral layer of recrystallized grain structure surrounding an unrecrystallized core. Since the recrystallized grain material is somewhat less resistant to fatigue than the unrecrystallized structure, its thickness should be minimized. For critical applications, a considerable percentage of the length from the rear of the extrusion is discarded to accomplish this, because the recrystallized layer thickness increases from front to rear of the extrusion. In the most critical applications, complete removal of the recrystallized materials by machining or chemical milling may be required.

Extrusions, which generally have unrecrystallized structures, exhibit somewhat higher directionality of tensile properties than rolled products of equivalent cross section that also are unrecrystallized. This difference, primarily evidenced by higher longitudinal strength values in the extruded product, which may be as much as 10% higher, is attributed to more pronounced preferred grain orientation generated by the deformation of extrusion.

**Grain Structure.** The grain size of aluminum alloy ingots and castings is typically controlled by the introduction of inoculants that form intermetallic compounds containing titanium and/or boron. During deformation processing, the grain structure becomes modified. Most aluminum alloy products undergo dynamic recovery during hot working as the dislocations form networks of subgrains. New dislocation-free grains may form between and following rolling passes (static recrystallization) or during deformation processing (dynamic recrystallization). During deformation, the crystal lattice of the aluminum matrix rotates at its interfaces between constituent and coarse precipitate particles. These high-energy sites serve to nucleate recrystallization. This process is termed particle-stimulated nucleation and is an important mechanism in the recrystallization process of aluminum. The particle size that will serve as a nucleus decreases as deformation temperature decreases and strain and strain rate increase. Dispersoid particles retard the movement of high-angle grain boundaries. Consequently, hot-worked structures are resistant to recrystallization and often retain the dynamically recovered subgrain structure in the interiors of elongated cast grain boundaries. In heat-treated products containing a sufficient quantity of dispersoids, the unrecrystallized structure of hot-worked plate, forgings, and extrusions can be retained after solution heat treatment.

Degree of recrystallization of hot-worked products has an effect on fracture toughness. Unrecrystallized products develop higher toughness than do products that are either partially or completely recrystallized. This behavior is attributed to precipitation on the recrystallized high-angle grain boundaries during the quench. These particles increase the tendency

for low-energy intergranular fracture. Products such as sheet, rods, and tubing that are cold rolled invariably recrystallize during solution heat treatment or annealing to O temper.

Decreasing the grain size can increase strength of 5xxx alloy products in the O temper by 7 to 28 MPa (1 to 4 ksi), but grain size is not a major factor in increasing strength of other aluminum alloy products. Several measures of formability are influenced by grain size, however, so grain size is controlled for this reason. One particular use of grain size control is to produce stable, fine grains, which are essential in developing super-plastic behavior in aluminum alloy sheet.

**Crystallographic Texture.** Cast aluminum ingots and shapes generally have a random crystallographic texture; the orientation of the unit cells comprising each grain are not aligned. With deformation, however, certain preferred crystallographic orientations develop. Many of the grains rotate and assume certain orientations with respect to the direction of deformation. For flat-rolled products and extrusions having a high aspect ratio of width to thickness, the deformation texture is similar to that in pure fcc metals. These orientations are described by using the Miller indices of the planes {nnn} in the grains parallel to the plane of the worked product and directions {nnn} parallel to the working direction. The predominant textures are {110}[112], {123}[634], and {112}[111]. During recrystallization, a high concentration of grains in the {001}[100] or {011}[100] orientations may develop. Alternatively, if particle-stimulated nucleation is present to a large extent, the recrystallized texture will be random. Control of crystallographic texture is particularly important for non-heat-treatable sheet that will be drawn. If texture is not random, ears form during the drawing process. In extruded or drawn rod or bar, the texture is a dual-fiber texture in which almost all grains are aligned so that the grain directions are either [001] or [111]. In heat-treatable alloys, texture has the most potent effect on the properties of extrusions that have the dual-fiber texture. Strengthening by this process is so potent that the longitudinal yield strengths of extruded products exhibiting this texture are about 70 MPa (10 ksi) higher than strength in the transverse direction. If this dual-fiber texture is lost by recrystallization, strength in the longitudinal direction decreases to that in the transverse directions.

## Product Forms

Table 1 summarizes the various product forms in which commonly used wrought aluminum alloys are available. Recommended tempers are also listed. Temper designations are described in the article "Alloy and Temper Designation Systems for Aluminum" in this Section.

Table 1 Wrought alloy products and tempers

Alloy	Sheet	Plate	Tube		Pipe	Structural profiles (shapes) <sup>(a)</sup>	Extruded wire, rod, bar, and profiles (shapes)	Rolled or cold-finished			Rivets	Forgings and forging stock	Foil	Fin stock

- (a) Rolled or extruded.
- (b) Products listed for these alloys are for electric conductors only.
- (c) T74-type tempers, although not previously registered, have appeared in various literature and specifications as T736-type tempers.

## Flat-Rolled Products

Flat-rolled products include plate, sheet, and foil. These products are semifabricated to rectangular cross section by sequential reductions in the thickness of cast ingot by hot and cold rolling. Properties in work-hardened tempers are controlled by degree of cold reduction, partial or full annealing, and the use of stabilizing treatments. Plate, sheet, and foil produced in heat-treatable compositions may be solution heat treated, quenched, precipitation hardened, and thermally or mechanically stress relieved.

Sheet and foil may be rolled with textured surfaces. Sheet and plate rolled with specially prepared work rolls may be embossed to produce products such as tread plate. By roll forming, sheet in corrugated or other contoured configurations can be produced for such applications as roofing, siding, ducts, and gutters.

**Plate** refers to a product having a thickness greater than 6.3 mm (0.250 in.). Plate up to 200 mm (8 in.) thick is available in some alloys. Extra-large plates--e.g., 22 mm ( $\frac{7}{8}$  in. thick) by 2.25 m (89 in.) wide by 32 m (105 ft) long--are supplied for construction of the wings of wide-body aircraft. Plate usually has either sheared or sawed edges and can be cut into circles, rectangles or odd-shape blanks. Plate of certain alloys--notably the high-strength 2xxx and 7xxx series alloys--also is available in clad form. The most commonly used plate alloys are 2024, 2124, 2219, 7050, 7178, and 7475 for aircraft structures; 5083, 5086, and 5456 for marine, cryogenic and pressure-vessel applications, and 1100, 3003, 5052, and 6061 for general applications. Table 1 lists the various alloys that are commonly forged.

**Sheet.** When a flat rolled product is over 0.15 through 6.3 mm (0.006 through 0.249 in.) in thickness, it is classified as "sheet". Sheet edges can be sheared, slit or sawed. Sheet is supplied in flat form, in coils, or in pieces cut to length from coils. Current facilities permit production of a limited amount of extra-large sheet, for example, up to 5 m (200 in.) wide by 25 m (1000 in.) long. Aluminum sheet is available in several surface finishes that range from "mill finishes," which have uncontrolled surface appearance that may vary from sheet to sheet, to bright finishes on one or two sides, to "aircraft skin quality." It may also be supplied embossed, patterned, painted, or otherwise surface treated, and with combinations of such treatments. Special products include corrugated, V-beam, and ribbed roofing and siding, duct sheet, fin stock, recording circles, and computer memory disks.

Among standard products are the alclad composites, which consists of heat treated 2xxx or 7xxx alloys clad on either or both sides with an appropriate anodic alloy or with aluminum. For sheet thicknesses, cladding thickness may range from  $\frac{1}{2}$  to as much as 10% of sheet thickness, the greater percentages applying to thinner products. A series of products termed "brazing sheet" is available. These products are also composites clad one or both sides with brazing alloy. For architectural uses, clad non-heat-treatable alloys may be supplied. These provide a variety of special finishing characteristics, integral color finishing capability, greater uniformity in appearance, and improved corrosion resistance.

With a few exceptions, most alloys in the 1xxx, 2xxx, 3xxx, 5xxx, and 7xxx series are available in sheet form (see Table 1). Along with alloy 6061, they cover a wide range of applications from builders' hardware to transportation equipment and from appliances to aircraft structures. Alloys 6009, 6111, and 6022 are widely used for automobile body panels and hood and deck stampings.

**Foil** is a product up through 0.15 mm (0.006 in.) thick. Most foil is supplied in coils, although it is also available in rectangular form (sheets). One of the largest end uses of foil is household wrap. There is a wider variety of surface finishes for foil than for sheet. Foil often is treated chemically or mechanically to meet the needs of specific applications. Common foil alloys are 1100, 1145, 1235, 3003, 5052, and 5056 (Table 1). Higher-strength foil of alloy 2024, 5052, or 5056 is used to produce the honeycomb cores used in bonded honeycomb sandwich panels.

## Bar, Rod, and Wire

Bar, rod, and wire are defined as solid products that are extremely long in relation to their cross-section. They differ from each other only in cross-sectional shape and in thickness or diameter. When the cross section is round or nearly round and is over 10 mm ( $\frac{3}{8}$  in.) in diameter, it is called *rod*. It is called *bar* when the cross section is square, rectangular, or in the shape of a regular polygon and when at least one perpendicular distance between parallel faces (thickness) is over 10 mm. *Wire* refers to a product, regardless of its cross-sectional shape, whose diameter or greatest perpendicular distance between parallel faces is 10 mm or less.

Rod and bar can be produced by either hot rolling or hot extruding and brought to final dimensions with or without additional cold working. Wire usually is produced and sized by drawing through one or more dies, although roll flattening also is used. Alclad rod or wire for additional corrosion resistance is available only in certain alloys. Many aluminum alloys are available as bar, rod, and wire; among these alloys, 2011 and 6262 are specially designed for screw-machine products, and 2117 and 6053 for rivets and fittings (Table 1). Alloy 2024-T4 is a standard material for bolts and screws. Alloys 1350, 6101, and 6201 are extensively used as electrical conductors. Alloy 5056 is used for zippers, and alclad 5056 for insect-screen wire.

## ***Tubular Products***

Tubular products include tube and pipe. They are hollow wrought products that are long in relation to their cross section and have uniform wall thickness except as affected by corner radii. Tube is round, elliptical, square, rectangular or regular polygonal in cross section. When round tubular products are in standardized combinations of outside diameter and wall thickness, commonly designated by "nominal pipe sizes" and "ANSI schedule numbers," they are classified as pipe.

Tube and pipe may be produced from a hollow extrusion ingot, by piercing a solid extrusion ingot, or by extruding through a porthole die or bridge die. They also may be made by forming and welding sheet. Tube may be brought to final dimensions by drawing through dies. Tube (both extruded and drawn) for general applications is available in such alloys as 1100, 2014, 2024, 3003, 5050, 5086, 6061, 6063, and 7075 (Table 1). For heat-exchanger tube, alloys 1060, 3003, alclad 3003, 5052, 5454, and 6061 are most widely used. Clad tube is available only in certain alloys and is clad only on one side (either inside or outside). Pipe is available in alloy 1350, 3003, 6061, 6063, 6101, and 6351 (Table 1).

## ***Shapes***

Shapes are products that are long in relation to their cross-sectional dimensions and that have cross-sectional shapes other than those of sheet, plate, rod, bar, wire, or tube. Most shapes are produced by extruding or by extruding plus cold finishing; shapes are now rarely produced by rolling because of economic advantages of the extrusion process. Shapes may be solid, hollow (with one or more voids), or semihollow. The 6xxx series (Al-Mg-Si) alloys, because of their easy extrudability, are the most popular alloys for producing shapes. Alloys of the 2xxx and 7xxx series are used in applications requiring higher strength.

Standard structural shapes such as I-beams, channels, and angles produced in alloy 6061 are made in different and fewer configurations than similar shapes made of steel; the patterns especially designed for aluminum offer better section properties and greater structural stability than those designed for steel, as a result of more efficient metal usage. The dimensions, weights, and properties of the alloy 6061 standard structural shapes, along with other information needed by structural engineers and designers, are contained in the *Aluminum Construction Manual*, published by the Aluminum Association, Inc.

Most aluminum alloys can be obtained as precision extrusions with good as-extruded surfaces; major dimensions usually do not need to be machined, because tolerances of the as-extruded product often permit manufacturers to complete the part by simple cutoff, drilling, or other minor operations.

In many instances, long aircraft structural elements incorporate large attachment fittings at one end. Such elements often are more economical to machine from stepped aluminum extrusions, with two or more cross sections in one piece, rather than from extrusions of uniform cross section that are large enough for the attachment fittings.

Aluminum shapes are produced in a great variety of cross-sectional designs that place the metal where it is needed to meet functional and appearance requirements. Full utilization of this capability of the extrusion process depends on the ingenuity of designers in creating new and useful configurations. However, the alloy extruded and the cross-sectional design greatly influence tooling cost, production rate, surface finish, and production cost. Therefore, the extruder should be consulted during the design process to ensure producibility, dimensional control, and finish capabilities that are required for the application.

Producibility is limited by metal-flow characteristics and is a function of alloy composition, extrusion temperature, press size, and shape complexity. Shapes are classified with respect to producibility into solid, hollow, and semihollow types and further classified by rules based on the dimensions of the features. The difficulty of extrusion can be estimated from the dimensions, taking into account the alloy to be extruded.

The overall size of the shape affects ease of extrusion and dimensional tolerances. As the circumscribing circle size (smallest diameter that completely encloses the shapes; see Fig. 5) increases, extrusion becomes more difficult. Metal flow is most rapid at the center of the die face. As circle size increases, differences in flow rate from the center to the outside of the shape increase, and die design and construction to counteract this effect are more difficult.

**Fig. 5** Illustration of circumscribing circle method of characterizing the size of an extruded shape

Complexity and production difficulty also increase with increasing "shape factor," which is the ratio of the perimeter of a shape to its weight per unit length. Increasing thickness aids extrusion, and shapes having uniform thickness are most easily extruded. Although weight and metal cost decrease with decreasing thickness, the increasing extrusion cost may offset the savings in metal cost. Limits on minimum practical thickness, which depend on circle size, classification, and alloy, are given in Table 2.

**Table 2** Standard manufacturing limits (in inches) for aluminum extrusions

(a) Minimum inside diameter is one-half the circumscribing diameter, but never under 1 in. for alloys in first three columns or under 2 in. for alloys in last two columns.

(b) Minimum hole size for all alloys is 0.110 in.<sup>2</sup> in area of 0.375 in. in diam.

Alloy selection for extruded shapes has an important effect on producibility and cost as well as on minimum thickness. The extrusion speed possible for a given shape is strongly affected by the composition being extruded and may vary by as much as a factor of 20 (see Table 3).

### ***Forgings***

The term "hand forgings" is applied to most of the open-die forgings produced on flat or contoured dies generally in hydraulic presses with capacities up to 445 MN (50,000 tonf). The most usual are of rectangular or cylindrical cross section and may be produced in economical lengths (multiple length) and later cut into shorter pieces. The general category includes disk-shape parts sometimes referred to as "biscuits" as well as more complicated pieces that may vary in cross section through the length or be bent, curved, or contoured. These forgings fill a frequent need in which the number of pieces required does not justify the time and expense of impression dies. Mandrel-forged rings are another type of open-die-forged product.

Forgings of all types, produced on hammers, mechanical presses, or hydraulic presses, range in size from 45 g (0.1 lb) to 1360 kg (3000 lb) or over. Those weighing up to 450 kg (1000 lb) are produced regularly, those weighing between 450 and 900 kg (1000 and 2000 lb) are less common, and pieces weighing more than 900 kg are special items.

Most aluminum forgings are produced in closed dies and can vary widely in detail and closeness of approach to the final dimensions desired. The ultimate in shaping parts by forging is represented by "precision forgings," which are essentially net-shape parts requiring little or no machining. The advantage of closed-die forgings is that the metallurgical-structure alignment follows the part contours. This is sometimes called the "grain-flow pattern." This alignment is highly favorable for static strength and fatigue resistance (refer to Fig. 3 and 4). In working operations preliminary to final shaping, the metal may be upset and drawn in ways that further improve final mechanical properties.

Particularly for die forgings, which represent engineered products designed to perform specific functions in specific machines or vehicles, the choice of forging process and tooling must be approached on a cost-effective basis involving quantities needed, tooling, forging, and machining costs, and the net effects of these factors. There are great variations in this problem, from the extreme case of simple parts for which tooling costs are inconsequential to parts ordered in large quantities, which usually justify the tooling cost of dies to produce a part with conventional machining allowances or even the higher initial costs of precision forging.

The alloy used affects costs, reflecting the relative alloy forgeability (see Fig. 6). This factor, combined with those discussed in the preceding paragraph, may account for a price ratio of up to 10 to 1 for parts of the same weight. Forgings

dies are more expensive than extrusion dies by a factor varying from the ratio 4 to 1 to the ratio 3 to 1, for small and large sections. Factors in formulating decisions as to whether parts should be shaped by machining from bar or plate stock or be produced as hand or die forgings are considered in the section of this article "Product Economics, Selection, and Design." In many cases, a die forging may serve to replace an assembly of parts produced from mill products and stampings or shapes.

**Fig. 6 Forgeability vs forging temperature for seven aluminum alloys. Forgeability increases as the arbitrary unit increases.**

The alloys most prominent in forgings are of the 2xxx, 6xxx, and 7xxx types; 1xxx, 3xxx, 4xxx, and 5xxx are producible but are used with less frequency (see Table 1). Limitations on controlled strain-hardening capability and on use of strain to produce T8-type tempers influence the use of some of these alloys. The largest forging tonnages in markets other than aerospace are accounted for by automobile and truck wheels of alloy 6061, whereas the aerospace industry uses forgings principally of 2xxx and 7xxx alloys (2014, 2219, 7049, 7050, 7075, and 7175).

Mandrel-forged or ring-rolled rings are produced in some forging plants. More information on a variety of representative die forgings, including the alloys and tempers used, the types of forging equipment used, and comments on selection factors, is given in Volume 14, *Forming and Forging*, of the *ASM Handbook*.

## Impacts

Impacts are formed in a confining die from a lubricated slug, usually cold, by a single-stroke application of force through a metal punch, causing the metal to flow around the punch or die. The process lends itself to high production rates, with precision parts being produced to exacting quality standards. Impacts involve a combination of cold extrusion and cold forging and, as such, combine most of the advantages of both the forging and extrusion processes. Impacts usually have properties in the longitudinal direction equal to those specified for other product forms of similar composition.

There are three basic types of impacting, all of which are used on aluminum. Reverse impacting is used to make shells with forged bases and extruded sidewalls. The slug is placed in a die cavity and struck by a punch, which forces the metal to flow back (upward) around the punch, and then through the opening between the punch and die, to form a simple shell. Forward impacting somewhat resembles conventional extrusion in that the metal is forced through an orifice in the die by the action of a punch, causing the metal to flow in the direction of punch travel. The punch fits the walls of the die so closely that no metal escapes backwards. Forward impacting with a flat-face punch is used to form round, nonround, straight, and ribbed rods, and forward impacting with a stop-face punch is used to form thin-wall tubes with one or both ends open, and with parallel or tapered sidewalls. If the punch is smaller than the die and the die contains an orifice, reverse and forward impacting can be combined to produce a combination impact.

A major consideration in designing aluminum impacts is selection of the appropriate alloy. Alloys 1100, 2014, 3003, 6061, 6351, and 7075 are most often utilized in aluminum impacts. These alloys offer a range of mechanical properties that fits most applications. Generally, the stronger the alloy impacted is, the shorter the tool life and the higher the

production costs. Although each part must be considered individually, the stronger alloys generally require greater minimum wall thicknesses.

Alloy 1100, which has excellent corrosion resistance in rural, industrial, and marine atmospheres, is commonly impacted to form containers for liquid and semiliquid materials such as food preserves and products sprayed by aerosols. Alloy 3003 is used for many of the same applications as alloy 1100, but it is selected when higher strength than that of 1100 is required. Alloy 6061, which is heat treatable and has excellent corrosion resistance, is widely used in the manufacture of parts for automotive, aircraft, and marine applications, especially where welding is involved or high strength is required. Alloy 6351 is a medium-to-high-strength heat treatable alloy with good corrosion resistance. Alloy 2014 is a heat treatable alloy used for general applications where high tensile and yield strengths, combined with good ductility and good fatigue resistance, are essential. It is widely used in structural applications and in aircraft, automobile, and ordnance parts. Alloy 7075 has the highest strength and hardness of these alloys. This heat treatable alloy is used for many of the same applications as those of alloy 2014, but it is selected where highest stresses are expected or for maximum weight savings.

## ***Other Mill Products***

**Fin stock** is coiled sheet or foil in specific alloys, tempers, and thickness ranges suitable for manufacture of fins for heat-exchanger applications. As shown in Table 1, commonly used alloys include 1100, 1145, 3003, 7072.

**Alclad Products.** As described earlier, aluminum products sometimes are coated on one or both surfaces with a metallurgically bonded, thin layer of pure aluminum or aluminum alloy. If the combination of core and cladding alloys is selected so that the cladding is anodic to the core, it is called *alclad*. The cladding of alclad products electrochemically protects the core at exposed edges and at abraded or corroded areas. When a corrosive solution is in contact with the product, current from the anodic cladding flows through the electrolyte to the cathodic core, and the cladding tends to dissolve preferentially, thus protecting the core. Sustained protection is dependent on obtaining the optimum quantity of current (which is influenced by the potential difference between the cladding and core), the conductivity of the corroding medium, film formation, and polarization (see the article "Corrosion Resistance of Aluminum and Aluminum Alloys" in this Section).

The corrosion potentials of cladding and core alloys are important in selecting a coating that is sufficiently anodic to electrochemically protect the core. Copper in solid solution in aluminum is less anodic as copper content increases. Consequently, pure aluminum is anodic to aluminum-copper-magnesium alloys in the naturally aged T3x and T4x tempers by about 0.154 V and is used as the cladding for most alclad 2xxx products. Increasing zinc in solid solution increases the anodic potential of aluminum alloys, while Mg<sub>2</sub>Si and manganese have little effect. Alloy 7072, Al-1Zn, has a more anodic potential than pure aluminum and is used as the cladding for Alclad 3003, 5052, 6061, and 7075, as well as others.

The most widely used alclad products are sheet and plate, although wire, tube, and other forms are also produced. The most generally accepted method of fabricating alclad sheet and plate consists of hot rolling to pressure weld the cladding slabs to a scalped core ingot. In fabricating alclad products, the temperature and time of thermal treatments should be minimized to avoid extensive diffusion of soluble elements from the core. This is particularly important in the 2xxx alloys, as diffusion of copper in the cladding makes it less anodic. It is less important in alloys containing zinc and magnesium, because these elements make the cladding more anodic.

The percentage of cladding thickness is determined principally by the thickness of the finished part. Because the objective is to provide an adequate absolute thickness, the percentage of thicker parts need not be as great as the percentage for thinner parts. A listing of the most widely used alclad products is given in Table 4.

## Product Economics, Selection, and Design

In the "cost-effective" approach to the problem of material selection, the only valid basis for choosing a particular material is that it will perform all required functions at the lowest overall cost. The material chosen may be the most cost-effective because (a) it is lowest in first cost and provides service and durability at least equal to those offered by any alternative material; (b) it is most economical in the long run due to lowest operating or maintenance costs; or (c) it has special characteristics not matched by any alternative material. These considerations at times are "warped" by artificial factors arising from such sources as legislation or the "energy crisis." Also, they may at times be greatly influenced, or even outweighed, by factors of availability or delivery time.

The choice between aluminum and some other material on the cost-effective basis is sometimes simple and at other times quite complex; in these cases the choice may shift from one time to another as relative costs change. Machining, joining, or finishing capabilities, as well as physical properties (predominantly density, conductivity, or reflectivity), are foremost considerations in many cases. The competitive position of aluminum in this race is often greatly augmented by the myriad design possibilities offered by aluminum shapes and forged parts. (Aluminum engineered castings also offer many of these advantages.)

Product selection is based primarily on shape, dimensional, and mechanical requirements. The piece needed may be required to cover or enclose an area, to fill a certain space, to connect or attach to other pieces, or to conduct or contain a fluid or gas, or it may be limited by weight or other factors. There is seldom any question concerning the best choice in the case of products like foil, wire, tube, or large-area applications for sheet. In other cases, an intelligent choice from among the various products is a complex engineering problem involving many factors in addition to first cost of the product itself. Shapes or die forgings frequently offer the advantage of a single piece having such features as ribs for stiffening, fins for heat dissipation, and bosses or pads for attachment, replacing several pieces that must be cut, formed, and joined. Mechanical-property considerations may be important in some cases, that is such matters as the availability or unavailability of an alloy and temper in a particular product type, the higher longitudinal static strength of extruded versus rolled or forged products, or the matching of metallurgical-structure alignment (or grain-flow pattern) with surface contours, a matter that is characteristic of die forgings.

For the most stringent structural applications, the greatest hazards are those posed by dynamic stresses and by combinations of static stresses from assembly interferences or misfits with dynamic applied stresses and corrosive environments. To avoid premature failure from fatigue cracking or stress-corrosion cracking, good mechanical design to minimize such stresses, stress concentrations and exposure to and entrapment of corrosive media are of paramount importance. The type of product and the alloy and temper selected also play a strong role in the design process.

## Product Dimensions and Dimensional Tolerances

The ranges of thickness in which foil, sheet, and plate are available were stated previously. By definition, foil is no greater than 0.15 mm (0.006 in.) thick and for some purposes is as thin as 0.0043 mm (0.00017 in.), sheet ranges from over 0.15 to 6.3 mm (over 0.006 to 0.249 in.) thick, and plate ranges from 6.3 to ~200 mm (0.250 to ~8 in.) thick. Corresponding width, length, and coil-size limitations are matters for inquiry with producers.

Standard dimensional tolerances for all mill products are contained in the American National Standard Institute document H35.2-1993, Annual Book of *ASTM Standards*, Volume 02.02 and in the Aluminum Association publication *Aluminum Standards and Data*. These dimensional tolerances on thickness, width, length, diameter, squareness, flatness, straightness, lateral bow, and twist, as applicable, vary with product type and are not tabulated in this Handbook.

The limiting dimensions for extruded products, including rod and bar, and for other solid, hollow, and semihollow shapes, with respect to maximum circumscribing circle size and minimum wall thickness, are alloy dependent, as indicated in Table 2. Various sizes of structural shapes (angles, channels, I-beams, H-beams, Tees, and Zees) produced from alloy 6061-T6 have been established as standard products by the Aluminum Association. Detailed dimensions, weights per lineal foot, and section properties (moment of inertia, section modulus, and radius of gyration) for these standard structural shapes--data which are useful for design--are also tabulated in the Aluminum Association publication *Aluminum Standards and Data*. These data, as well as those given in the same publication for standard pipe sizes, are not repeated in this Handbook.

Limiting dimensions in design of die forgings include total plan area, which may be as great as  $\sim 0.3 \text{ m}^2$  ( $\sim 500 \text{ in.}^2$ ) for forgings produced in mechanical presses,  $\sim 1.9 \text{ m}^2$  ( $\sim 3000 \text{ in.}^2$ ) for hammer forgings, and  $\sim 3.2 \text{ m}^2$  ( $\sim 5000 \text{ in.}^2$ ) for parts made in the largest hydraulic presses. Other limiting design features are web thickness, rib thickness and height, draft angles, and minimum radii for fillets and corners.

Cylindrical and other axisymmetric shapes are easiest to produce as impacts, but nonsymmetrical shapes may also be produced. Longitudinal ribs can be incorporated in sidewalls, either inside or outside. Lugs, bosses, grooves, depressions, and even ribs can be incorporated in the end or base configuration. Dimensional limitations apply to maximum diameter (dependent on press size), length-to-diameter ratio (a maximum of 18 to 1, with 12 to 1 more normal), and minimum wall thickness. All of these shape factors are alloy dependent.

### ***Effective Design and Use of Wrought Product Capabilities***

Good design for aluminum can be defined as making the most effective use of its capabilities. An outstanding example of this is the two-piece all-aluminum beverage container. Thin, coiled sheet of relatively high-strength alloys (3004 for the can body; 5182 for the lid), rolled at extremely high speeds, is drawn and ironed to produce the body and formed to produce easy-open ends. Both of these manufacturing operations produce the parts at extremely high rates. The favorable economics of lowest first cost, lower shipping costs (because of low weight), and recyclability combine with functional advantages to make these containers a viable and successful product in a highly competitive market. Such containers are pressure vessels in addition to being subject to considerable abuse from handling, and these factors require the best possible balance among alloy strength, fabricability, and design. Tool design for production of these containers played a key role in making them successful.

Roofing and siding for highway freight trailers represent another highly effective, high-volume use of aluminum alloy sheet with advantages in both first and lifetime costs. These applications employ semi-monocoque (stressed skin) construction and moderately high-strength, non-heat-treatable alloys. Skins for aircraft wings, control surfaces, and fuselages (pressure vessels) are likewise effective in both cost and function. These applications employ high-strength, heat treatable alloys, and forming operations ranging from mild to severe. In some cases, the good formability of freshly quenched, very long wing-skin panels is preserved by refrigeration during transcontinental shipment by rail in special cars from mill to aircraft factory. The fact that sheet accounts for such a high percentage of all aluminum mill products produced and shipped annually (nearly 60% in 1996) attests to the versatility and high efficiency of this form in a myriad of applications.

**Plate** is an obvious selection for many purposes. One example is large welded storage tanks used on space vehicles with formed and welded plate members serving the dual function of containing the fuel and oxidizers (cryogenic liquids) as well as forming the structure of the vehicle. For such applications, as well as for aircraft wings, plate may be extensively machined or chemically milled to form integral stiffening ribs or waffle patterns. When only longitudinal stiffening ribs are required, an alternative product is wide extruded panels with integral ribs.

For some designs, machining may be the most economical production technique, because the setup time may account for a large part of the cost of machining. In Fig. 7, for instance, the machined plate was the least expensive method of producing the aluminum part until production reached 600 pieces. At that point, the quantity was sufficient to compensate for the cost of the extrusion die. The built-up design, with skin on both surfaces, was heavier and costlier.

Fig. 7 Cost comparison for producing an alloy 2024-T4 part by three methods

Chemical milling (removal of metal by dissolution in an alkaline or acid solution) is routine for specialized operations on aluminum. For flat parts on which large areas having complex or wavy peripheral outlines are to be reduced only slightly in thickness, chemical milling is usually the most economical method.

For sheet metal parts that cannot be formed after machining, chemical milling is the only practical method by which metal can be removed to obtain a waffle-type grid with uniform skin thickness. Even then, allowance must often be made for some springback resulting from metal removal and the consequent redistribution of residual forming stresses.

Chemical milling can normally produce a stiffened skin to a thickness tolerance of  $\pm 0.13$  mm ( $\pm 0.005$  in.), with the cladding left intact on the unmilled surface. Mechanical milling of skins from sheet thicker than 3 mm ( $\frac{1}{8}$  in.) requires a cleanup "skim" cut for flatness on the hold-down surface, because of hold-down limitations.

**Extruded Shapes.** Extrusions, with their great design versatility, good surface quality, and precise dimensions, frequently do not have to be machined extensively; the configuration and dimensional precision of the as-extruded product often permits a manufacturer to complete the part by simple cutoff, drilling, broaching, or other minor machining operations. For any part that can be produced as an extrusion, the cost of the extrusion die is usually written off after a few parts have been produced.

Cost of machining may be the only selection consideration. This is illustrated in Fig. 8 by the cost figures for a fuel-tank attachment fitting. The design of this part permitted the use of an extrusion, which required very little machining compared with the same part fabricated from solid bar. After about 100 pieces, the cost per piece decreased substantially.

**Fig. 8** Cost of an extruded fuel-tank attachment fitting as a function of quantity. A part completely machined from bar stock is rated 100.

**Interconnecting Shapes.** It is becoming increasingly common to include an interconnecting feature in the design of an extruded shape to facilitate its assembly to a similar shape or to another product. It can be a simple step to provide a smooth lapping joint or a tongue and groove for a nesting joint (see Fig. 9). Such connections can be secured by any of the common joining methods. Of special interest when the joint is to be arc welded is the fact that lapping and nesting types of interconnections can be designed to provide edge preparation and/or integral backing for the weld (see sketch at bottom right in Fig. 9).

**Fig. 9** Four examples of interconnecting extrusions that fit together or fit other products, and four examples of joining methods

Interlocking joints can be designed to incorporate a free-moving hinge (see top sketch in Fig. 10) when one part is slid lengthwise into the mating portion of the next. Panel-type extrusions with hinge joints have found application in conveyor belts and roll-up doors.

**Fig. 10** Two examples of extrusions with nonpermanent interconnections

A more common type of interlocking feature used in interconnecting extrusions is the nesting type that requires rotation of one part relative to the mating part for assembly (see bottom sketch in Fig. 10). Such joints can be held together by gravity or by mechanical devices. If a nonpermanent joint is desired, a bolt or other fastener can be used, as illustrated in the bottom sketch in Fig. 10.

When a permanent joint is desired, a snapping or crimping feature can be added to interlocking extrusions (see Fig. 11). Crimping also can be used to make a permanent joint between an interlocking extrusion and sheet (Fig. 11). Extrusions also can be provided with longitudinal teeth or serrations, which will permanently grip smooth surfaces as well as surfaces provided with mating teeth or serrations; this is illustrated in the sketch at the bottom of Fig. 11.

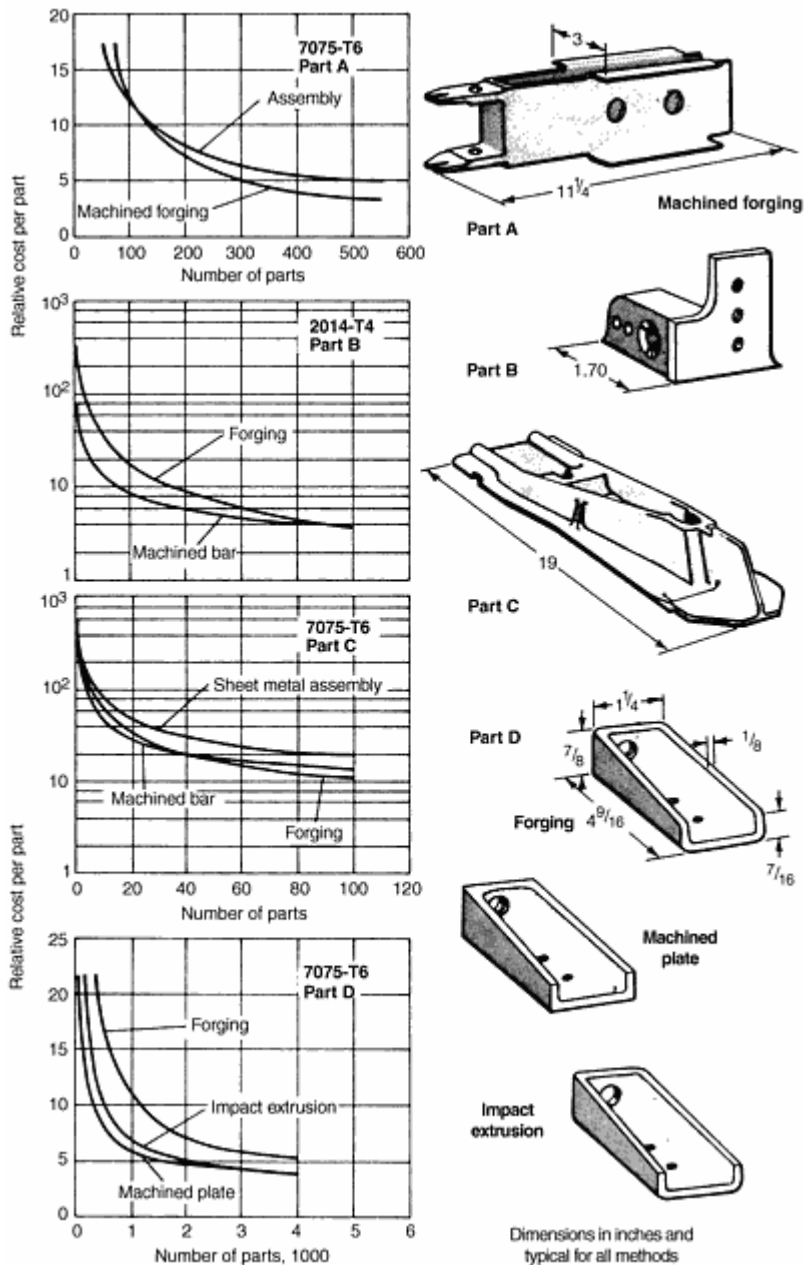

**Fig. 11** Six examples of interconnecting extrusions that lock together or lock to other products

Applications for interconnecting extrusions include doors; wall, ceiling, and floor panels; pallets; aircraft landing mats; highway signs; window frames; and large cylinders.

**Die Forgings.** The diversity of geometrical possibilities offered by aluminum die forgings frequently makes them highly advantageous choices in that they can be produced without costly machining, joining, or assembly operations. When compared with alternative methods of achieving the same functions, the integral product is often ahead in a value analysis. Tool (die) costs play a major role in the decision when the choice is between machining parts from bar or plate stock and purchasing die forgings. In other cases, the differences in directionality of wrought structure of the different products, which affect expected resistance to directional stresses and service environments, may be the principal deciding factor.

The cost of machining a few parts from a bar or slab is usually less than the cost of making a die and producing the parts by forging. When greater numbers of parts are to be produced, forging usually is the less-expensive method. In borderline cases, a detailed study of machining and die costs is necessary to determine the crossover point. In determining this point, it is necessary to calculate only the original cost of the die, because the supplier of the forging is responsible for die replacements caused by breakage or wear. This replacement cost is included in the price of the forgings. Die cost varies with the size and intricacy of the part.

In Fig. 12, a die forging (part A) is compared with a built-up design. Although 75% of the metal was machined away from the rough forging, the machined forging was more economical than the assembly for quantities greater than 125.

**Fig. 12** Relative costs of aluminum die forgings and similar components fabricated by other methods. The comparison for Part A is between a built-up design and a die forging. Although the rough forging was machined on all surfaces, a saving in fabrication cost was evident after about 125 forged fittings had been made. Part B is a simpler part, and the costs of forging compared with machining from bar were the same at about the 100th piece. For a more complicated forging (part C), the crossover point where the machined bar became more expensive than the forging occurred at 40 pieces. Part D, a relatively simple fitting, was made as a die forging, an impact extrusion, and a hollowed-out fitting. Forging was the most expensive approach. The cost of extrusion and of machining from plate were about the same for 3000 fittings.

In some large, complicated forgings, the break-even point may be at the first or second forging. It also may be desirable to rough forge the part in relatively inexpensive roughing dies and complete the part by machining if only a few pieces are desired. When this technique is used, the desirable flow of metal induced by forging and the consequent improvement in properties can be obtained at a lower cost than would have to be paid for a part forged to final dimensions.

The curves in Fig. 12 compare costs of parts of different size and shape, produced by competitive methods. For the simpler part, B, the crossover point occurs at about 100 pieces. For the complicated forging (part C), the crossover point occurs at 40 pieces. The items considered in determining the costs of these two parts include fabrication-shop learning

curves, unit-run labor, amortized setup, labor, tooling costs (including dies and fixtures), raw materials, and overhead charges.

Die forging is not always the cheapest method of producing a large quantity of parts. A relatively simple fitting (part D in Fig. 12) was analyzed for production costs as a die forging, as an impact extrusion, and as a part machined from plate. The machined fitting was more economical for all quantities, because the cost of the finishing operations required for the die forging closely approached the cost of producing the part by machining only. The thin walls and deep crevices of this fitting should have made it ideally suited to impact extrusion. Analysis showed that this method of manufacture was only slightly more expensive than machining for small quantities and identical in cost for quantities greater than  $\sim 3000$  parts.

The examples represented by the parts shown in Fig. 12 serve to relate design and cost, and emphasize the necessity for conducting a detailed cost analysis of each of the several methods of fabrication.

**Precision Forgings.** Precision-forged aluminum alloys are a significant commercial forging product form that has undergone major growth in use and has been the subject of significant technological development and capital investment by the forging industry. Precision aluminum forgings normally require no subsequent machining by the purchaser other than, in some cases, the drilling of attachment holes. They are produced with very thin ribs and webs; sharp corner and fillet radii; undercuts, backdrafts, and/or contours; and frequently, multiple parting planes that may optimize grain flow characteristics.

Selection of precision aluminum forging from the candidate methods of achieving a final aluminum alloy shape is based on value analyses for the individual shape in question. Figure 13 presents a cost comparison for a channel-type aluminum alloy part machined from plate, as-machined from a conventional aluminum forging, and produced as a precision forging; costs as a function of production quantity include application of all material, tooling, setup, and fabrication costs. The break-even point for the precision-forging method versus conventional forging occurs with a quantity of 50 pieces, and when compared to the cost of machining the part from plate, the precision forging is always less expensive. Figure 13 also illustrates the potential cost advantages of precision aluminum alloy forgings. It has generally been found that precision aluminum forgings are highly cost effective when alternate fabrication techniques include multiple-axis machining in order to achieve the final part.

**Fig. 13** Cost comparison for the manufacture of an aluminum alloy 7075-T73 component

Recent evaluations by the forging industry and users have shown that precision aluminum forgings can reduce final part costs by up to 80 to 90%, in comparison to machined plate, and 60 to 70%, in comparison to machined conventional forgings. Machining labor can be reduced by up to 90 to 95%.

## Specifications for Wrought Mill and Engineered Products

In the United States, specifications and standards for wrought aluminum products are issued/published by ASTM, governmental bodies (military and federal specifications), SAE International (Aerospace Materials Specifications, AMS), the American Society of Mechanical Engineers (ASME), and the American Welding Society (AWS). Table 6 provides a cross reference of the various specifications covering wrought aluminum products.

Table 6 Aluminum mill product specifications

Properties of Wrought Aluminum Alloys

Table 1 Nominal densities and specific gravities of wrought aluminums and aluminum alloys

Density and specific gravity are dependent on composition, and variations are discernible from one cast to another for most alloys. The nominal values given here should not be specified as engineering requirements but are used in calculating typical values for weight per unit length, weight per unit area, covering area, etc. The density values were derived from metric and subsequently rounded; these values are not to be back-converted to the metric.

Alloy	Density, lb/in. <sup>3</sup>	Specific gravity

- (a) Coefficient from 20 to 100 °C (68 to 212 °F).
- (b)

Melting ranges shown apply to wrought products of 6.35 mm ( $\frac{1}{4}$  in.) thickness or greater.
- (c) Based on typical composition of the indicated alloys.
- (d) Eutectic melting can be completely eliminated by homogenization.
- (e) Eutectic melting is not eliminated by homogenization.
- (f) Although not formerly registered, the literature and some specifications have used T736 as the designation for this temper.
- (g) Homogenization can raise eutectic melting temperature 10 to 20 °C (20 to 40 °F) but usually does not eliminate eutectic melting.

**Table 3 Typical mechanical properties of wrought aluminum and aluminum alloys**

The following typical properties are not guaranteed, because in most cases they are averages for various sizes, product forms, and

methods of manufacture and may not be exactly representative of any one particular product or size. The data are intended only as a basis for comparing alloys and tempers and should not be specified as engineering requirements or used for design purposes.

Alloy and temper	Ultimate tensile strength		Tensile yield strength		Elongation in 50 mm (2 in.), %		Hardness, HB <sup>(a)</sup>	Ultimate Shearing strength		Fatigue endurance limit <sup>(b)</sup>		Modulus of elasticity <sup>(c)</sup>	
	MPa	ksi	MPa	ksi	1.6 mm $\left(\frac{1}{16}\text{ in.}\right)$ thick specimen	1.3 mm $\left(\frac{1}{2}\text{ in.}\right)$ diam specimen		MPa	ksi	MPa	ksi	GPa	10 <sup>6</sup> psi

(a) 500 kg load and 10 mm ball.

- (b) Based on 500,000,000 cycles of completely reversed stress using the R.R. Moore type machine and specimen.
- (c) Average of tension and compression moduli. Compression modulus is  $\sim 2\%$  greater than tension modulus.
- (d) 1350-O wire will have an elongation of  $\sim 23\%$  in 250 mm (10 in.).
- (e) 1350-H19 wire will have an elongation of approximately  $1\frac{1}{2}\%$  in 250 mm (10 in.).
- (f) Tempers T361 and T861 were formerly designated T36 and T86, respectively.
- (g) Based on  $10^7$  cycles using flexural type testing of sheet specimens.
- (h) T7451, although not previously registered, has appeared in literature and in some specifications as T73651.

**Table 4 Effect of temperature on the tensile strengths of wrought aluminum and aluminum alloys**

----------------------------	-----------	----------	----------	-------------	----------	----------	----------	---------	----------	----------

- (a) These data are based on a limited amount of testing and represent the lowest strength during 10,000 h of exposure at testing temperature under no load; stress applied at 34 MPa/min (5000 psi/min) to yield strength and then at strain rate of 0.05 mm/mm per min (0.05 in./in. per min) to failure. Under some conditions of temperature and time, the application of heat will adversely affect certain other properties of some alloys.

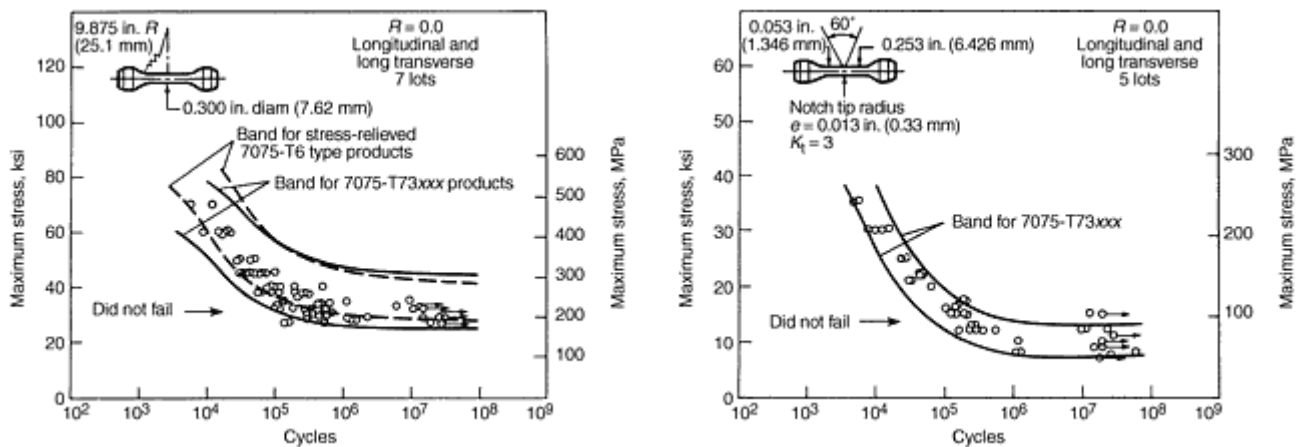

Fig. 1 Smooth and notched axial stress fatigue data for 7050-T7451 plate, 1 to 6 in. (25 to 152 mm) thick, shown in relation to bands established for 7075 wrought products in T6 and T73xx tempers

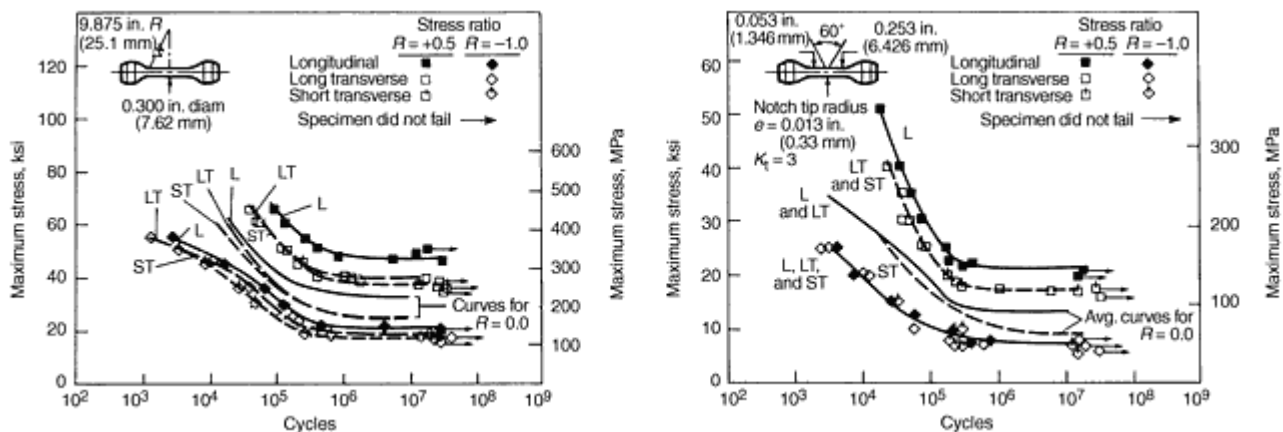

Fig. 2 Smooth and notched axial stress fatigue data for 7050-T7452 hand forgings,  $4\frac{1}{2} \times 22 \times 84$  in. (144 × 559 × 2133 mm)

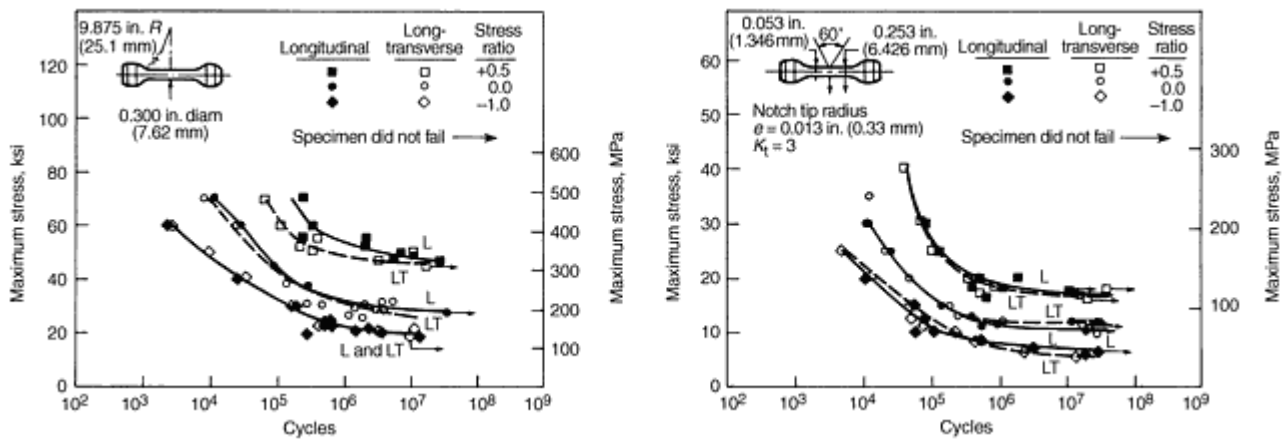

Fig. 3 Smooth and notched axial stress fatigue data for 7050-T7651x extruded shapes, 1.161 in. (29.5 mm) thick

Table 5 Effect of temperature on the yield strengths of wrought aluminum and aluminum alloys

(a) These data are based on a limited amount of testing and represent the lowest strength during 10,000 h of exposure at testing temperature under no load; stress applied at 34 MPa/min (5000 psi/min) to yield strength and then at strain rate of 0.05 mm/mm per min (0.05 in./in. per min) to failure. Under some conditions of temperature and time, the application of heat will adversely affect certain other properties of some alloys.

Converted SI (metric) values are for information only and are not to be used for purposes of specification, acceptance, or rejection.

- (a) Type of test specimen used depends on thickness of material.
- (b) Minimum yield strengths are not determined unless specifically requested.
- (c) In 50 mm (2 in.) or 4*d*.
- (d) For the corresponding H2 temper, limits for maximum tensile strength and minimum yield strength do not apply.
- (e) When tested upon receipt by the purchaser, material in this temper is required to pass the exfoliation corrosion resistance test (ASSET method). The improved resistance to exfoliation corrosion of individual lots is determined by microscopic examination to ensure a microstructure that is predominantly free of a continuous grain-boundary network of aluminum-magnesium precipitate. The microstructure is compared with that in a previously established acceptable reference photomicrograph.

(f) Also applies to material previously designated H117.

(g) This material is subject to some recrystallization and the attendant loss of brightness.

**Table 8 Mechanical-property limits for heat treatable aluminum alloy sheet and plate**

Converted SI (metric) values are for information only and are not to be used for purposes of specification, acceptance, or rejection.

- (a) In 50 mm (2 in.) or 4*d*.
- (b) For stress-relieved tempers, the characteristics and properties other than those specified may differ somewhat from the corresponding characteristics and properties of material in the basic temper.
- (c) Upon artificial aging, material in the T3/T31, T37, T351, T36, and T451 tempers is capable of developing the mechanical properties applicable to material in the T81, T87, T851, T861 and T651 tempers, respectively.
- (d) These properties usually can be obtained by the user when the material is properly solution heat treated or solution and precipitation heat treated from the O (annealed) or F (as fabricated) temper. These properties also apply to samples of material in the O and F tempers, which are solution heat treated or solution and precipitation heat treated by the producer to determine that the material will respond to proper heat treatment. Properties attained by the user, however, may be lower than those listed if the material has been formed or otherwise cold or hot worked, particularly in the annealed temper, prior to solution heat treatment.
- (e) This temper is not available from the material producer.
- (f) Tempers T361 and T861 were formerly designated T36 and T86, respectively.
- (g) This table specifies properties applicable to test specimens, and, because for plate in thicknesses of 0.500 in. or greater the cladding material is removed during preparation of specimens, the listed properties are applicable to the core material only. Tensile and yield strengths of the composite plate are slightly lower depending on cladding thickness.
- (h) The properties given for this thickness apply only to the T651 temper.
- (i) When subjected to stress-corrosion testing, material in this temper is capable of exhibiting no evidence of stress-corrosion cracking when exposed for a period of 30 days in the short-transverse direction at a stress level of 75% of the specified yield strength. The stress-corrosion resistance capabilities of individual lots are determined by testing the previously selected tensile-test specimens in accordance with the applicable electrical conductivity acceptance criteria.
- (j) Material in this temper, when tested upon receipt by the purchaser, is capable of passing an exfoliation corrosion resistance test and the stress-corrosion criteria of some tests except that the stress level should be 25.0 ksi. The improved resistance to exfoliation corrosion and stress-corrosion cracking of individual lots is determined by testing the previously selected tensile-test specimens in accordance with the applicable electrical conductivity acceptance criteria.
- (k) L, longitudinal; LT, long transverse; ST, short transverse

(l) Applies to 38.10 mm (1.500 in.) thickness only

**Fig. 4** Fatigue-crack-growth rates as functions of stress-intensity factor for two thicknesses of 7050-T7451 plate tested in three directions and in three environments

Converted SI (metric) values are for information only and are not to be used for purposes of specification, acceptance, or rejection.

- (a) The thickness of the cross section from which the tensile-test specimen is taken determines the applicable mechanical properties.
- (b) In 50 mm (2 in.) or  $4d$ . For material of such dimensions that a standard test specimen cannot be taken, or for shapes thinner than 0.062 in., the test for elongation is not required.
- (c) For stress relieved tempers, the characteristics and properties other than those specified may differ somewhat from the corresponding characteristics and properties of material in the basic temper.
- (d) Upon artificial aging, material in the T3/T31, T3510, T3511, T4, T4510, and T4511 tempers is capable of developing the mechanical properties applicable to material in the T81, T8510, T8511, T6, T6510, and T6511 tempers, respectively.
- (e) These properties usually can be obtained by the user when the material is properly solution heat treated or solution and precipitation heat treated from the O (annealed) or F (as fabricated) temper. These properties also apply to samples of material in the O and F tempers, which are

solution heat treated or solution and precipitation heat treated by the producer to determine that the material will respond to proper heat treatment. Properties attained by the user, however, may be lower than those listed if the material has been formed or otherwise cold or hot worked, particularly in the annealed temper, prior to solution heat treatment.

- (f) This temper is not available from the material producer.
- (g) When subjected to stress-corrosion testing, material in this temper is capable of exhibiting no evidence of stress-corrosion cracking when exposed for a period of 30 days in the short-transverse direction at a stress level of 75% of the specified yield strength. The stress-corrosion resistance capabilities of individual lots are determined by testing the previously selected tensile-test specimens in accordance with the applicable electrical conductivity acceptance criteria.
- (h) Material in this temper, when tested upon receipt by the purchaser, is capable of passing an exfoliation corrosion resistance test and the stress-corrosion resistance criteria of note <sup>(g)</sup> above except that the stress level is to be 25.0 ksi. The improved resistance to exfoliation corrosion and stress-corrosion cracking of individual lots is determined by testing the previously selected tensile-test specimens in accordance with the applicable electrical conductivity acceptance criteria.

Converted SI (metric) values are for information only and are not to be used for purposes of specification, acceptance, or rejection.

- (a) As-forged thickness. When forgings are machined prior to heat treatment, the properties given here also will apply to the machined thickness provided that the machined thickness is not less than one-half the original (as forged) thickness.
- (b) In 50 mm (2 in.) or 4*d*.
- (c) For information only. Brinell hardness usually is measured on the surface of the heat treated forging using a 500 kg load and a 10 mm penetrator ball.
- (d) Properties of forgings in H111 and H112 tempers depend on the equivalent cold work in the forgings. The properties listed should be attainable in any forging within the prescribed thickness range and may be considerably exceeded in some instances.
- (e) When separately forged coupons are used to verify acceptability of forgings in the indicated thicknesses, the properties shown for thicknesses up through 1 in., including test-coupon elongation, apply.

- (a) R, recrystallized; UR, unrecrystallized.
- (b) Unless otherwise specified as only a minimum (min) or a typical (typ) value, the two values given for a property represent the minimum and typical value. The minimum values are proposed by various customer and national specifications and do not reflect a uniform registration.
- (c)  $K_c$ , plane-stress fracture toughness;  $K_{Ic}$ , plane-strain fracture toughness

# Aluminum Foundry Products

## Introduction

ALUMINUM CASTING ALLOYS are the most versatile of all common foundry alloys and generally have the highest castability ratings. As casting materials, aluminum alloys have the following favorable characteristics:

- Good fluidity for filling thin sections
- Low melting point relative to those required for many other metals
- Rapid heat transfer from the molten aluminum to the mold, providing shorter casting cycles
- Hydrogen is the only gas with appreciable solubility in aluminum and aluminum alloys, and hydrogen solubility in aluminum can be readily controlled by processing methods.
- Many aluminum alloys are relatively free from hot-short cracking and tearing tendencies.
- Chemical stability
- Good as-cast surface finish with lustrous surfaces and little or no blemishes

Aluminum alloy castings are the cost-effective answer to many needs and problems in construction of machines, equipment, appliances, vehicles and structures, usually serving a primarily mechanical function, but often combining this with an appearance or decorative function. This requires cast parts in a great variety of geometric configurations, frequently combining several different basic forms in an integral or monolithic piece. These parts include covers and housings, which may be ribbed for reinforcement or finned for heat conduction or dissipation; frames and boxlike parts; cylindrical or spherical tanks for containment of gases or fluids; brackets; pistons; wheels; disks; impellers; bulkheads; and clamps. The list of forms produced is nearly endless, and many such parts have a multitude of cored holes in bosses for fastening or as passage for fluids.

## Casting Processes

Aluminum alloy castings are routinely produced by pressure-die, permanent-mold, green- and dry-sand, investment, and plaster casting. Aluminum alloys are also readily cast with vacuum, low-pressure, centrifugal, and pattern-related processes such as lost foam.

**Die Casting.** In die casting, which is the process used for the highest volume of production, molten metal is injected into cavities formed by heat treated steel dies and cores under pressures up to 140 MPa (20 ksi). Part size is limited only by machine capacity, and some machines are capable of producing castings weighing over 50 kg (100 lb), although casting weights up to ~5 kg (10 lb) are more common. As-cast surfaces are very smooth and detailed; machining is generally required only to provides fits or seals with other parts. Die casting permits metal sections thinner than those obtainable by sand or permanent mold casting. High mechanical properties and resistance to fatigue can be developed in die castings without heat treatment because of the fine microstructures produced by the rapid solidification.

Alloys most frequently used in die casting differ in composition from those employed in other casting processes, because the fine die cast microstructure allows higher volume fractions of second-phase constituents, silicon, and intermetallic compounds without damaging effects on ductility or impact resistance. Iron contents up to ~1%, which would impair both strength and ductility of other more slowly solidified castings, are quite beneficial in die casting compositions, minimizing the tendency of the aluminum to "solder" or adhere to the steel dies. Common die cast aluminum alloys and their typical applications include:

<b>Alloy 308.0</b>	<b>Lawnmower housings, gear cases, and cylinder heads for air-cooled engines</b>
<b>Alloy A380.0</b>	Streetlamp housings, typewriter frames, and dental equipment
<b>Alloy 360.0</b>	Frying skillets, cover plates, instrument cases, and parts requiring corrosion resistance
<b>Alloy 413.0</b>	Outboard motor parts such as pistons, connecting rods, and housings
<b>Alloy 518.0</b>	Escalator parts, conveyor components, aircraft and marine hardware, and fittings

**Permanent mold casting** employs metal molds and cores with either gravity or low-pressure introduction of molten metal. Most permanent mold castings weigh less than 10 kg (20 lb), but castings weighing up to 25 kg (50 lb), and sometimes even up to 100 kg (200 lb), are not uncommon. Permanent mold castings have smoother surfaces than those of sand castings and exhibit superior pressure tightness. Tapered metal cores are used to form straight-wall cavities, and collapsible metal cores are used to form internal ribs and undercuts, which also can be formed by expendable (dry sand or plastic) cores. When the latter are used, the process is referred to as semi-permanent mold casting. Mechanical properties (including fatigue resistance) of permanent mold castings are very high because of the fine microstructure and the capability for heat treatment.

Some common aluminum permanent mold casting alloys, and typical products cast from them, are presented in the following table:

Alloy 336.0	Automotive pistons
Alloys 355.0, C355.0, A357.0	Timing gears, impellers, compressors, and aircraft and missile components requiring high strength
Alloys 356.0, A356.0	Machine tool parts, aircraft wheels, pump parts, marine hardware, valve bodies
Alloy B443.0	Carburetor bodies, waffle irons
Alloy 513.0	Ornamental hardware and architectural fittings

Other aluminum alloys commonly used for permanent mold castings include 296.0, 319.0, and 333.0. Specifications for permanent mold castings are cross referenced in Table 1.

- (a) Former designations. ASTM adopted the Aluminum Association designation system in 1974.
- (b) Former designations used in SAE specifications J452 and/or J453. In 1990, SAE J452 adopted the ANSI/Aluminum Association numbering system for alloys. SAE J453-1986 has also superceded SAE J452.
- (c) Designation in MIL-21180c.
- (d) Alloy 356.0 is specified in AMS 4217, 4260, 4261, 4284, 4285, and 4286.
- (e) Alloy 512.0 is no longer active; it is included for reference purposes only.

**Sand casting** is in some ways the most versatile foundry method, with few limitations on the type of alloy that can be used or on part size or shape and extent of coring to form internal cavities and passages. This process is employed for relatively large parts, when required quantities are small, or when the design or the alloy dictates use of an expendable mold material. Size or weight limitations are generally established by melting, metal, or mold-handling capabilities. Sand castings weighing over 9,000 kg (18,000 lb) with dimensions of 5.5 m (18 ft) and over have been produced. As-cast surfaces are rougher than for other processes, and required dimensional tolerances are greater. A full range of mechanical properties is available because both non-heat-treatable alloys and heat treatable alloys of high strength capability can be used.

Typical products made from some common aluminum sand casting alloys include:

<b>Alloy C355.0</b>	<b>Air-compressor fittings, crankcases, and gear housings</b>
<b>Alloy A356.0</b>	Automobile transmission cases, oil pans, and rear-axle housings
<b>Alloy 357.0</b>	Pump bodies and cylinder blocks for water-cooled engines
<b>Alloy 443.0</b>	Pipe fittings, cooking utensils, and ornamental marine fittings

<b>Alloy 520.0</b>	Aircraft fittings, truck and bus frame components, levers, and brackets
<b>Alloy 713.0</b>	General-purpose casting alloy for applications requiring strength without heat treatment or involving brazing

Other aluminum alloys commonly used for sand castings include 319.0, 355.0, 356.0, 514.0, and 535.0. Specifications for sand-cast aluminum alloys are cross referenced in Table 1.

**Shell Mold Casting.** In this process the mold cavity is formed by a shell of resin-bonded sand only 10 to 20 mm (0.4 to 0.8 in.) thick--much thinner and lighter than the massive molds commonly used in sand foundries. Shell mold castings surpass ordinary sand castings in surface finish and dimensional accuracy and cool at slightly higher rates. Equipment costs are higher, and the size and complexity of castings that can be produced are more limited.

**Plaster and Investment Casting.** These processes are capable of producing intricate, thin-section parts with great dimensional accuracy, sharp reproduction of fine detail, and very smooth surfaces. Most castings produced by these methods are small and of thin section. Other mold materials or composite molds are generally required to provide adequate chilling capacity for castings having thick sections.

**Composite Mold Casting.** Use of more than one mold material having different heat-extraction (chilling) capabilities is the basis for composite mold casting. The mold materials are arranged to optimize the sequence of solidification from one part of the casting to another, providing increased soundness and strength with good dimensional control.

**Evaporative (lost-foam) pattern casting (EPC)** is a sand casting process that uses an unbonded sand mold with an expendable polystyrene pattern placed inside of the mold. This process is somewhat similar to investment casting in that an expendable material can be used to form relatively intricate patterns in a surrounding mold material. Unlike investment casting, however, EPC involves a polystyrene foam pattern that vaporizes during the pouring of molten metal into a surrounding mold of unbonded sand. With investment casting, a wax or plastic pattern is encased in a ceramic mold and removed by heat prior to the filling of the mold with molten metal.

**Centrifugal Casting.** Axisymmetric parts, such as those of tubular shape, are sometimes produced by true centrifugal casting in a metal mold. For nonsymmetrical shapes, mold filling can be assisted by centrifuging the molten metal into the mold cavity. In this process, multiple mold cavities are usually arranged around a central pouring sprue.

**Continuous Casting.** Long shapes of simple cross section (such as round, square, and hexagonal rods) can be produced by continuous casting, which is done in a short, bottomless, water-cooled metal mold. The casting is continuously withdrawn from the bottom of the mold; because the mold is water cooled, cooling rate is very high. As a result of continuous feeding, castings generally are free of porosity. In most instances, however, the same product can be made by extrusion at approximately the same cost and with better properties, and thus use of continuous casting is limited. The largest application of continuous casting is production of ingot for rolling, extrusion, or forging.

**Hybrid permanent mold processes** include both squeeze casting (liquid-metal forging) and semi-solid forming. Both of these processes offer net shape capabilities, but produce components that have mechanical properties well in excess of permanent mold castings and approaching those of forgings. Automotive components made from alloys 356 and 357 have been produced by these methods.

## Selection of Casting Process

Many factors affect the selection of a casting process for producing a specific part. In many cases the decision is influenced strongly by geometric configuration and design features, which determine the feasibilities of the different processes. When the casting can be produced by several of the available methods, relative weights, quantity requirements, and unit costs are frequently determinative. Selection can also depend on quality factors, such as soundness, pressure tightness, surface finish, machining requirements, mechanical properties, environmental service conditions, or special conditions of installation, assembly, or joining (such as by welding or brazing). Close cooperation between designers and potential producers is essential in coupling design and process to achieve the most cost-effective results. As with all procurement, availability and delivery may sometimes be prevailing factors.

Table 2 lists the principal technical factors of comparison among the basic sand, permanent mold, and die casting processes. Figure 1, presents the comparative microstructures of an Al-5%Si alloy (443.0 type) cast by these three processes and the corresponding typical tensile properties. These differences may be important factors in process selection.

**Table 2 Factors affecting selection of casting process for aluminum alloys**

Factor	Casting process		
	Sand casting	Permanent mold casting	Die casting
<b>Cost of equipment</b>	Lowest cost if only a few items required	Less than die casting	Highest
<b>Casting rate</b>	Lowest rate	11 kg/h (25 lb/h) common; higher rates possible	4.5 kg/h (10 lb/h) common; 45 kg/h (100 lb/h) possible
<b>Size of casting</b>	Largest of any casting method	Limited by size of machine	Limited by size of machine
<b>External and internal shape</b>	Best suited for complex shapes where coring is required	Simple sand cores can be used, but more difficult to insert than in sand castings	Cores must be able to be pulled because they are metal; undercuts can be formed only by collapsing cores or loose pieces
<b>Minimum wall thickness</b>	3.0-5.0 mm (0.125-0.200 in.) required; 4.0 mm (0.150 in.) normal	3.0-5.0 mm (0.125-0.200 in.) required; 3.5 mm (0.140 in.) normal	1.0-2.5 mm (0.100-0.040 in.); depends on casting size
<b>Types of cores</b>	Complex baked sand cores can be used	Reusable cores can be made of steel, or nonreusable baked cores can be used	Steel cores; must be simple and straight so they can be pulled
<b>Tolerance obtainable</b>	Poorest; best linear tolerance is 300 mm/m (300 mils/in.)	Best linear tolerance is 10 mm/m (10 mils/in.)	Best linear tolerance is 4 mm/m (4 mils/in.)
<b>Surface finish</b>	6.5-12.5 $\mu$ m (250-500 $\mu$ in.)	4.0-10 $\mu$ m (150-400 $\mu$ in.)	1.5 $\mu$ m (50 $\mu$ in.); best finish of the three casting processes
<b>Gas porosity</b>	Lowest porosity possible with good technique	Best pressure tightness; low porosity possible with good technique	Porosity may be present
<b>Cooling rate</b>	0.1-0.5 °C/s (0.2-0.9 °F/s)	0.3-1.0 °C/s (0.5-1.8 °F/s)	50-500 °C/s (90-900 °F/s)
<b>Grain size</b>	Coarse	Fine	Very fine on surface
<b>Strength</b>	Lowest	Excellent	Highest, usually used in the as-cast condition
<b>Fatigue</b>	Good	Good	Excellent

properties			
Wear resistance	Good	Good	Excellent
Overall quality	Depends on foundry technique	Highest quality	Tolerance and repeatability very good
Remarks	Very versatile in size, shape, and internal configurations	. . .	Excellent for fast production rates

Typical tensile properties				
Tensile strength		Yield strength		Elongation, %
MPa	ksi	MPa	ksi	
130	19	55	8	8

Typical tensile properties		Elongation, %

<b>230</b>	33	110	16	9

**Fig. 1** Al-5% Si alloy microstructures resulting from different solidification rates characteristic of different casting processes. Dendrite cell size and constituent particle size decrease with increasing cooling rate, from sand cast to permanent-mold cast to die cast. Etchant, 0.5% hydrofluoric acid. 500×

Unit costs are highly quality dependent because of tooling amortization costs. In general, the lower the tooling investment (patterns, molds, dies, and auxiliary equipment), the greater the cost of producing each piece. When only a few pieces are required, the method involving the least expensive tooling will result in the lowest unit cost, even though the cost of casting each piece is high. For very large production runs, where the tooling cost is shared by a large number of castings, more elaborate tooling decreases unit casting cost sufficiently to outweigh the initial investment. A typical analysis for production of a small part by various casting processes (sand, permanent mold, die, and investment casting) and by die forging, on the basis of relative unit cost versus quantity required, is illustrated graphically in Fig. 2.

**Fig. 2** Relative unit costs of producing a small connecting rod in various quantities by four casting processes and by forging. Tooling costs appropriate to process and quantity requirements are assumed. Dimensions are in inches.

**Design and Function.** The objective of casting design for mechanical function is to prevent failure due to the loads and stresses of normal operation plus those resulting from abuse and accidents. Basic principles applicable to any mechanical metal part apply, such as avoidance of sharp corners and other stress-concentrating features. Sections varying in thickness must be carefully blended, and wide thickness variations must be avoided. Thick sections isolated by thin sections cannot be "fed," and internal unsoundness or surface shrinkage can result. Each process has generally applicable minimum-section-thickness requirements, but these vary considerably depending on the area of the section and the character of surrounding features. As indicated previously, there is no substitute for experience in linking design, producibility and quality, and early consultation with foundry personnel during casting design will save time and avoid difficulties.

**Casting Quality.** When applied to castings, the term "quality" embraces many features including fidelity of reproduction of intended shape and dimensions, surface continuity and smoothness, as well as degree of soundness (freedom from cracks, porosity, and surface imperfections). These quality features are affected by design, casting process, alloy, and foundry procedures and control. Metallurgical microstructures are highly dependent on local rates of solidification and may vary substantially from one part of the casting to another. Solidification rate depends on section thickness and on the heat-extraction (chilling) capability of the mold or die, which in turn depends on two factors--the mold or die material, and the degree of persistence of thermal contact between the solidifying metal and the cavity surfaces. This obviously is process dependent, because not only the mold materials but also the pressure of the metal in the cavity vary with the process. Thus solidification rates increase in the following order: plaster, sand, permanent mold, centrifugal, and die casting. Table 2 lists some nominal cooling rates.

Grain size is refined by increasing solidification rate but is also highly dependent on the presence of grain-refining elements (principally titanium and boron) in the alloy. Even more importantly, solidification rate establishes the fineness of the microstructure--that is, the size and spacing of dendrites and the size and distribution of second-phase constituent particles. Relative values of dendrite-arm spacing (DAS), the most convenient feature for metallographic measurement and quantification, are closely correlated with constituent size and the effects on strength and ductility. Nominal DAS values are listed for three casting processes (sand, permanent mold, and die casting) in Table 2, and the correlation between mechanical properties and microstructure for alloy 443.0-F is apparent in Figure 1.

In general, two types of porosity can occur in cast aluminum: gas porosity and shrinkage porosity. Gas porosity, which generally is fairly spherical in shape, results either from precipitation of hydrogen during solidification (because the solubility of this gas is much higher in the molten metal than in the solid metal) or from occlusion of gas bubbles during the high-velocity injection of molten metal in die casting. The other source of porosity is the liquid-to-solid shrinkage, which frequently takes the form of interdendritically distributed voids. These voids can be enlarged by hydrogen, and, because larger dendrites result from slower solidification, the size of such porosity also increases as solidification rate decreases. It is not fair to the various processes to establish inherent ratings with respect to anticipated porosity, because castings made by any process can vary substantially in soundness--from nearly completely sound to very unsound--depending on casting size and design as well as on foundry techniques.

All aspects of casting quality are affected significantly by alloy composition, and each process tends to operate most effectively, providing the highest productivity and quality, with a specific alloy or with alloys of a specific type. It is on the basis of experience with this factor that certain alloys are indicated as being intended for use primarily in sand, permanent mold, or die casting. Some alloys are used for several (or all) processes.

## Alloy Systems

Aluminum casting alloys are based on the same alloy systems as those of wrought aluminum alloys, are strengthened by the same mechanisms (with the general exception of strain hardening), and are similarly classified into non-heat-treatable and heat treatable types. The major difference is that the casting alloys used in the greatest volumes contain alloying additions of silicon far in excess of the amounts in most wrought alloys.

Alloy selection for some types of applications is purely a matter of meeting functional requirements. For example, where very high electrical conductivity is essential, as in the pressure-cast integral conductor bars and collector rings of electric-motor rotors, only the unalloyed 1xx.x aluminum compositions can be used. For marine and salt water exposures, highest resistance to corrosion requires use of 5xx.x aluminum-magnesium alloys, as do many decorative, bright-finish, and food-processing-machinery applications.

The 2xx.x aluminum-copper group includes compositions capable of developing the highest strengths among all casting alloys, and these alloys are used where this is a predominant requirement. These alloys (A201.0, 202.0, 204.0, and A206.0) contain 4 to 6% Cu and 0.25 to 0.35% Mg, with highly restrictive impurity (iron and silicon) limits, and in some cases also contain 0.25 to 0.35% Mn or Cr and (in alloys 201.0, A201.0, and 202.0) 0.7% Ag. Good casting design and foundry techniques must be employed to realize full mechanical-property capabilities and consistently high quality for these alloys.

The 2xx.x alloys also have the highest strengths and hardnesses of all casting alloys at elevated temperatures (to 300 °C, or 600 °F), and this factor accounts for their use in some applications. Alloys 222.0, 224.0, 238.0, 240.0, 242.0, and 243.0, some with higher copper contents up to 2% Mg (6% in alloy 240.0) and additions of manganese, nickel, vanadium, and/or zirconium, are used primarily at elevated temperatures.

Heat treatment is required with the 2xx.x alloys for development of highest strength and ductility and must be properly applied to ensure high resistance to stress-corrosion cracking. General corrosion resistance of these alloys is lower than those of other types of casting alloys, and protection by surface coatings is required in critical applications.

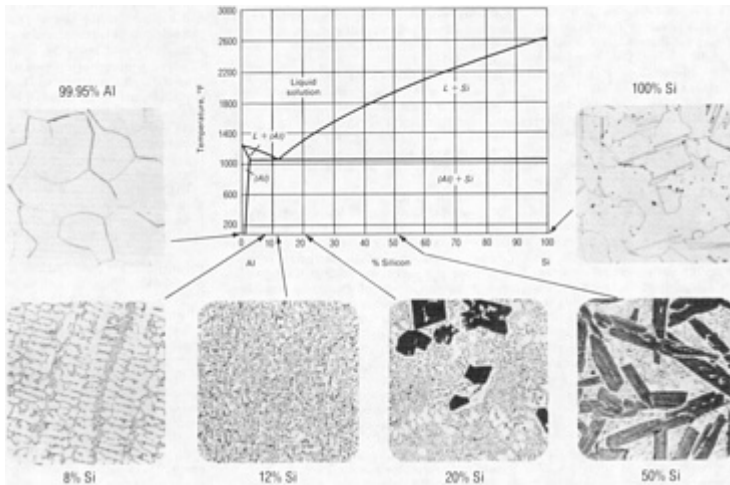

The 7xx.x aluminum-zinc-magnesium alloys are notable for their combinations of good finishing characteristics, good general corrosion resistance, and the capability of developing high strength through natural aging without heat treatment. The 8xx.x aluminum-tin alloys are special-purpose compositions used for sleeve bearings and bushings.

Almost all of the alloys in the 2xx.x, 5xx.x, 7xx.x, and 8xx.x groups are limited with respect to the casting configurations that can be produced with good recovery and quality. Greater care and adaptations in mold design are required to produce highest-quality castings with these alloys than with those of the 3xx.x and 4xx.x groups that have higher silicon contents.

Silicon is the alloying element that literally makes the commercial viability of the high-volume aluminum casting industry possible. Silicon contents from ~4% to the eutectic level of ~12% reduce scrap losses, permit production of much more intricate designs with greater variations in section thickness, and yield castings with higher surface and internal quality. These benefits derive from the effects of silicon in increasing fluidity, reducing cracking, and improving feeding to minimize shrinkage porosity.

Figure 3 shows the complete phase diagram of the binary aluminum-silicon system. This is a simple eutectic system with limited terminal solubility and is the basis for the 4xx.x alloys. Metallographic structures of the pure components and of several intermediate compositions show typical morphologies. The intermediate compositions are mixtures of aluminum containing ~1% Si in solid solution as the continuous phase, with particles of essentially pure silicon. Alloys with <12% Si are referred to as "hypoeutectic," those with close to 12% Si as "eutectic," and those with >12% Si as "hypereutectic."

**Fig. 3 Aluminum-silicon phase diagram and cast microstructures of pure components and of alloys of various compositions. Alloys with less than 12% Si are referred to as hypoeutectic, those with close to 12% Si as eutectic, and those with over 12% Si as hypereutectic.**

Resistance to cracking during casting is favored by a small range of solidification temperature, which drops from  $\sim 78^\circ\text{C}$  ( $140^\circ\text{F}$ ) at 1% Si to zero at  $\sim 12\%$  Si. Good feeding characteristics to minimize shrinkage porosity are benefited by a profile of volume fraction solidified versus temperature, which is weighted toward the lower portion of the temperature range--that is, toward increased eutectic. In the binary system, under the nonequilibrium conditions of casting, the volume fraction of eutectic increases linearly from  $\sim 0$  to 1 as silicon content increases from 1 to 12%.

The highest-volume-usage alloys are those in the 3xx.x group, which, in addition to silicon, contain magnesium, copper, or both, and in specific cases, supplementary additions of nickel or beryllium. In general, they fall into one of three types: Al-Si-Mg, Al-Si-Cu, or Al-Si-Cu-Mg. Silicon contents range from 5 to 22%. Copper contents range from 0% (alloys 356.0 through 361.0) to a maximum of 4.5%. Most of these alloys have nominal magnesium contents ranging from as low as 0.3% to  $\sim 0.6\%$  for the high-strength compositions and 1.0% for the piston alloys 332.0 and 336.0. The principal alloys of this group requiring low magnesium contents (0.10% maximum) are the die casting compositions 380.0 through 384.0.

Both copper and magnesium increase strength and hardness in the as-cast (F) temper through increased solid-solution hardening. Much greater increases are afforded by artificial aging only (T5-type tempers) or by complete solution plus artificial aging treatments (T6- or T7-type tempers). Depending on composition, the precipitation hardening is the result of precipitate structures based on  $\text{Mg}_2\text{Si}$ ,  $\text{Al}_2\text{Cu}$ ,  $\text{Al}_2\text{CuMg}$ , or combinations of these phases. The alloys containing both copper and magnesium have higher strengths at elevated temperatures.

Higher-silicon-content alloys are preferred for casting by the permanent mold and die casting processes. The thermal expansion coefficient decreases with increasing silicon and nickel contents. A low expansion coefficient is beneficial for engine applications such as pistons and cylinder blocks. When the silicon content exceeds 12%, as in alloys 390.0 through 393.0, primary silicon crystals are present and, if fine and well distributed, enhance wear resistance.

Alloys of the 4xx.x group, based on the binary aluminum-silicon system and containing from 5 to 12% Si, find many applications where combinations of moderate strength and high ductility and impact resistance are required. Bridge railing support castings are a representative example.

Alloys of the 8xx.x group contain  $\sim 6\%$  Sn and small amounts of copper and nickel for strengthening. These alloys were developed for bearing applications (tin imparts lubricity), for example, connecting rods and crankcase bearings for diesel engines.

## Mechanical Properties

Typical mechanical properties of various aluminum casting alloys are given in the compilations of the following article, "Properties of Aluminum Castings." These typical values should be used only for assessing the suitability of an alloy for a

particular application and not for design purposes. Design-stress values are significantly below typical properties as discussed in the section "Mechanical Test Methods" later in this article. Actual design strength depends on several factors, including:

- Section size
- Expected degree of porosity
- Presence of sharp corners
- Probability of cyclic loading in service

Minimum mechanical property limits are usually defined by the terms of general procurement specifications, such as those developed by government agencies and technical societies. These documents often specify testing frequency, tensile bar type and design, lot definitions, testing procedures, and the limits applicable to test results. By references to general process specifications, these documents also invoke standards and limits for many additional supplier obligations, such as specific practices and controls in melt preparation, heat treatment, radiographic and liquid penetrant inspection, and test procedures and interpretation.

**Mechanical Test Methods.** Typical and minimum mechanical-property values commonly reported for castings of particular aluminum alloys are determined using separately cast test bars that are  $\frac{1}{2}$  in. diameter (for sand and permanent mold castings) or  $\frac{1}{4}$  in. diameter (for die castings). As such, these values represent properties of sound castings, 13 or 6 mm ( $\frac{1}{2}$  or  $\frac{1}{4}$  in.) in section thickness, made using normal casting practice; they do not represent properties in all sections and locations of full-size production castings. Typical and minimum properties of test bars, however, are useful in determining relative strengths of the various alloy/temper combinations. Minimum properties--those values listed in applicable specifications--apply, except where otherwise noted, only to separate cast test bars. These values, unlike minimum values based on bars cut from production castings, are not usable as design limits for production castings. However, they can be useful in quality assurance. Actual mechanical properties, whether of separately cast test bars or of full-size castings, are dependent on two main factors:

- Alloy composition and heat treatment
- Solidification pattern and casting soundness

Some specifications for sand, permanent mold, plaster, and investment castings have defined the correlation between test results from specimens cut from the casting and separately cast specimens. A frequent error is the assumption that test values determined from these sources should agree. Rather, the properties of separately cast specimens should be expected to be superior to those of specimens machined from the casting. In the absence of more specific guidelines, one rule of thumb defines the average tensile and yield strengths of machined specimens as not less than 75% of the minimum requirements for separately cast specimens and elongation as not less than 25% of the minimum requirement. These relations may be useful in establishing the commercial acceptability of parts in dispute.

**Test Specimens.** Accurate determination of mechanical properties of aluminum alloy castings (or of castings of any other metal) requires proper selection of test specimens. For most wrought products, a small piece of the material often is considered typical of the rest, and mechanical properties determined from that small piece also are considered typical. Properties of castings, however, vary substantially from one area of a given casting to another, and may vary from casting to casting in a given heat.

If castings are small, one from each batch can be sacrificed and cut into test bars. If castings are too large to be economically sacrificed, test bars can be molded as an integral part of each casting, or can be cast in a separate mold.

Usually, test bars are cast in a separate mold. When this is done, care must be taken to ensure that the metal poured into the test-bar mold is representative of the metal in the castings that the test bars are supposed to represent. In addition, differences in pouring temperature and cooling rate, which can make the properties of separately cast test bars different from those of production castings, must be avoided.

For highly stressed castings, integrally cast test bars are preferable to separately cast bars. When integrally cast bars are selected, however, gating and risering must be designed carefully to ensure that test bars and castings have equivalent microstructure and integrity. Also, if there are substantial differences between test-bar diameter and wall thickness in critical areas of the casting, use of integrally cast test panels equal in thickness to those critical areas, instead of standard test bars, should be considered.

ASTM E 8 defines the test bars suitable for evaluation of aluminum castings. The use of test bars cut from die castings is not recommended; simulated service (proof) testing is considered more appropriate.

**Premium engineered castings** provide higher levels of quality and reliability than are found in conventionally produced parts. These castings may display optimum performance in one or more of the following characteristics: mechanical properties (determined by test coupons machined from representative parts), soundness (determined radiographically), dimensional accuracy, and finish. However, castings of this classification are notable primarily for mechanical property attainment that reflects extreme soundness, fine dendrite arm spacing, and well-refined grain structure. These technical objectives require the use of chemical compositions competent to display premium engineering properties. Alloys considered to be premium engineered compositions appear in separately negotiated specifications or in specifications such as military specification MIL-A-21180, which is extensively used in the United States for premium engineered casting procurement.

Alloys commonly considered premium by definition and specification are 201.0, C355.0, A206.0, A356.0, 224.0, A357.0, 249.0, 358.0, and 354.0. All alloys employed in premium engineered casting work are characterized by optimum concentrations of hardening elements and restrictively controlled impurities. Although any alloy can be produced in cast form with properties and soundness conforming to a general description of premium values relative to corresponding commercial limits, only those alloys demonstrating yield strength, tensile strength, and especially elongation in a premium range belong in this discussion. They fall into two categories: high-strength aluminum-silicon compositions and those alloys of the 2xx series, which, by restricting impurity element concentrations, provide outstanding ductility, toughness, and tensile properties with notably poorer castability.

**Hot isostatic pressing** of aluminum castings reduces porosity and can thus decrease the scatter in mechanical properties. The method also makes possible the salvaging of castings that have been scrapped for reasons of internal porosity, thereby achieving improved foundry recovery. This advantage is of more significant importance in the manufacture of castings subject to radiographic inspection when required levels of soundness are not achieved in the casting process. The development of hot isostatic pressing is pertinent to the broad range of premium castings, but is especially relevant for the more difficult-to-cast aluminum-copper series. Figure 4 shows the improvement in the fatigue life of Al-Cu cast alloy A201-T7 as the result of hot isostatic pressing.

**Fig. 4** Stress-life fatigue data for alloy A201-T7 castings with and without hot isostatic pressing (HIP).

cgs, centimeter-gram-second.

- (a) S = sand cast; P = permanent mold; D = die cast.
- (b) The specific gravity and density data in this table assume solid (void-free) metal. Because some porosity cannot be avoided in commercial castings, their specific gravities and densities are slightly less than the theoretical values.

**Table 2 Ratings of castability, corrosion resistance, machinability, and weldability for aluminum casting alloys**

Alloy	Resistance to hot cracking <sup>(a)</sup>	Pressure tightness	Fluidity <sup>(b)</sup>	Shrinkage tendency <sup>(c)</sup>	Corrosion resistance <sup>(d)</sup>	Machinability <sup>(e)</sup>	Weldability <sup>(f)</sup>

1, best; 5, worst. Individual alloys may have different ratings for other casting processes.

- (a) Ability of alloy to withstand stresses from contraction while cooling through hot short or brittle temperature range.
- (b) Ability of liquid alloy to flow readily in mold and to fill thin sections.
- (c) Decrease in volume accompanying freezing of alloy and a measure of amount of compensating feed metal required in the form of risers.
- (d) Based on resistance of alloy in standard salt spray test.
- (e) Composite rating based on ease of cutting, chip characteristics, quality of finish, and tool life.
- (f) Based on ability of material to be fusion welded with filler rod of the same alloy.

**Table 3 Typical mechanical properties of aluminum sand casting alloys based on tests of separately cast specimens**

Tensile and hardness values determined by tests on standard 13 mm ( $\frac{1}{2}$  in.) diam test specimens, without surface machining, each cast in a green sand mold.

- (a) Offset; 0.2%.
- (b) 500 kg (1102 lb) load on 10 mm (0.4 in.) ball.
- (c) Endurance limits based on 500 million cycles of completely reversed stresses using rotating beam-type machine and specimen.
- (d) Average tension and compression moduli, compression modulus is ~2% greater than tension modulus.
- (e) Properties of T4 approach those of T6 after standing for several weeks at room temperature.
- (f) Tests completed approximately 30 days after casting.
- (g) (g) Tests completed ten days after casting.

Tension and hardness values determined by tests on standard 13 mm ( $\frac{1}{2}$  in.) diam test specimens, without surface machining, each cast in permanent mold.

(a) At 0.2% offset.

(b) 500 kg (1102 lb) load on 10 mm (0.4 in.) ball.

(c) Endurance limits based on 500 million cycles of completely reversed stresses using rotating beam-type machine and specimen.

(d) Average of tension and compression moduli; compression modulus is  $\sim$ 2% greater than tension modulus.

(e) Properties of T4 approach those of T6 after standing for several weeks at room temperature.

(f) Tests made approximately 30 days after casting.

Tension properties are average values determined from ASTM standard 6 mm ( $\frac{1}{4}$  in.) diam test specimens cast on a cold chamber (high-pressure) die casting machine.

- (a) At 0.2% offset.
- (b) 500 kg (1102 lb) load on 10 mm (0.4 in.) ball.
- (c) Endurance limits based on 500 million cycles of completely reversed stresses using rotating beam-type machine and specimen.
- (d) Average of tension and compression moduli; compression modulus is  $\sim$ 2% greater than tension modulus.
- (e) Estimated

(a) These values represent properties obtained from separately cast test bars and are derived from ASTM B 26, Standard Specification for Aluminum Alloy Sand Castings; Federal Specification QQ-A-601e, Aluminum Alloy Sand Castings; and Military Specification MIL-A-21180C, Aluminum Alloy Castings, High Strength. Unless otherwise specified, the average values of tensile strength, yield strength, and elongation for specimens cut from castings should not be less than 75% of the tensile and yield strength values, and not less than 25% of the elongation values, given above. The customer should keep in mind that some foundries may offer additional tempers for the above alloys and that foundries are constantly improving casting techniques and, as a result, may offer minimum properties in excess of those given here.

(b) Mechanical properties of this alloy depend on the casting process. For further information, consult the individual foundries.

# Aluminum Powder Metallurgy Products

## Introduction

ALUMINUM POWDER METALLURGY (P/M) products constitute a very small part of the overall aluminum industry. In fact, the majority of the aluminum powder produced is not used for structural components. Instead, aluminum powders are used in unconsolidated form for use in paints/pigments for roof and automotive coatings; in powder metal-filled plastics; for fuel propellants, pyrotechnics (fireworks), and commercial explosives; metal powder cutting operations (iron-aluminum powders); and thermit welding (aluminothermic compounds). Nevertheless, interest in aluminum P/M alloys for structural applications continues because P/M processing provides much finer and homogeneous microstructures, better mechanical properties, and near-net shape parts producibility for aluminum alloys in comparison with ingot metallurgy (I/M). In addition to the conventional blending and consolidation of elemental or prealloyed powders into near-net shape parts (pressed-and-sintered P/M parts), emerging processes such as mechanical alloying (MA) and rapid solidification (RS) create powders that upon subsequent consolidation provide significant improvements in room- and elevated-temperature strength, fracture toughness, fatigue life, and resistance to corrosion and stress-corrosion cracking (SCC). Another advantage of advanced P/M processing methods, including the spray deposition/forming process, is in the production of new alloys (and composites) with metallurgical structures and compositions that cannot be produced by I/M. Rapid solidification processing extends the solubility of alloying elements, particularly transition and rare earth elements, and refines the structure of intermetallic phases responsible for improved mechanical properties. Mechanical alloying is a dry, high-energy milling process that produces dispersions of insoluble oxides and carbides that stabilize the microstructure leading to high strength at elevated temperature in the consolidated materials.

Despite the advantages of P/M processing for aluminum alloys, their large-scale commercialization has not been realized. Notwithstanding the high cost that remains a major concern for their use, there are other technological challenges such as reproducibility/reliability, machining, joining, and recycling that need to be addressed.

## Pressed-and-Sintered P/M Parts

Pressed and sintered alloys consist of aluminum powder admixed with small amounts of copper, magnesium, and silicon (Table 1). Compacts are pressed at 140 to 345 MPa (10 to 25 tsi) and sintered at 595 to 620 °C (1100 to 1150 °F) in nitrogen to 90 to 95% of theoretical density (sintering in dissociated ammonia or vacuum leads to slightly inferior properties). The as-sintered products have relatively low strengths, and they require heat treatment and/or deformation processing (rolling, extrusion, or forging) for improved properties (Table 2). Applications for sintered aluminum parts include business machines (the largest market), appliances, automotive components, and power tools.

## High-Performance P/M Alloys

### *Processing*

The steps in processing of high-performance aluminum P/M alloys can be combined in various ways, but they are most conveniently described as:

- *Powder production.* Powder can be made by various RS methods including atomization, splat quenching to form particulates, and melt spinning to form ribbon.
- *Powder processing* (optional), which includes mechanical alloying or comminution of melt-spun ribbon into powder for subsequent handling. Mechanical alloying is used for fabricating oxide-dispersion strengthened alloys. Pure metal and alloying ingredients are mechanically alloyed using high-energy ball mills. During this process, a heavy working of powder particles results in the intimate alloying by a process of repeated welding, fracturing, and rewelding. In the case of aluminum alloys, carbon derived from process control agents is incorporated into the processed powder and reacts with aluminum to form very fine carbides. These carbides and the fine oxide particles derived from the breakup of surface films on the initial powder particles create a dispersion that stabilizes the fine-grained microstructure. Therefore, a portion or all of the strengthening may be obtained from the ultrafine grain size stabilized by the oxide and carbide dispersions.
- *Degassing.* Powder is encapsulated in a can and degassed to prevent hydrogen porosity

- *Consolidation.* Powder is vacuum hot pressed or hot isostatically pressed into billets, which are subsequently rolled, extruded, or forged

## Classes of High-Performance Alloys

**High Room-Temperature Strength SCC/Corrosion-Resistant Alloys.** Rapid solidification processing is used to produce Al-Zn-Mg-Cu alloys 7091 and 7090, which are similar in composition to I/M alloy 7175, but contain 0.4 and 1.5% Co, respectively (Table 3). Cobalt forms  $\text{Co}_2\text{Al}_9$  or  $(\text{Co,Fe})_2\text{Al}_9$  particles which are homogeneously dispersed. These dispersoids refine the grain size for improved high strength and ductility, and enhance resistance to SCC (Table 4).

**Table 3 Nominal compositions of high-strength corrosion-resistant P/M aluminum alloys**

Alloy	Composition, wt %

(c) Longitudinal-transverse orientation per ASTM E 399

Mechanically alloyed alloys Al-9052 and Al-905XL (Table 3) also exhibit improved ambient temperature properties and improved corrosion and SCC resistance. Alloy Al-9052 is dispersion strengthened by magnesium oxides, aluminum oxides, and aluminum carbide; solid-solution strengthened by magnesium; and strengthened by its fine grain/subgrain structure. Alloy Al-905XL is strengthened by similar features, although it does display a slight artificial aging response from lithium-containing precipitates. Table 5 lists properties of AL-905XL forgings, and Fig. 1 compares the SCC resistance of RS, MA, and I/M aluminum alloys.

**Fig. 1** Crack velocity versus stress intensity factor for P/M alloys Al-9052, 7090, and 7091, as well as conventional alloy 7075. All alloys were in their highest-strength conditions.

**Elevated-Temperature Alloys.** Conventional high-strength I/M aluminum alloys contain precipitate particles that interact with moving dislocations, thus providing high strength at room temperature. However, when these alloys are exposed to elevated temperatures, the precipitate particles undergo dissolution and/or coarsening, thereby reducing the strength of the base alloy. This behavior precludes the use of these alloys for elevated-temperature applications. The RS-P/M alloys, based on hypereutectic Al-Fe-X compositions (Table 6), derive their high strengths from dispersion strengthening; the dispersoids resist dissolution and coarsening when the alloys are exposed to elevated temperatures. These alloys contain ternary and quaternary additions of transition and rare earth metals such as molybdenum, nickel, cerium, vanadium, and silicon. These alloy additions exhibit low solid solubility and low solid-state diffusivity in  $\alpha$  aluminum, and consequently, they tend to form thermally stable dispersoid particles. Conventional I/M processing of these compositions produces equilibrium or near-equilibrium microstructures containing coarse Al<sub>3</sub>Fe-type primary intermetallic particles in a coarse  $\alpha$ -aluminum matrix. Such microstructures exhibit poor ductility and cannot be used for structural applications. In contrast, RS-P/M processing of these chemistries suppresses the formation of Al<sub>3</sub>Fe-type primary intermetallic particles. It instead produces particulates exhibiting refined metastable microstructures, such as Al-Al<sub>6</sub>Fe-type microeutectic and/or a solute-supersaturated dendritic aluminum. In other words, RS-P/M processing conditions produce refined hypoeutectic-type microstructures from hypereutectic melts. During subsequent thermomechanical processing, the as-solidified hypoeutectic-type microstructures undergo solid-state phase transformations and produce fine (<1  $\mu$ m) dispersoid particles in an  $\alpha$ -aluminum matrix. As shown in Fig. 2, RS-P/M Al-Fe-X alloys retain 100% of their strength at temperatures as high as 315 °C (600 °F); conventional I/M alloys retain only about 50% of their strength at this temperature and are generally not used at temperatures exceeding 150 °C (300 °F).

**Table 6 Chemical compositions of dispersion-strengthened aluminum-base alloys produced by RS-P/M**

Fig. 2 Percent of room-temperature strength retained after elevated-temperature exposure of Al-Fe-Ce alloys

**Low density/high-stiffness alloys** include alloying elements that increase the elastic modulus or decrease density. Lithium and beryllium are the only elements that generally increase both properties in aluminum, and RS-P/M, MA, and spray forming have been used to produce Al-Li and Al-Be-Li alloys. Spray forming is a high-deposition-rate metal spraying process for the production of near-net-shape parts at a relatively low cost. In this method, molten metal is rapidly atomized to form a fine spray of droplets that are deposited onto a stationary or moving collector. The resulting preform is typically free from macrosegregation and prior particle boundaries that are occasionally present in I/M products. The spray forming process is useful in extending the maximum solute content of alloying elements and achieving a finer distribution of second-phase particles in an equiaxed grain structure. Such homogeneous, low-segregation, fine-scale alloy microstructures are useful for subsequent rolling, forging, extrusion, and superplastic forming operations. Alloys produced by spray forming can have higher levels of lithium than is possible with I/M alloys (2.5% Li is the practical limit for I/M alloys). Examples of spray-formed Al-Li alloys include Al-3.0Li-1.0Cu-0.7Mg-0.3Zr and Al-4Li-0.2Zr, both of which have higher levels of lithium and zirconium than does the commonly used I/M Al-Li alloy 8090 (Al-2.5Li-1.0Cu-0.7Mg-0.12Zr). The P/M Al-Li alloys exhibit a 4.4% increase in specific modulus over 8090.

Neither the Al-Li or Al-Be-Li P/M alloys have achieved commercial success, largely because of the success of I/M Al-Li alloys and the development of metal-matrix composites, such as Al-SiC and Al-TiB<sub>2</sub> systems. Examples of aluminum-matrix composites produced by P/M processing are described in the Section "Special-Purpose Materials" in this Handbook.

# Corrosion Resistance of Aluminum and Aluminum Alloys

## Introduction

ALUMINUM and most aluminum alloys have good corrosion resistance in natural atmospheres, fresh waters, seawater, many soils, many chemicals and their solutions, and most foods. This resistance to corrosion is the result of the presence of a very thin, compact, and adherent film of aluminum oxide on the metal surface. Whenever a fresh surface is created by cutting or abrasion and is exposed to either air or water, a new film forms rapidly, growing to a stable thickness. The film formed in air at ambient temperatures is  $\sim 5$  nm (50 Å) thick. The thickness increases with increasing temperature and in the presence of water. The oxide film is soluble in alkaline solutions and in strong acids, with some exceptions, but is stable over a pH range of  $\sim 4.0$  to 9.0.

There are different types of corrosion and various interactions with induced or imposed stresses so that the effects can range from unimportant to highly damaging. For some types of applications, a distinction should be made between appearance and durability. The surface can become unattractive because of roughening by shallow pitting and can darken with dirt retention, but these conditions may have no effect on durability or function. On the other hand, stress-corrosion cracking (SCC) or highly localized, severe corrosion due to heavy-metal ions in solutions, stray electrical currents, or galvanic couples with more-anodic metals can be quite damaging. Good design and application practices must be observed to avoid these conditions. This includes selection of alloys appropriate for the conditions of the application.

## Effects of Alloy Composition

Among the principal alloying elements (magnesium, silicon, copper, manganese, and zinc), the element that has the greatest effect on general corrosion resistance is copper. Copper reduces resistance because it replates from solution as minute metallic particles forming highly active corrosion couples. The effects are apparent at copper contents exceeding a few tenths of one percent. In the heat treatable 2xxx or 2xx.x alloys with several percent copper, the state of solution or precipitation affects the type of corrosion attack as well as susceptibility to SCC. These effects are recognized in the alloy/temper ratings for general corrosion and SCC that appear in Table 1 for wrought alloys and Table 2 for casting alloys.

**Table 1 Relative ratings of resistance to general corrosion and to SCC of wrought aluminum alloys**

(a) Ratings are relative and in decreasing order of merit, based on exposure to sodium chloride solution by intermittent spraying or immersion. Alloys with A and B ratings can be used in industrial and seacoast atmospheres without protection. Alloys with C, D, and E ratings generally should be protected, at least on faying surfaces.

(b) Stress-corrosion cracking ratings are based on service experience and on laboratory tests of specimens exposed to alternate immersion in 3.5% NaCl solution. A, no known instance of failure in service or in laboratory tests; B, no known instance of failure in service; limited failure in laboratory tests of short transverse specimens; C, service failures when sustained tension stress acts in short-transverse direction relative to grain structure; limited failures in laboratory tests of long transverse specimens; D, limited service failures when sustained stress acts in longitudinal or long-transverse direction relative to grain structure.

(c) In relatively thick sections, the rating would be E.

(d) This rating may be different for material held at elevated temperatures for long periods.

- (a) Relative ratings of general corrosion resistance are in decreasing order of merit, based on exposures to NaCl solution by intermittent spray or immersion.
- (b) Relative ratings of resistance to SCC are based on service experience and on laboratory tests of specimens exposed to alternate immersion in 3.5% NaCl solution. A, no known instance of failure in service when properly manufactured; B, failure not anticipated in service from residual stresses or from design and assembly stresses below about 45% of the minimum guaranteed yield strength given in applicable specifications; C, failures have occurred in service with either this specific alloy/temper combination or with alloy/temper combinations of this type; designers should be aware of the potential SCC problem that exists when these alloys and tempers are used under adverse conditions.
- (c) For electric motor rotors

Among the common impurity elements, iron is probably the most important, degrading general corrosion resistance by increasing the volume fraction of cathodic and surface-film-weakening intermetallic-phase microconstituents.

The 7xxx Al-Zn-Mg alloys without copper have high general corrosion resistance. The alloys of this group that contain more than 1% Cu are less resistant to general corrosion. Appropriate tempers should be used to avoid SCC.

The 3xxx alloys are generally among those having the highest general corrosion resistance, as are those of the 5xxx group, which outperform any of the others in marine exposures. The 6xxx alloys also have high resistance.

## Corrosion in Atmospheres

Alloys other than those with the higher copper contents have excellent resistance to atmospheric corrosion (often called weathering) and in many outdoor applications require no protection or maintenance. Products widely used under such conditions include electrical conductors, outdoor lighting poles, bridge railings, and ladders. These often retain a bright metallic appearance for many years but may darken with mild surface roughening caused by shallow pitting and with accumulation of dirt.

An important characteristic of weathering, as well as corrosion of aluminum under many other environmental conditions, is that the rate of corrosion decreases with time. Figure 1 shows typical curves of the average changes that occurred in exposures of two generic types, seacoast and industrial, over a 30 year period with sheet specimens of 1100, 3003, and 3004 alloys, all in H14 temper. The curve shapes are similar, whether the amount of corrosion is measured by weight loss, depth of pitting, or loss in strength. Leveling-off usually occurs in 6 months to 2 years, after which the rate becomes approximately linear at a low rate. In rural atmospheres the weight-loss rate may be less than 0.025  $\mu\text{m}/\text{year}$  (0.001 mil/year). In industrial locations, rates vary from  $\sim 0.75$  to 2.75  $\mu\text{m}/\text{year}$  (0.03 to 0.11 mil/year) with a few particularly aggressive sites at which rates up to 12.5  $\mu\text{m}/\text{year}$  (0.5 mil/year), based on maximum pit depth, were observed. Table 3 compares atmospheric corrosion rates for wrought aluminum alloy 1100-H14 with that of commercially pure copper, lead, and zinc.

(e) Prime western zinc (98.9% Zn)

**Fig. 1** Depth of corrosion and loss of tensile strength for alloys 1100, 3003, and 3004 (shown in graphs a, b, and c, respectively). Data are given for the average performance of the three alloys, all in the H14 temper. Seacoast exposure was at a severe location (Pt. Judith, RI); industrial exposure was at New Kensington, PA. Tensile strengths were computed using original cross-sectional areas, and loss in strength is expressed as a percentage of original tensile strength.

Castings of 4xx.x and low-copper 3xx.x alloys have been used for many years in such applications as bridge guard-rail supports and lighting-pole bases with little adverse effect from corrosion. The 5xx.x casting alloys with 4 to 8% Mg are particularly suitable for cast parts that are used in marine and seawater exposure sites. Copper-containing alloys such as 295.0, 333.0, 380.0, and even 355.0 require surface protection for satisfactory use in corrosive marine or industrial atmospheres. Stress-corrosion cracking has been encountered occasionally with some of the 7xx.x alloys and alloy 520.0-T4 in atmospheric exposures of stressed parts. Applications for these alloys must be carefully engineered to avoid such problems.

## Corrosion in Waters

Corrosion resistance of aluminum in high-purity water, distilled or deionized, and in steam condensate is so high that these fluids are regularly contained and handled in aluminum equipment. Resistance is also high in most natural fresh waters. Soft waters have the least pitting tendency. Components of natural waters that increase pitting are copper ions, bicarbonate, chloride, sulfate, and oxygen. Thus, harder waters with more bicarbonate have a higher pitting tendency.

Service experience with aluminum alloys in marine and coastal applications, including structures, buoys, pipelines, lifeboats, motor launches, cabin cruisers, patrol boats, barges and larger vessels, has demonstrated their good resistance and long life under conditions of partial, intermittent, and total immersion. Wrought alloys of the 3xxx, 5xxx, and 6xxx groups are used. Those alloys of the 5xxx aluminum-magnesium group are most resistant and most widely used because

of favorable strength and good weldability. The rate of corrosion based on weight loss does not exceed  $\sim 5 \mu\text{m/year}$  (0.2 mil/year), which is  $<5\%$  of the rate for unprotected low-carbon steel in seawater. Corrosion is mainly pitting, decelerating with time from rates of 2.5 to 5  $\mu\text{m/year}$  (0.1 to 0.2 mil/year) in the first year to average rates over a 10 year period of 0.75 to 1.5  $\mu\text{m/year}$  (0.03 to 0.06 mil/year). The curve of maximum depth of pitting versus time follows an approximate cube-root law, from which it follows that doubling material thickness increases time to perforation by a factor of 8.

Casting alloys of the 5xx.x group with up to 8% Mg have high resistance to seawater corrosion and are used for fittings. Al-Si and Al-Si-Mg alloys are less resistant although 443.0 and 356.0T6 are sometimes used. Resistance of 2xxx, 2xx.x, 7xxx, and 7xx.x alloys is distinctly inferior, and their use without cladding or metallizing is not recommended.

## Corrosion in Soils

Soils differ widely in mineral content, texture, permeability, moisture, pH, and electrical conductivity as well as aeration, organic matter, and microorganisms. With this variability, corrosion performance of unprotected buried aluminum, like that of other metals, varies considerably. However, in many cases where carbon steel requires protective coatings, unprotected aluminum alloys have performed well. In most cases protection is recommended for buried applications. Use of 2xxx or 7xxx alloys or their cast counterparts is generally not recommended. Stray-current effects and contact with more-cathodic metals should be avoided. Successful applications include pipelines employing alloys 3003, 6061, and 6063 and culverts made of alclad 3004.

## Exposure to Foods

Aluminum alloys of the 3xxx and 5xxx groups are resistant to most foods and beverages. Aluminum products constitute a substantial share of the domestic cooking-utensil market and are used extensively for commercial handling and processing of foods. Large quantities of foil, foil laminated to plastics or paper, and cans are used for packaging and marketing of foods and beverages. Beverage-can bodies are generally produced from alloy 3004, food-can bodies from 5352 or 5050, and can ends from 5182. These cans generally have internal and external organic coatings, not for corrosion protection, but for decoration and prevention of effects on product taste.

## Exposure to Chemicals

Aluminum alloys are used in storing, processing, handling, and packaging of a variety of chemical products. They are compatible with most dry inorganic salts. Within the passive pH range, about 4 to 9, they resist corrosion in solutions of most inorganic chemicals but are subject to pitting in aerated solutions, particularly of halides. Aluminum alloys are not suitable for containing or handling mineral acids with the exceptions of nitric acid in concentrations over 82 wt% and sulfuric acid in concentrations from 98 to 100 wt%.

Aluminum alloys resist most alcohols; however, some may cause corrosion when extremely dry and at elevated temperatures. Similar characteristics are associated with phenol. Aldehydes have little or no corrosive effects. Care must be taken in using aluminum with halogenated organic compounds because under some conditions when moisture is present, they may hydrolyze and react violently.

Resistance of aluminum and aluminum alloys to many foods and chemicals, representing practically all classifications, has been established in laboratory tests and, in many cases, by service experience. Data are readily available from handbooks, proprietary literature, and trade association publications. (See, for example, *Guidelines for the Use of Aluminum with Food and Chemicals* published by the Aluminum Association Inc.)

## Exposure to Nonmetallic Building Materials

Aluminum alloys are not corroded seriously by long-time embedment in portland cement concrete, standard or lime brick mortar, hardwall plaster, or stucco. Superficial etching of the aluminum occurs while these products are setting, but after curing further attack is minimal. Special consideration should be given to protection where crevices between the concrete and the metal can entrap environmental contaminants. For example, highway railings and streetlight standards or stanchions usually are coated with a sealing compound where they are fastened to concrete, to prevent entry of salt-laden road splash into crevices.

Absorbent materials, such as paper, wood refuse, and wallboard in contact with aluminum under conditions where it may become wet, will cause corrosion. Composite-bonded insulated aluminum panels employ a moisture barrier on the inside to prevent condensation and wetting of the insulation. Some insulating materials, such as magnesia, are alkaline and quite aggressive to aluminum. Magnesium oxychloride, a flooring compound sometimes used in subway and railway passenger cars and ship decks, is very corrosive and should not be used with aluminum. Although wood usually is not corrosive, it can become corrosive if moisture content exceeds 18 to 20%. Wood preservatives containing copper are detrimental, and those containing mercury should not be used where aluminum is involved.

## Forms of Corrosion

Form or type of corrosion can be categorized by the morphology, which may or may not be related to the microstructure of the metal, or by the conditions causing the corrosion. Uniform attack or dissolution, which may occur if the surface oxide film is soluble in the corroding medium, is infrequent in service. Most corrosion in service is localized in one way or another. When the oxide film is insoluble in the corroding medium, corrosion is localized at weak spots in the film, which can result from microstructural features such as the presence of microconstituents. Local cells are formed by such nonuniformities in the metal as well as environmental nonuniformities, such as those created by differential aeration cells or by heavy metals plated out on the surface. Localized corrosion in a microscopic sense results from galvanic coupling and stray-current effects.

**Pitting** is the most common form of localized corrosion and frequently is difficult to associate with specific metallographic features. Pit shape can vary from shallow depressions to cylindrical or roughly hemispherical cavities. These shapes distinguish pitting from intergranular or exfoliation corrosion. Superpurity aluminum has the highest resistance to pitting, and, among the 1xxx and 1xx.x aluminums, resistance improves with purity. Among commercial alloys, those of the 5xxx group have the lowest pitting probability and penetration rates, followed by alloys of the 3xxx group.

**Intergranular corrosion** is a selective attack of grain boundaries. The mechanism is electrochemical, resulting from local cell action in the boundaries. Microconstituents precipitated in grain boundaries have a corrosion potential differing from that of adjacent solid solution and transition precipitate structure and form cells with it. In alloys of the 5xxx and 7xxx groups, the precipitates ( $\text{Al}_8\text{Mg}_5$ ,  $\text{MgZn}_2$ , and  $\text{Al}_2\text{Mg}_3\text{Zn}_3$ ) are anodic to the matrix. In 2xxx alloys, the precipitates ( $\text{Al}_2\text{Cu}$  and  $\text{Al}_2\text{CuMg}$ ) are cathodic. Intergranular corrosion can occur with either type. Susceptibility depends on the extent of intergranular precipitation, which is controlled by fabricating or heat treating parameters.

In 2xxx alloys, grain-boundary precipitation is caused by an inadequate cooling rate during the quenching operation of heat treatment. Thick-section products cannot be cooled sufficiently rapidly to completely avoid susceptibility to intergranular corrosion in T3- and T4-type tempers. Resistance to this type of attack is much higher in T6- and T8-type tempers. Alloys of the 6xxx group with a balanced magnesium/silicon ratio ( $\text{Mg}_2\text{Si}$  proportions) show little tendency toward intergranular corrosion; susceptibility is higher in those with excess silicon over the  $\text{Mg}_2\text{Si}$  ratio. Alloys of the 7xxx group may corrode intergranularly; overaging to T7-type tempers provides high resistance.

Because intergranular corrosion is involved in SCC of aluminum alloys (see discussion below), it is often presumed to be more deleterious than pitting or general (uniform) corrosion. However, in alloys that are not susceptible to SCC--for example, the 6xxx series alloys--intergranular corrosion is usually no more severe than pitting corrosion, tends to decrease with time, and, for equal depth of corrosion, the effect on strength is no greater than that of pitting corrosion, although fatigue cracks can be more likely to initiate at areas of intergranular corrosion than at random pits.

**Exfoliation corrosion** is selective attack that proceeds along multiple subsurface paths roughly parallel to the surface. It can be intergranular but also is associated with striated insoluble microconstituents and dispersoid bands aligned parallel to the product surface. It is most common in thin-section products with highly worked, flattened, and elongated metallurgical structures. Leafing or delamination accompanied by swelling caused by expansion of corrosion products is characteristic and is apparent in metallographic section (see Fig. 2). Exfoliation frequently proceeds from sheared edges and may be initiated at pit surfaces. It is not accelerated by applied stress but is intensified by slightly acidic solutions and by galvanic coupling.

**Fig. 2** Exfoliation corrosion in an alloy 7178-T651 plate exposed to a seacoast environment. Cross section of the plate shows how exfoliation develops by corrosion along boundaries of thin, elongated grains.

In 2xxx and copper-containing 7xxx alloys, exfoliation is considerably affected by section thickness and corresponding microstructure and by temper. The 2xxx alloys are susceptible only in T3- and T4-type tempers and are resistant in T6- or T8-type tempers. In the copper-containing 7xxx group alloys, resistance is greatly improved by overaging beyond peak strength (T6-type tempers), so that these materials are resistant in T7-type tempers. In extrusions of these heat-treated alloys, the recrystallized peripheral zone near surfaces is often highly resistant to exfoliation while the underlying unrecrystallized portion may be vulnerable to this type of attack.

The 1xxx aluminums and 3xxx alloys are highly resistant to exfoliation in all tempers. Exfoliation has been encountered in highly cold worked, high-magnesium 5xxx alloys such as 5456-H321 boat hull plate. Improved tempers (H116 and H117) with high resistance have been established.

**Galvanic Corrosion.** Most forms of corrosion discussed previously are electrochemical in nature and involve cells formed by microstructural or environmental features. A number of other conditions establish potential differences that intensify and localize corrosion. The accelerated corrosion resulting from electrical contact with a more-noble metal or with a nonmetallic conductor such as graphite is termed "galvanic corrosion." The most common examples occur when aluminum alloys are joined to steel or copper and are exposed to wet saline environments. In such situations the aluminum is more rapidly corroded than it would be in the absence of the dissimilar metal.

For each environment, metals can be arranged in a galvanic series from most to least active. Table 4 lists potentials based on measurements in sodium chloride solution. The rate of corrosive attack when two metals are coupled depends on several factors: (a) the potential difference, (b) the electrical resistance between the metals, (c) the conductivity of the electrolyte, (d) the cathode/anode area ratio, and (e) the polarization characteristics of the metals. Although the corrosion potential can be used to predict which metal will be attacked galvanically, the extent of attack cannot be predicted because of polarization. For example, the potential difference between aluminum and stainless steel exceeds that between aluminum and copper; however, the galvanic effect of stainless steel on aluminum, because of polarization, is much less than that of copper, which shows little polarization.

- (a) The potential of an aluminum alloy is the same in all tempers wherever the temper is not designated. S is sand cast; PM is permanent mold cast.
- (b) Measured in an aqueous solution of 53 g of sodium chloride and 3 g of  $\text{H}_2\text{O}_2$  per liter at 25 °C; 0.1N calomel reference electrode.
- (c) Potential varies  $\pm 0.01$  to 0.02 V with quenching rate.

In natural environments, including saline solutions, zinc is anodic to aluminum and corrodes preferentially, giving protection to the aluminum. Magnesium is also protective, although in severe marine environments, it can cause corrosion of aluminum because of an alkaline reaction. Cadmium is neutral to aluminum and can be used safely in contact with it. Copper and copper alloys, brass, bronze, and monel are the most harmful, followed closely by carbon steel in saline environments. Nickel is less aggressive than copper, approaching stainless steel in effect, as does chromium electroplate. Lead can be used with aluminum, except in marine environments.

**Stray-Current Corrosion.** Whenever an electric current is conducted from aluminum to an environment such as water, soil, or concrete, the aluminum is corroded in the area of anodic reaction in proportion to the current. At low current densities, the corrosion may be in the form of pitting, while at higher current densities, considerable metal destruction can occur at rates that do not diminish with time.

In soils, stray-current corrosion can be caused by close proximity to other buried metal systems, which are protected by an impressed-current cathodic-protection system. The ground current can leak onto a buried aluminum structure at one point, then off at another where the corrosion occurs, taking a lower-resistance path between the driven buried anode and the nearby structure being protected. Common bonding of all buried metal systems in close proximity is the usual way to avoid such attack.

**Deposition corrosion** is a special form of galvanic corrosion that causes pitting. It occurs when particles of a more-cathodic metal plate out of solution on the aluminum surface, setting up local galvanic cells. The ions aggressive to aluminum are copper, lead, mercury, nickel and tin, often referred to as heavy metals. Their effects are greater in acidic solutions and are much less severe in alkaline solutions in which their solubility is low.

Copper ions most commonly cause this type of corrosion in applications of aluminum. For example, rain runoff from copper roof flashing can cause corrosion of aluminum gutters with no electrical contact between the two metals. Very small amounts of copper in solution (as low as 0.05 ppm) can be detrimental. The inferior general corrosion resistance of alloys containing copper is attributed to deposition corrosion by copper replated from the dissolved corrosion products.

Mercury is the ion most aggressive to aluminum, and even traces can cause serious problems. Liquid mercury does not wet aluminum, but if the natural oxide film on the aluminum surface is broken, aluminum dissolves in the mercury, forming amalgam, and the corrosion reaction becomes catastrophic. In corrosive solutions, any concentration of mercury greater than a few parts per billion should be cause for concern.

**Crevice Corrosion.** If an electrolyte is present in a crevice formed between two facing aluminum surfaces or between an aluminum surface and a nonmetallic material such as a gasket, localized corrosion in the form of pits or etch patches can occur. This is the result of formation of a concentration cell or differential aeration cell. Staining that occurs on inter-wrap surfaces of coiled sheet or foil or in packages of flat sheet or circles is a result of the same mechanism and can be preliminary to more severe corrosion that will make separation difficult. Such damage can be prevented by ensuring that the product is initially dry and by avoiding ingress of moisture by protecting it against condensation, rain, and other sources of contamination.

**Filiform corrosion**, sometimes termed "worm-track" corrosion, occurs on aluminum when it is coated with an organic coating and exposed to warm, humid atmospheres. The corrosion appears as threadlike filaments that initiate at defects in the organic coating, are activated by chlorides, and grow along the metal/coating interface at rates to 1 mm/day (0.04

in./day). The moving end of the filament is called the head, and the remainder of the track is called the tail (Fig. 3a). The occurrence of filiform corrosion on painted surfaces in aircraft (Fig. 3b) exposed to marine and other high-humidity environments has been controlled by use of chemical conversion coatings, anodizing, or application of chromate-inhibited primers prior to final coating.

**Fig. 3** Examples of filiform corrosion of aluminum. (a) Aluminum foil coated with polyvinyl chloride showing the advancing head and cracked tail section of a filiform cell. SEM. 80×. (b) Filiform corrosion of a painted aluminum aircraft skin

**Stress-Corrosion Cracking.** Time-dependent cracking under the combined influence of sustained tensile stress and a corrosive environment is labeled SCC. In aluminum products, SCC, which is characteristically intergranular in nature, has been experienced only in higher-strength alloys and tempers of the 2xxx, 7xxx, and 5xxx types (with more than 3% Mg) and of the 6xxx type (with excess silicon). The relative resistances of aluminum products made of such alloys in various tempers, and with respect to the direction of tensile stress, is indicated by the ratings listed in Table 5. No SCC problems have been encountered in service with 1xxx aluminum or with 3xxx, 6xxx (Mg<sub>2</sub>Si ratio) or 5xxx (containing 3% Mg or less) alloys. 6061-T6, which is included in Table 5, is a balanced-ratio alloy.

**Table 5** Relative stress-corrosion-cracking ratings for wrought products of high-strength aluminum alloys

Resistance ratings are as follows: A, very high, no record of service problems, stress-corrosion cracking not anticipated in general applications, B, high, no record of service problems, stress-corrosion cracking not anticipated at stresses of the magnitude caused by solution heat treatment. Precautions must be taken to avoid high sustained tensile stresses (exceeding 50% of the minimum specified yield strength) produced by any combination of sources, including heat treatment, straightening, forming, fit up, and sustained service loading. C, intermediate. Stress-corrosion cracking not anticipated if total sustained tensile stress is maintained below 25% of minimum specified yield strength. This rating is designated for the short-transverse direction in products used primarily for high resistance to exfoliation corrosion in relatively thin structures, where appreciable stresses in the short-transverse direction are unlikely, D, low. Failure from stress-corrosion cracking is anticipated in any application involving sustained tensile stress in the designated test direction. This rating is currently designated only for the short-transverse direction in certain products.

- (a) Ratings apply to standard mill products in the types of tempers indicated and also in Tx5x and Tx5xxx (stress-relieved) tempers, and may be invalidated in some instances by use of nonstandard thermal treatments, or mechanical deformation at room temperature by the user.
- (b) Test direction refers to orientation of direction in which stress is applied relative to the directional grain structure typical of wrought alloys, which for extrusions and forgings may not be predictable on the basis of the cross-sectional shape orientation of direction in which stress is applied relative to the directional grain structure typical of wrought alloys, which for extrusions and forgings may not be predictable on the basis of the cross-sectional shape of the product: L, longitudinal; LT, long transverse; ST, short transverse.
- (c) Sections with width-to-thickness ratios equal to or less than two, for which there is no distinction between LT and ST properties.

(d) Rating not established because product not offered commercially.

(e) Rating is one class lower for thicker sections: extrusions, 25mm (1 in.) and thicker; plate and forgings, 40mm (1.5 in.) and thicker

In general, high-tensile stress is a prerequisite to cracking when the stress direction is parallel to either the longitudinal or the long-transverse direction. When the tensile stress is in the short-transverse direction (perpendicular to the surfaces of plate or across the flash plane of die forgings), SCC can occur in susceptible alloy/temper combinations at relatively low stresses. Cracking is accelerated by aggressive, chloride-containing environments, but can occur in humid air.

Because of the orientation-dependence of SCC, it is important to minimize stresses in the most susceptible direction. In addition to the stresses imposed by service loading, the residual stresses from quenching or forming, and any resulting from interference fits or assembly misfits, must be taken into account. Minimizing these stresses in the short-transverse direction greatly reduces the probability of SCC failure of susceptible alloy/temper combinations. Use of resistant tempers is recommended.

For thin-section products used under conditions that induce little or no stress in the short-transverse direction, resistance of 2xxx alloys in T3- or T4-type tempers or of 7xxx alloys in T6-type tempers is often satisfactory. For rolled, extruded, or forged thick-section products, resistance in the short-transverse direction or across the flash plane of die forgings usually controls their use. Overaging stress-relief treatments that sacrifice some strength are very effective in providing high resistance to SCC in the copper-containing 7xxx alloys--7075, 7175, 7475, 7049, and 7050--in the T73, T736, and T74 tempers. Overaging of the premium strength 2xxx casting alloys to T63 to T7 tempers provides good resistance to SCC, and 2219 in the T6 temper is similarly overaged with respect to strength to achieve high SCC resistance.

Medium-strength copper-free and low-copper alloys of the 7xxx group tend to be susceptible to SCC. Successful use of 7039, which has poor resistance, in armor-plate applications requires control of short-transverse stresses and weld overlays. Alloys 7016, 7021, and 7029 with copper contents up to 1% have good formability and finishing properties for automotive applications such as bumpers. Maximum SCC resistance is obtained by forming in the freshly quenched (W) temper followed by two-step aging. Casting alloys of the 7xxx group have compositions similar to those of the aforementioned wrought alloys, and some SCC problems have occasionally been encountered in their applications.

**Corrosion Fatigue.** Fatigue strengths of aluminum alloys are lower in such corrosive environments as seawater and other salt solutions than in air, especially when evaluated by low-stress, long-duration tests. Such corrosive environments produce smaller reductions in fatigue strength in the more corrosion-resistant alloys, such as the 5xxx and 6xxx series, than in the less resistant alloys, such as 2xxx and 7xxx series.

Like SCC, corrosion fatigue requires the presence of water. In contrast to SCC, however, corrosion fatigue is not appreciably affected by test direction, because the fracture that results from this type of attack is predominantly transgranular.

**Hydrogen Embrittlement.** Only recently has it been determined that hydrogen embrittles aluminum. For many years, all environmental cracking of aluminum and aluminum alloys was represented as SCC; however, testing in specific hydrogen environments has revealed that aluminum is susceptible to hydrogen damage. Hydrogen damage in aluminum alloys may take the form of intergranular or transgranular cracking or blistering. Blistering is most often associated with the melting or heat treatment of aluminum, in which reaction with water vapor produces hydrogen. Blistering due to hydrogen is frequently associated with grain-boundary precipitates or the formation of small voids. Blister formation is different from that in ferrous alloys in that in aluminum it is more common to have a multitude of near-surface voids that coalesce to produce a large blister.

In a manner similar to the mechanism in iron-base alloys, hydrogen diffuses into the aluminum lattice and collects at internal defects. This occurs most frequently during annealing or solution treating in air furnaces prior to age hardening.

Most of the work on hydrogen embrittlement of aluminum has been on the 7xxx alloys; therefore, the full extent of hydrogen damage in aluminum alloys has not been determined and the mechanisms have not been established.

**Erosion-Corrosion.** In noncorrosive environments, such as high-purity water, the stronger aluminum alloys have the greatest resistance to erosion-corrosion because resistance is controlled almost entirely by the mechanical components of the system. In a corrosive environment, such as seawater, the corrosion component becomes the controlling factor; thus, resistance may be greater for the more corrosion-resistant alloys even though they are lower in strength. Corrosion inhibitors and cathodic protection have been used to minimize erosion-corrosion, impingement, and cavitation on aluminum alloys.

**Corrosion at Joints**

Joints fastened by mechanical fasteners--bolts, screws, cold headed rivets, and threaded connections--or by pressure or adhesive bonding require special attention to avoid galvanic effects, crevice corrosion, and assembly stresses in products susceptible to SCC. Methods of joining that involve heat--welding, brazing, and soldering--alter metallurgical structures of the parent material adjacent to the fusion zones and introduce composition differences between the joint proper and the parent metal. These can be a source of galvanic effects, particularly in heat treatable alloys, and are a factor of importance in selection of appropriate joining materials.

**Alclad Products**

In alclad aluminum products, the difference in solution potential between the core alloy and the cladding alloy is used to provide cathodic protection to the core. These products, primarily sheet and tube, consist of a core coated on one or both surfaces with a metallurgically bonded layer of an alloy that is anodic to the core alloy. The thickness of the cladding layer usually is less than 10% of the over-all thickness of the product. Cladding alloys generally are of the non-heat-treatable type, although, for higher strength, heat-treatable alloys sometimes are used. Composition relationships of core and cladding alloys generally are designed so that the cladding is 80 to 100 mV more anodic than the core. Table 6 lists several core alloy/cladding alloy combinations for common alclad products. Because of the cathodic protection provided by the cladding, corrosion progresses only to the core/cladding interface, and then spreads laterally. This is highly effective in eliminating perforation of thin products.

**Table 6 Combination of aluminum alloys used in some alclad products**

Core alloy	Cladding alloy
2014	6003 or 6053
2024	1230
2219	7072
3003	7072
3004	7072 or 7013
6061	7072
7075	7072, 7008, or 7011
7178	7072

**Protective Coatings**

Paints and other coatings are applied to aluminum alloy products for decorative as well as protective purposes. Almost any type of paint for metals (acrylic, alkyl, polyester, vinyl, etc.) is suitable; the performance of a particular paint on aluminum, when applied properly, is better than the performance on steel. As with any metal, surface preparation is important. Conversion coatings, of either the chromate or the phosphate type, are recommended for preparation of aluminum alloys. For milder environments, the paint can be applied to the conversion coating; for more aggressive environments such as those containing chlorides, a chromated primer should be applied first. Aluminum alloys are especially amenable to waterborne paints, which are being used increasingly because of environmental considerations. Many products precoated in a variety of colors for agricultural, industrial, and residential applications are available commercially.

Although more expensive, and restricted to in-plant application, anodized coatings provide excellent protection for aluminum alloys. They are also sometimes used as bases for paints. The many monumental buildings with outer walls of anodized aluminum alloys attest to the durability of these materials under conditions of weathering. Anodized coatings also provide a variety of colorations, most commonly shades of gray and bronze, produced by selection of both alloy and anodizing process.

Anodized coatings are produced by an electrolytic process in which the surface of an alloy that is made the anode is converted to aluminum oxide; this oxide is bound to the alloy as tenaciously as the natural oxide film but is much thicker. Coatings used to provide corrosion resistance range in thickness from 5 to 30  $\mu\text{m}$  (0.2 to 1.2 mils); little or no additional protection is provided by thicker coatings. As with the alloys themselves, anodized coatings are not resistant to most environments with pH values outside the range from 4 to 9. Within this range, resistance to corrosion can be improved by an order of magnitude or more; in atmospheric weathering tests, the number of pits that developed in the base metal was found to decrease exponentially with coating thickness.

# Introduction and Overview of Copper and Copper Alloys

## Introduction

COPPER AND COPPER ALLOYS constitute one of the major groups of commercial metals, ranking third behind only iron/steel and aluminum in terms of production and consumption. Copper and copper alloys are widely used because of their excellent electrical and thermal conductivities, outstanding resistance to corrosion, and ease of fabrication, together with good strength and fatigue resistance. Copper offers the designer moderate levels of density ( $8.94 \text{ g/cm}^3$ ), elastic modulus (115 GPa, or  $17 \times 10^6 \text{ psi}$ ), and melting temperature ( $1083^\circ\text{C}$ , or  $1981^\circ\text{F}$ ). It forms many useful alloys to provide a wide variety of engineering property combinations and is available in wrought, cast, and powder metallurgy(P/M) product forms. Wrought products include wire, flat products (plate, sheet, strip, and foil), tube, rod, bar, extrusions (shapes), and forgings. Castings can be produced by a variety of methods including sand (the most common casting method), continuous, centrifugal, die, investment, plaster, and permanent mold casting. Unique components, such as self-lubricating bearings and filters, are made by P/M methods. Structural parts, including high-strength oxide-dispersion-strengthened (ODS) copper alloys are also produced by P/M.

## Characteristics of Copper and Copper Alloys

### *Property Characteristics*

**Conductivity.** The electrical conductivity of commercially available pure copper,  $\sim 101\%$  International Annealed Copper Standard (IACS), is second only to that of commercially pure silver ( $\sim 103\%$  IACS). Standard commercial copper is available with higher purity and, therefore, higher conductivity than what was available when the electrical resistivity value at  $20^\circ\text{C}$  ( $70^\circ\text{F}$ ) was picked to define the 100% level on the IACS scale in 1913. The thermal conductivity for copper is also high,  $391 \text{ W/m} \cdot \text{K}$  ( $226 \text{ Btu/ft} \cdot \text{h} \cdot ^\circ\text{F}$ ), being directly related to the electrical conductivity through the Wiedemann-Franz relationship.

As with other metal systems, copper is intentionally alloyed to improve strength without unduly degrading ductility or workability. However, it should be recognized that additions of alloying elements also degrade electrical and thermal

conductivity by various amounts depending on the alloying element, and the concentration and location in the microstructure (solid solution or dispersoid). The choice of alloy and condition is most often based on the trade off between strength and conductivity (Fig. 1). Alloying also changes the color from reddish brown to yellow (with zinc, as in brasses) and to metallic white or "silver" (with nickel, as in U.S. cupronickel coinage).

**Fig. 1** Relationship between strength and electrical conductivity for copper and copper alloys

**Corrosion Resistance.** Copper is a noble metal, but, unlike gold and other precious metals, it can be attacked by common reagents and environments. Pure copper resists attack quite well under most corrosive conditions. Some copper alloys, however, have limited usefulness in certain environments because of hydrogen embrittlement or stress-corrosion cracking (SCC).

Hydrogen embrittlement is observed when tough pitch coppers, which are alloys containing cuprous oxide, are exposed to a reducing atmosphere. Most copper alloys are deoxidized and thus are not subject to hydrogen embrittlement.

Stress-corrosion cracking most commonly occurs in brass that is exposed to ammonia or amines. Brasses containing more than 15% Zn are the most susceptible. Copper and most copper alloys that either do not contain zinc or are low in zinc content generally are not susceptible to SCC. Because SCC requires both tensile stress and a specific chemical species to be present at the same time, removal of either the stress or the chemical species can prevent cracking. Annealing or stress relieving after forming alleviates SCC by relieving residual stresses. Stress relieving is effective only if the parts are not subsequently bent or strained in service; such operations reintroduce stresses and resensitize the parts to SCC.

Dealloying is another form of corrosion that affects zinc-containing copper alloys. In dealloying, the more active metal is selectively removed from an alloy, leaving behind a weak deposit of the more noble metal.

Copper-zinc alloys containing more than 15% Zn are susceptible to a dealloying process called dezincification. In the dezincification of brass, selective removal of zinc leaves a relatively porous and weak layer of copper and copper oxide. Corrosion of a similar nature continues beneath the primary corrosion layer, resulting in gradual replacement of sound brass by weak, porous copper. Unless arrested, dealloying eventually penetrates the metal, weakening it structurally and allowing liquids or gases to leak through the porous mass in the remaining structure.

A more detailed description of the corrosion resistance of copper is found in the article "Corrosion Characteristics of Copper and Copper Alloys" in this Section.

### ***Fabrication Characteristics***

**Workability.** Copper and copper alloys are readily cast into cake (slabs of pure copper, generally 200 mm thick and up to 8.5 m long, or 8 in. by 28 ft), billet, rod, or plate--suitable for subsequent hot or cold processing into plate, sheet, rod, wire, or tube--via all the standard rolling, drawing, extrusion, forging, machining, and joining methods. Copper and copper alloy tubing can be made by the standard methods of piercing and tube drawing as well as by the continuous induction welding of strip. Copper is hot worked over the temperature range 750 to 875 °C (1400 to 1600 °F), annealed between cold working steps over the temperature range 375 to 650 °C (700 to 1200 °F), and is thermally stress relieved usually between 200 and 350 °C (390 and 660 °F). Copper and copper alloys owe their excellent fabricability to the face-centered cubic crystal structure and the twelve available dislocation slip systems. Many of the applications of copper and

copper alloys take advantage of the work-hardening capability of the material, with the cold processing deformation of the final forming steps providing the required strength/ductility for direct use or for subsequent forming of stamped components. Copper is easily processible to more than 95% reduction in area. The amount of cold deformation between softening anneals is usually restricted to 90% maximum to avoid excessive crystallographic texturing, especially in rolling of sheet and strip.

Although copper obeys the Hall-Petch relationship and grain size can be readily controlled by processing parameters, work hardening is the only strengthening mechanism used with pure copper. Whether applied by processing to shape and thickness, as a rolled strip or drawn wire, or by forming into the finish component, as an electrical connector, the amount of work hardening applied is limited by the amount of ductility required by the application. Worked copper can be recrystallized by annealing at temperatures as low as 250 °C (480 °F), depending on the prior degree of cold work and the time at temperature. While this facilitates processing, it also means that softening resistance during long-time exposures at moderately elevated temperatures can be a concern, especially in electrical and electronic applications where resistance ( $I^2R$ ) heating is a factor.

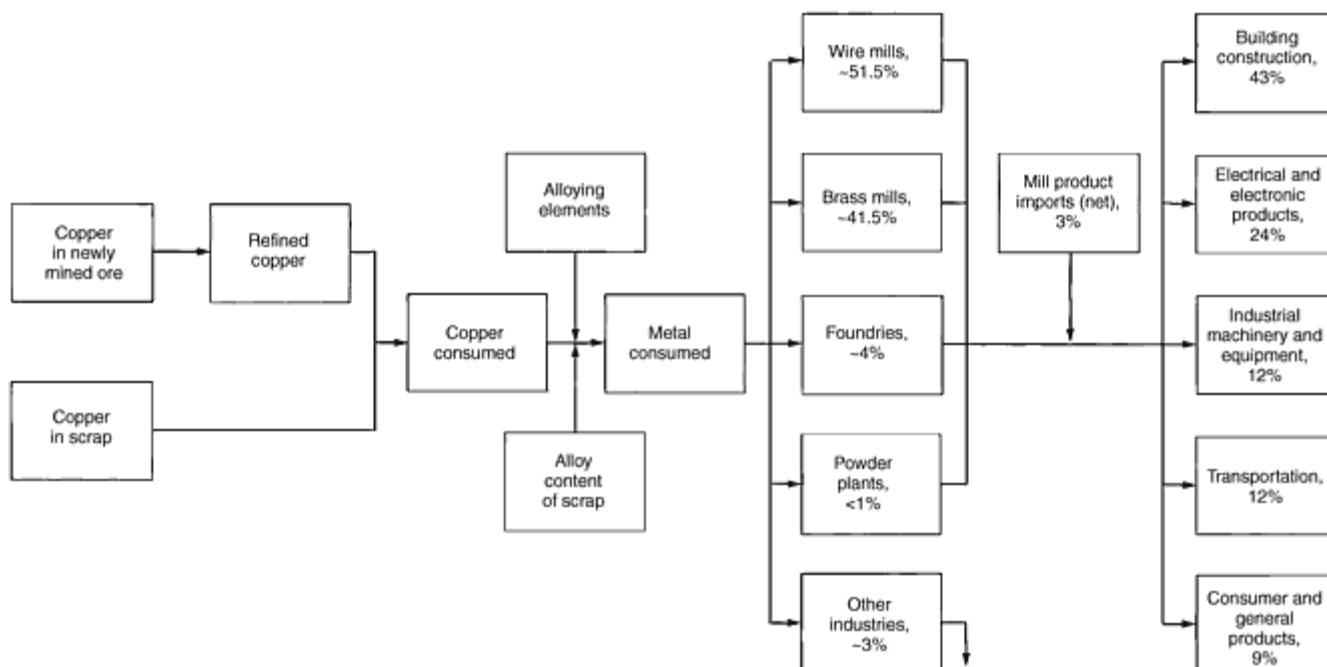

**Weldability.** Copper and copper alloys are most frequently welded using gas tungsten arc welding (GTAW), especially for thin sections, because high localized heat input is important in materials with high thermal conductivity. In thicker sections, gas metal arc welding (GMAW) is preferred. The weldability varies among the different alloys for a variety of reasons, including the occurrence of hot cracking in the leaded (free-machining) alloys and unsound welds in alloys containing copper oxide. Tin and zinc both reduce the weldability of copper alloys. The presence in the alloy of residual phosphorus is beneficial to weldability, because it combines with absorbed oxygen, thereby preventing the formation of copper oxide in the weld. Resistance welding is also widely used, particularly in alloys with low-thermal conductivity. Most copper alloys can be brazed satisfactorily. Oxygen-bearing coppers can be subject to gassing and embrittlement, particularly in oxyacetylene welding.

**Surface Finishes.** For decorative parts, standard alloys in specific colors are readily available. Copper alloys can be polished and buffed to almost any desired texture and luster. They can be plated, coated with organic substances, or chemically colored to further extend the variety of available finishes.

## The Copper Industry

The copper industry in the United States, broadly speaking, is composed of two segments: producers (mining, smelting, and refining companies) and fabricators (wire mills, brass mills, foundries, and powder plants). The end products of copper producers, the most important of which are refined cathode copper and wire rod, are sold almost entirely to copper fabricators. The end products of copper fabricators can be generally described as mill products and foundry products, and they consist of wire and cable, sheet, strip, plate, rod, bar, mechanical wire, tubing, forgings, extrusions, castings, and P/M shapes. These products are sold to a wide variety of industrial users. Certain mill products--chiefly wire, cable, and most tubular products--are used without further metalworking. On the other hand, most flat-rolled products, rod, bar, mechanical wire, forgings, and castings go through multiple metalworking, machining, finishing, and/or assembly operations before emerging as finished products.

**Copper Producers.** Figure 2 is a simplified flow chart of the copper industry. The box at the upper left represents mining companies, which remove vast quantities of low-grade material, mostly from open-pit mines, to extract copper from the crust of the earth. Approximately two tons of overburden must be removed along with each ton of copper ore. (The ratio of overburden to ore is sometimes as high as 5 to 1.) The ore itself averages only ~0.7% Cu.

**Fig. 2** Copper supply and consumption in the United States for 1996. See text for details. Source: Copper Development Association Inc.

Copper ore normally is crushed, ground, and concentrated, usually by flotation, to produce a beneficiated ore containing ~25% Cu. The ore concentrates are then reduced to the metallic state, most often by a pyrometallurgical process. Traditionally, the concentrated ore is processed in a primary smelting reactor, such as a reverberatory furnace, to produce a copper sulfide-iron sulfide matte containing up to 60% Cu. Reverberatory technology is rapidly being replaced by oxygen/flash smelting, which greatly reduces the volume of off gases. Sulfuric acid is manufactured from the sulfur dioxide contained in these off gases and is an important coproduct of copper smelting. The matte is oxidized in a converter to transform the iron sulfides to iron oxides, which separate out in a slag, and to reduce the copper sulfide to blister copper, which contains at least 98.5% Cu. Current technology combines the converter step with the preceding smelting step. Fire refining of blister copper then removes most of the oxygen and other impurities, leaving a product at least 99.5% pure, which is cast into anodes. Finally, most anode copper is electrolytically refined, usually to a purity of at least 99.95%.

The resulting cathodes are the normal end product of the producer companies and are a common item of commerce. In recent years, many producers have installed continuous casting rod mills to directly convert cathode copper to wire rod (typically, 8 mm or  $\frac{5}{16}$  in., in diameter), which is the feed material for the wire mills. Primary producers may also convert the cathode to cakes or billets of copper for sale to brass mills.

Hydrometallurgical processing is an increasingly important alternative to pyrometallurgy, particularly for nonsulfide ores such as oxides, silicates, and carbonates. In this process, weak acid is percolated through ore or waste dumps of rejected materials. Copper is leached out and recovered from the pregnant leach liquor, most often by solvent extraction, to produce an electrolyte suitable for electrowinning. In electrowinning, copper is extracted electrolytically in much the same way as anode copper is electrorefined. Copper extracted by electrowinning is equal in quality to that produced by electrolytic refining.

The box at the lower left in Fig. 2 represents the portion of the copper supply provided by scrap. In recent years, well over half the copper consumed in the United States has been derived from recycled scrap, and this percentage has grown somewhat over the last three decades. Approximately 55% of this scrap has been new scrap, such as turnings from screw-machined rod, as opposed to old scrap, such as used electrical cable or auto radiators. Scrap recycled within a particular plant or company (runaround scrap) is not included in these statistics. About one-third of the scrap recycled in the United States is fed into the smelting or refining stream and quickly loses any identity. The remainder is consumed directly by

brass mills; by ingot makers, whose main function is to process scrap into alloy ingot for use by foundries; by foundries themselves; by powder plants; and by others, such as the chemical, aluminum, and steel industries.

The box labeled "copper consumed" in Fig. 2 represents the total tonnage of refined copper plus the copper content of scrap consumed directly by fabricator companies. The various alloying elements used in producing copper alloys and the alloy content of the directly consumed scrap are added to obtain the total metal consumed by copper fabricators and other industries.

**Copper Fabricators.** The four classes of copper fabricators together account for ~97% of the total copper(including alloying metal) consumed each year in the United States (Fig. 2). Other industries, such as steel, aluminum, and chemical producers, consume the remaining 3%.

The share of metal consumed by wire rod mills has grown sharply over the last 30 years to the present (1996) level of ~51.5%; consumption by brass mills has dropped to 41.5%. Foundries account for about 4% of fabricated mill products, and powder plants use less than 1% of the U.S. supply of copper.

Wire mill products are destined for use as electrical conductors. Starting with wire rod, these mills cold draw the material (with necessary anneals)to final dimensions through a series of dies. The individual wires can be stranded and normally are insulated before being gathered into cable assemblies.

Brass mills melt and alloy feedstock to make strip, sheet, plate, tube, rod, bar, mechanical wire, forgings, and extrusions. Less than half the copper input to brass mills is refined; the rest is scrap. Fabricating processes such as hot rolling, cold rolling, extrusion, and drawing are employed to convert the melted and cast feedstock into mill products.

Approximately 45% of the output of U.S. brass mills is unalloyed copper and high-copper alloys, chiefly in such forms as plumbing and air conditioning tube, busbar and other heavy-gage current-carrying flat products, and roofing sheet. Copper alloys make up the remaining 55%. Free-cutting brass rod, which exhibits outstanding machinability and good corrosion resistance, and brass strip, which has high strength, good corrosion resistance, excellent formability, and good electrical properties, together constitute ~80% of the total tonnage of copper alloys shipped from U.S. brass mills. Other alloy types of major commercial significance include tin bronzes (phosphor bronzes), which are noted for their excellent cold-forming behavior and strength; tin brasses, known for outstanding corrosion resistance; copper-nickels, which are strong and particularly resistant to seawater; nickel silvers, which combine a silvery appearance with good formability and corrosion resistance; beryllium-coppers, which provide outstanding strength when hardened; and aluminum bronzes, which have high strength along with good resistance to oxidation, chemical attack, and mechanical abrasion.

Foundries use prealloyed ingot, scrap, and virgin metal as raw materials. Their chief products are shaped castings for many different industrial and consumer goods, the most important of which are plumbing products and industrial valves. Centrifugal and continuously cast products find major application as bearings, cylinders, and other symmetrical components. Powder plants produce powder and flake for further fabrication into powder metallurgy parts, chiefly small sintered porous bronze bearings.

**Markets and Applications.** The five major market categories shown at the far right in Fig. 2 constitute the chief customer industries of the copper fabricators. Of the chief customer industries, the largest is building construction, which purchases large quantities of electrical wire, tubing, and parts for building hardware and for electrical, plumbing, heating, and air-conditioning systems. The second largest category is electrical and electronic products, including those for telecommunications, electronics, wiring devices, electric motors, and power utilities. The industrial machinery and equipment category includes industrial valves and fittings; industrial, chemical, and marine heat exchangers; and various other types of heavy equipment, off-road vehicles, and machine tools. Transportation applications include road vehicles, railroad equipment, and aircraft parts;automobile radiators and wiring harnesses are the most important products in this category. Finally, consumer and general products include electrical appliances, fasteners, ordnance, coinage, and jewelry.

In service in these five market areas, copper and copper alloys fulfill five primary functions: electrical conductivity, corrosion resistance, heat transfer, structural capability, and aesthetics. The analysis of the consumption of copper for 1996 by these primary functions reveals the following distribution:

Function	Consumption	
	<b>lb × 10<sup>6</sup></b>	<b>%</b>
<b>Electrical</b>	4401	58
<b>Corrosion resistance</b>	1650	21.7
<b>Heat transfer</b>	947	12.5
<b>Structural</b>	486	6.4
<b>Aesthetics</b>	107	1.4
Total	<b>7591</b>	<b>100</b>

### Alloy and Temper Designation Systems

**Alloy Designations.** In North America, the accepted designation for copper alloys is part of the Unified Numbering System (UNS). Under the UNS system, the identifiers of copper alloys take the form of five-digit codes preceded by the letter "C" (for copper). The five-digit codes are based on, and supersede, an older three-digit system administered by the Copper Development Association Inc. (CDA). The UNS designations for copper alloys are simply two-digit extensions of the CDA numbers. For example, the leaded brass (85Cu-5Sn-5Pb-5Zn, or 85-5-5-5), once known as CDA Alloy No. 836, became UNS C83600.

Table 2 summarizes the standard UNS designation system. As this table indicates, wrought alloys are assigned UNS numbers from C10000 through C79999; cast alloys are numbered from C80000 through C99999.

Table 2 Generic classification of copper alloys

Generic name	UNS No.	Composition
Wrought alloys		
Coppers	C10100-C15760	>99% Cu
High-copper alloys	C16200-C19600	>96% Cu
Brasses	C20500-C28580	Cu-Zn
Leaded brasses	C31200-C38590	Cu-Zn-Pb
Tin brasses	C40400-C49080	Cu-Zn-Sn-Pb
Phosphor bronzes	C50100-C52400	Cu-Sn-P
Leaded phosphor bronzes	C53200-C54800	Cu-Sn-Pb-P
Copper-phosphorus and copper-silver-phosphorus alloys	C55180-C55284	Cu-P-Ag

<b>Aluminum bronzes</b>	C60600-C64400	Cu-Al-Ni-Fe-Si-Sn
<b>Silicon bronzes</b>	C64700-C66100	Cu-Si-Sn
<b>Other copper-zinc alloys</b>	C66400-C69900	. . .
<b>Copper-nickels</b>	C70000-C79900	Cu-Ni-Fe
<b>Nickel silvers</b>	C73200-C79900	Cu-Ni-Zn
Cast alloys		
<b>Coppers</b>	C80100-C81100	>99% Cu
<b>High-copper alloys</b>	C81300-C82800	>94% Cu
<b>Red and leaded red bronzes</b>	C83300-C85800	Cu-Zn-Sn-Pb (75-89% Cu)
<b>Yellow and leaded yellow bronzes</b>	C85200-C85800	Cu-Zn-Sn-Pb (57-74% Cu)
<b>Manganese bronzes and leaded manganese bronzes</b>	C86100-C86800	Cu-Zn-Mn-Fe-Pb
<b>Silicon bronzes, silicon bronzes</b>	C87300-C87900	Cu-Zn-Si
<b>Tin bronzes and leaded tin bronzes</b>	C90200-C94500	Cu-Sn-Zn-Pb
<b>Nickel-tin bronzes</b>	C94700-C94900	Cu-Ni-Sn-Zn-Pb
<b>Aluminum bronzes</b>	C95200-C95810	Cu-Al-Fe-Ni
<b>Copper-nickels</b>	C96200-C96800	Cu-Ni-Fe
<b>Nickel silvers</b>	C97300-C97800	Cu-Ni-Zn-Pb-Sn
<b>Leaded coppers</b>	C98200-C98800	Cu-Pb
<b>Special alloys</b>	C99300-C99750	. . .

**Temper Designations.** Copper alloys are also described by their *tempers*, which are terms that define metallurgical condition, heat treatment, and/or casting method. The temper designations for wrought copper and copper alloys were traditionally specified on the basis of cold reduction imparted by rolling or drawing. This scheme related the nominal temper designations to the amount of reduction stated in Brown & Sharpe (B & S) gage numbers for rolled sheet and

drawn wire. Heat-treatable alloys and product forms such as rod, tube, extrusions, and castings were not readily described by this system. To remedy this situation, ASTM B 601, "Standard Practice for Temper Designations for Copper and Copper Alloys--Wrought and Cast," was developed. This standard established an alphanumeric code that can be assigned to each of the standard descriptive temper designations (Table 3).

**Table 3 ASTM B 601 temper designation codes for copper and copper alloys**

Temper designation	Temper name or material condition
Cold-worked tempers <sup>(a)</sup>	
H00	$\frac{1}{8}$ hard
H01	$\frac{1}{4}$ hard
H02	$\frac{1}{2}$ hard
H03	$\frac{3}{4}$ hard
H04	Hard
H06	Extra hard
H08	Spring
H10	Extra spring
H12	Special spring
H13	Ultra spring
H14	Super spring
Cold-worked tempers <sup>(b)</sup>	
H50	Extruded and drawn
H52	Pierced and drawn
H55	Light drawn; light cold rolled

<b>H58</b>	Drawn general purpose
<b>H60</b>	Cold heading; forming
<b>H63</b>	Rivet
<b>H64</b>	Screw
<b>H66</b>	Bolt
<b>H70</b>	Bending
<b>H80</b>	Hard drawn
<b>H85</b>	Medium-hard-drawn electrical wire
<b>H86</b>	Hard-drawn electrical wire
<b>H90</b>	As finned
Cold-worked and stress-relieved tempers	
<b>HR01</b>	H01 and stress relieved
<b>HR02</b>	H02 and stress relieved
<b>HR04</b>	H04 and stress relieved
<b>HR08</b>	H08 and stress relieved
<b>HR10</b>	H10 and stress relieved
<b>HR20</b>	As finned
<b>HR50</b>	Drawn and stress relieved
Cold-rolled and order-strengthened temper <sup>(c)</sup>	
<b>HT04</b>	H04 and order heat treated
<b>HT08</b>	H08 and order heat treated

As-manufactured tempers	
<b>M01</b>	As-sand cast
<b>M02</b>	As-centrifugal cast
<b>M03</b>	As-plaster cast
<b>M04</b>	As-pressure die cast
<b>M05</b>	As-permanent mold cast
<b>M06</b>	As-investment cast
<b>M07</b>	As-continuous cast
<b>M10</b>	As-hot forged and air cooled
<b>M11</b>	As-forged and quenched
<b>M20</b>	As-hot rolled
<b>M30</b>	As-hot extruded
<b>M40</b>	As-hot pierced
<b>M45</b>	As-hot pierced and rerolled
Annealed tempers <sup>(d)</sup>	
<b>O10</b>	Cast and annealed (homogenized)
<b>O11</b>	As-cast and precipitation heat treated
<b>O20</b>	Hot forged and annealed
<b>O25</b>	Hot rolled and annealed
<b>O30</b>	Hot extruded and annealed
<b>O31</b>	Extruded and precipitation heat treated

<b>O40</b>	Hot pierced and annealed
<b>O50</b>	Light annealed
<b>O60</b>	Soft annealed
<b>O61</b>	Annealed
<b>O65</b>	Drawing annealed
<b>O68</b>	Deep-drawing annealed
<b>O70</b>	Dead-soft annealed
<b>O80</b>	Annealed to temper, $\frac{1}{8}$ hard
<b>O81</b>	Annealed to temper, $\frac{1}{4}$ hard
<b>O82</b>	Annealed to temper, $\frac{1}{2}$ hard
Annealed tempers <sup>(e)</sup>	
<b>OS005</b>	Average grain size, 0.005 mm
<b>OS010</b>	Average grain size, 0.010 mm
<b>OS015</b>	Average grain size, 0.015 mm
<b>OS025</b>	Average grain size, 0.025 mm
<b>OS035</b>	Average grain size, 0.035 mm
<b>OS050</b>	Average grain size, 0.050 mm
<b>OS060</b>	Average grain size, 0.060 mm
<b>OS070</b>	Average grain size, 0.070 mm

- (a) Cold-worked tempers to meet standard requirements based on cold rolling or cold drawing.
- (b) Cold-worked tempers to meet standard requirements based on temper names applicable to specific products.
- (c) Tempers produced by controlled amounts of cold work followed by a thermal treatment to produce order strengthening.
- (d) Annealed to meet specific mechanical property requirements.
- (e) Annealed to meet prescribed nominal average grain size.
- (f) Tempers of fully finished tubing that has been drawn or annealed to produce specified mechanical properties or that has been annealed to produce a prescribed nominal average grain size are commonly identified by the appropriate H, O, or OS temper designation.

**International Alloy Designations.** A common designation system used within the International Organization for Standardization (ISO) is a compositional system described in ISO 1190 Part 1, based on the element symbols and the

descending order of magnitude of alloying elements. For example, a leaded brass containing 60% Cu and 2%Pb is designated CuZn38Pb2. Because this system is unwieldy when used to describe complex alloys, a European numbering system has been formulated by the ComitéEuropéen de Normalisation (CEN). CEN/TC 132 describes a six-digit alpha-numerical system. The first letter, "C," indicates a copper alloy. A second letter was introduced to indicate the material state (i.e., W for a wrought material, C for castings, and M for master alloys). Three numbers are then used to identify the material, and a final third letter is used to identify the classification of individual copper material groups and to enlarge the capacity of the designation system. Table 4 shows the preferred number ranges and letters allocated by the CEN numbering system to the different copper alloy groups. Table 5 cross references some ISO and CEN designations.

**Table 4 CEN European numbering system for copper and copper alloys, showing the preferred number ranges and letters allocated to the different material groups**

Introduction and Overview of Copper and Copper Alloys

Wrought Copper Alloys

The purpose of adding alloying elements to copper is to optimize the strength, ductility (formability), and thermal stability, without inducing unacceptable loss in fabricability, electrical/thermal conductivity, or corrosion resistance. Copper alloys show excellent hot and cold ductility, although usually not to the same degree as the unalloyed parent metal. Even alloys with large amounts of solution-hardening elements--zinc, aluminum, tin, and silicon--that show rapid work hardening are readily commercially processed beyond 50% cold work before a softening anneal is required to permit additional processing. The amount of cold working and the annealing parameters must be balanced to control grain size and crystallographic texturing. These two parameters are controlled to provide annealed strip products at finish gage that have the formability needed in the severe forming and deep drawing commonly done in commercial production of copper, brass, and other copper alloy hardware and cylindrical tubular products.

Table 6 lists chemical compositions of wrought coppers and copper alloys. Typical mechanical properties for these materials are given in Table 7.

Table 6 Chemical compositions of wrought copper and copper alloys

Composition values are given as maximum percentages, unless shown as a range or maximum.

Source: Copper Development Association Inc.

- (a) These are high conductivity coppers, which have in the annealed condition a minimum conductivity of 100% IACS.
- (b) Copper is determined by the difference between the impurity total and 100%.
- (c) The following additional maximum limits apply: Bi, 1 ppm (0.0001%); Cd, 1 ppm (0.001%); Fe, 10 ppm (0.0010%); Pb, 5 ppm (0.0005%); Mn, 0.5 ppm (0.00005%); Hg, 1 ppm (0.0001%); Ni, 10 ppm (0.0010%); oxygen, 5 ppm (0.0005%); Se, 3 ppm (0.0003%); Ag, 25 ppm (0.0025%); S, 15 ppm (0.0015%); Sn, 2 ppm (0.0002%); Zn, 1 ppm (0.0001%).
- (d) Includes P.
- (e) The following additional maximum limits apply: Oxygen and trace elements can vary depending on the process.
- (f) Se, 2 ppm (0.0002%); Bi, 1.0 ppm (0.00010%); group total, Te + Se + Bi, 3 ppm (0.0003%). Sn, 5 ppm (0.0005%); Pb, 5 ppm (0.0005%); Fe, 10 ppm (0.0010%); Ni, 10 ppm (0.0010%); S, 15 ppm (0.0015%); Ag, 25 ppm (0.0025%); oxygen, 100-650 ppm (0.010-0.065%). The total maximum allowable of 65 ppm (0.0065%) does not include oxygen.
- (g) Small amounts of Cd or other elements can be added by agreement to improve the resistance to softening at elevated temperatures.
- (h) Includes B + P.
- (i) This includes oxygen-free copper, which contains P in an agreed-upon amount.
- (j) Includes Te + Se.
- (k) Includes Cd. Deoxidized with lithium or other suitable agreed-upon elements.
- (l) Includes Cu + Ag + Sn.
- (m) Includes Te.

- (n) Includes oxygen-free or deoxidized grades with deoxidizers (such as phosphorus, boron, lithium, or other) in an agreed-upon amount.
- (o) All aluminum present as  $\text{Al}_2\text{O}_3$ ; 0.04% oxygen present as  $\text{Cu}_2\text{O}$  with a negligible amount in solid solution with copper.
- (p) Cu + sum of named elements, 99.5% min.
- (q) Ni + Co, 0.20% min; Ni + Fe + Co, 0.6% max.
- (r) Includes Co.
- (s) Cu + sum of named elements, 99.9% min.
- (t) Cu + sum of named elements, 99.8% min.
- (u) Cu + sum of named elements, 99.7% min.
- (v) Cu + sum of named elements, 99.6% min.
- (w) For tube over 5 in. outside diameter, the Pb can be <0.20%.
- (x) For flat products, the iron is 0.10% max.
- (y) Cu, 61.0% min for rod.
- (z) Pb can be reduced to 1.0% by agreement.
- (aa) For tubular products, the minimum Sn content can be 0.9%.
- (bb) Cu + Sn + Fe + P, 99.5% min.
- (cc) Cu + sum of named elements, 99.85% min.
- (dd) When the product is for subsequent welding applications and is so specified by the purchaser, Cr, Cd, Zr, and Zn will each be 0.05% max.
- (ee) Fe content shall not exceed Ni content.
- (ff) Not including Co.

(gg) Fe + Co, 1.8-2.3%.

(hh) Al + Zn, 25.1-27.1%.

(ii) The following additional maximum limits apply: When the product is for subsequent welding applications and is so specified by the purchaser, 0.50% Zn, 0.02% P, 0.02% Pb, 0.02% S (0.008% S for C71110), and 0.05% C.

(jj) The following additional maximum limits apply: 0.02% C, 0.015% Si, 0.003% S, 0.002% Al, 0.001% P, 0.0005%Hg, 0.001% Ti, 0.001% Sb, 0.001% As, 0.001% Bi, 0.05% Co, 0.10% Mg, and 0.005%oxygen. For C70690, Co will be 0.02% max.

(kk) The following maximum limits apply: 0.07% C, 0.15% Si, 0.024% S, 0.05%Al, and 0.03% P.

(ll) 0.02% P, max;0.25% Si, max; 0.01% S, max; 0.20-0.50% Ti.

(mm) 0.005% Pb, max, for hot rolling.

(nn) 0.05% Pb, max, for rod and wire.

(a) F, flat products; R, rod; W, wire; T, tube; P, pipe; S, shapes.

(b) Ranges are from softest to hardest commercial forms. The strength of the standard copper alloys depends on the temper (annealed grain size or degree of cold work) and the section thickness of the mill product. Ranges cover standard tempers for each alloy.

(c) Based on 100% for C36000.

(d) Values are for as-hot-rolled material.

(e) Values are for as-extruded material.

## Types

**The pure copper alloys**, also called the coppers (C10100 to C15900), are melted and cast in inert atmosphere from the highest-purity copper in order to maintain high-electrical conductivity(oxygen-free, or OF, copper, C10200). Copper is more commonly cast with a controlled oxygen content (0.04% O as in electrolytic tough pitch, or ETP, copper, C11000) to refine out impurity elements from solution by oxidation. Included in this group are the alloys that are deoxidized with small addition of various elements such as phosphorus (C12200, or Cu-0.03P) and the alloys that use minor amounts of alloy additions to greatly improve softening resistance, such as the silver-bearing copper alloys (C10500, Cu-0.034 min Ag) and the zirconium-bearing alloys (C15000 and C15100, Cu-0.1Zr).

**High-copper alloys** (C16000 to C19900) are designed to maintain high conductivity while using dispersions and precipitates to increase strength and soften resistance: iron dispersions in Cu-(1.0-2.5)Fe alloys (C19200, C19400),

chromium precipitates in Cu-1Cr (C18200), and the coherent precipitates in the Cu-(0.3-2.0)Be-Co,Ni age-hardening alloys (C17200, C17410, and C17500).

**Brass alloys** are a rather large family of copper-zinc alloys. A significant number of these are binary copper-zinc alloys (C20500 to C28000), utilizing the extensive region of solid solution up to 35% Zn, offering excellent formability with good work-hardening strength at reasonable cost. (These alloys are commonly referred to as alpha brasses.) The alloys below 15% Zn have good corrosion and stress-corrosion resistance. Alloys above 15% Zn need a stress-relieving heat treatment to avoid stress corrosion and, under certain conditions, can be susceptible to dezincification. Alloys at the higher zinc levels of 35 to 40% Zn contain the body-centered cubic (bcc) beta phase, especially at elevated temperatures, making them hot extrudeable and forgeable (alloy C28000 with Cu-40Zn, for example). The beta alloys are also capable of being hot worked while containing additions of 1 to 4% Pb, or more recently bismuth, elements added to provide the dispersion of coarse particles that promote excellent machinability characteristics available with various commercial Cu-Zn-Pb alloys (C31200 to C38500). The tin brasses (C40400 to C49000) contain various tin additions from 0.3 to 3.0% to enhance corrosion resistance and strength in brass alloys. Besides improving corrosion-resistance properties in copper-zinc tube alloys, such as C44300 (Cu-30Zn-1Sn), the tin addition also provides for good combinations of strength, formability, and electrical conductivity required by various electrical connectors, such as C42500 (Cu-10Zn-2Sn). A set of miscellaneous copper-zinc alloys (C66400 to C69900) provide improved strength and corrosion resistance through solution hardening with aluminum, silicon, and manganese, as well as dispersion hardening with iron additions.

**Bronze alloys** consist of several families named for the principal solid-solution alloying element. The familiar tin bronzes (C50100 to C54400) comprise a set of good work-hardening, solid-solution alloys containing from nominally 0.8% Sn (C50100) to 10% Sn (C52400), usually with a small addition of phosphorus for deoxidation. These alloys provide an excellent combination of strength, formability, softening resistance, electrical conductivity, and corrosion resistance. The aluminum-bronze alloys contain 2 to 15% Al (C60800 to C64200), an element adding good solid-solution strengthening and work hardening, as well as corrosion resistance. The aluminum-bronzes usually contain 1 to 5% Fe, providing elemental dispersions to promote dispersion strengthening and grain size control. The silicon-bronze alloys (C64700 to C66100) generally offer good strength through solution- and work-hardening characteristics, enhanced in some cases with a tin addition, as well as excellent resistance to stress corrosion and general corrosion.

**Cupronickels** are copper-nickel alloys (C70100 to C72900) that utilize the complete solid solubility that copper has for nickel to provide a range of single-phase alloys (C70600 with Cu-10Ni-1.5Fe, and C71500 with Cu-30Ni-0.8Fe, for example) that offer excellent corrosion resistance and strength. The family of copper-nickel alloys also includes various dispersion- and precipitation-hardening alloys due to the formation of hardening phases with third elements, such as Ni<sub>2</sub>Si in C70250 (Cu-3Ni-0.7Si-0.15Mg) and the spinodal hardening obtainable in the Cu-Ni-Sn alloys (C72700 with Cu-10Ni-8Sn, for example).

**Copper-nickel-zinc alloys**, also called nickel-silvers, are a family of solid-solution-strengthening and work-hardening alloys with various nickel-zinc levels in the Cu-(4-26)Ni-(3-30)Zn ternary alloy system valued for their strength, formability, and corrosion and tarnish resistance, and for some applications, metallic white color.

### ***Strengthening Mechanisms for Wrought Copper Alloys***

**Solution Hardening.** Copper can be hardened by the various common methods without unduly impairing ductility or electrical conductivity. The metallurgy of copper alloys is suited for using, singly or in combination, the various common strengthening mechanisms: solid solution and work hardening, as well as dispersed particle and precipitation hardening. The commonly used solid-solution hardening elements are zinc, nickel, manganese, aluminum, tin, and silicon, listed in approximate order of increasing effectiveness. Commercial alloys represent the entire range of available solid-solution compositions of each element up to 35% Zn, and up to (and even beyond) 50% Ni, 50% Mn, 9% Al, 11% Sn, and 4% Si. The relative amount of solution strengthening obtained from each element or particular combination of elements is determined by the ability of the solute to interfere with dislocation motion and is reflected in the work-hardening rate starting with the annealed condition, as illustrated by the increase in tensile strength with cold work shown in Fig. 3.

**Fig. 3** Tensile strength of single-phase copper alloys as affected by percentage reduction in thickness by rolling (temper). Curves of lesser slope indicate a low rate of work hardening and a higher capacity for redrawing. ETP, electrolytic tough pitch

**Work hardening** is the principal hardening mechanism applied to most copper alloys, the degree of which depends on the type and amount of alloying element and whether the alloying element remains in solid solution or forms a dispersoid or precipitate phase. Even those alloys that are commercially age hardenable are often provided in the mill hardened tempers; that is, they have been processed with cold work preceding and/or following an age-hardening heat treatment. For the leaner alloys (below  $\sim 12\% \text{Zn}$ , or  $\sim 3\% \text{Al}$ , for example), processing generates dislocations that develop into entanglements and into cells, with some narrow shear band formation beyond  $\sim 65\%$  cold reduction in thickness. After  $\sim 90\%$  cold work, the distinct "copper" or "metal" deformation crystallographic texture begins to develop. With the richer solid-solution alloys that lower the stacking-fault energy, planar slip is the dominant dislocation mechanism, with associated higher work hardening. Beyond  $\sim 40\%$  cold work in these richer alloys, stacking faults, shear banding, and deformation twinning become important deformation mechanisms that, beyond  $90\%$  cold work, lead to the "brass" or "alloy" type of crystallographic deformation texture and accompanying anisotropy of properties. Figure 4 shows the variation in tensile properties with cold working of an annealed Cu-30Zn alloy (C26000). The degree of work hardening seen with cold working several selected single-phase copper alloys is illustrated by the cold-rolling curves in Fig. 3. Many copper alloys are used in wrought forms in a worked temper, chosen for the desired combination of work-hardened strength and formability, either for direct use in service or for subsequent component fabrication.

**Fig. 4** The effect of cold rolling on the strength, hardness, and ductility of annealed copper alloy C26000 when it is cold rolled in varying amount up to 62% reduction in thickness.

**Dispersion strengthening** is used in copper alloys for hardening, controlling grain size, and providing softening resistance, as exemplified by iron particles in copper-iron alloys, C19200 or C19400, and in aluminum bronzes, C61300 or C63380. Cobalt silicide particles in alloy C63800 (Cu-2.8Al-1.8Si-0.4Co), for example, provide fine-grain control and dispersion hardening to give this alloy high strength with reasonably good formability. Alloy C63800 offers an annealed tensile strength of 570 MPa (82 ksi) and rolled temper tensile strengths of 660 to 900 MPa (96 to 130 ksi). Alloys offering exceptionally good thermal stability have been developed using powder metallurgy (P/M) techniques to incorporate dispersions of fine  $\text{Al}_2\text{O}_3$  particles (3 to 12 nm in size) in a basic copper matrix, which is finish processed to rod, wire, or strip products. This family of alloys, C15715 to C15760, can resist softening up to and above 800 °C(1472 °F). More detailed information on oxide-dispersion-strengthened copper alloys is found in the article "Copper Powder Metallurgy Products" in this Section.

**Precipitation Hardening.** Age-hardening mechanisms are used in those few but important copper systems that offer a decreasing solubility for hardening phases. The beryllium-copper system offers a series of wrought and cast age-hardening alloys, UNS C17000 to C17530 and C82000 to C82800. The wrought alloys contain 0.2 to 2.0% Be and 0.3 to 2.7%Co (or up to 2.2% Ni). They are solution heat treated in the 760 to 955 °C(1400 to 1750 °F) range and age hardened to produce the beryllium-rich coherent precipitates when aged in the 260 to 565 °C (500 to 1050 °F)range, with the specific temperature being chosen for the particular alloy and desired property combination (Fig. 5). The precipitation sequence during aging consists of the formation of solute-rich G-P zones, followed in sequence by coherent platelets of the metastable intermediate phases  $\gamma'$  and  $\gamma''$ . Overaging is marked by the appearance of the B2 ordered equilibrium  $\gamma$ -BeCu phase as particles within grains and along grain boundaries, large enough to be seen in the light microscope. The cobalt and nickel additions form dispersoids of equilibrium (Cu, Co, or Ni)Be that restrict grain growth during solution annealing in the two-phase field at elevated temperatures (Fig. 5b). A cold-working step following solution annealing is often used to increase the age-hardening response. Alloy C17200 (Cu-1.8Be-0.4Co), for example, can be processed to reach high strength; that is, tensile strengths after solutionization (470 MPa, or 68 ksi), after cold rolling to the hard temper (755 MPa, or 110 ksi) and after aging (1415 MPa, or 205 ksi). While they are commercially available in the heat-treatable (solutionized) condition, the beryllium-copper alloys are commonly provided in the mill-hardened temper with the optimal strength/ductility/conductivity combination suitable for the application.

**Fig. 5** Phase diagrams for beryllium-copper alloys. (a) Binary composition for high-strength alloys such as C17200. (b) Pseudobinary composition for C17510, a high-conductivity alloy

Other age-hardening copper alloys include the chromium coppers, which contain 0.4 to 1.2% Cr (C18100, C18200, and C18400); these alloys produce arrays of pure chromium precipitates and dispersoid particles when aged. The Cu-Ni-Si alloys, C64700 and C70250, age harden by precipitating the  $\text{Ni}_2\text{Si}$  intermetallic phase. Compositions in the Cu-Ni-Sn

system, C71900 and C72700, are hardenable by spinodal decomposition, a mechanism that provides high strength and good ductility through the formation of a periodic array of coherent, fcc solid-solution phases that require the electron microscope to be seen. Each of these alloys, including the beryllium-coppers can be thermomechanically processed to provide unique combinations of strength, formability, electrical conductivity, softening resistance, and stress-relaxation resistance.

## Copper Casting Alloys

The copper casting alloys are generally similar to the wrought counterparts, but they do offer their own unique composition/property characteristics. For example, they do offer the opportunity to add lead to levels of 25% that could not be easily made by wrought techniques in order to provide compositions in which dispersions of lead particles are useful for preventing galling in bearing applications. The copper casting alloys are used for their corrosion resistance and their high-thermal and electrical conductivity. The most common alloys are the general-purpose Cu-5Sn-5Pb-5Zn alloy (C83600), used for valves and plumbing hardware, and C84400, widely used for cast plumbing system components. C83600 contains lead particles dispersed around the single-phase matrix and offers good machinability, with moderate levels of corrosion resistance, tensile strength (240 MPa, or 35 ksi), ductility, and conductivity (15% IACS).

While the Cu-Sn-PB-(and/or Zn) casting alloys have only moderate strength, the cast manganese and aluminum bronzes offer higher tensile strengths, 450 to 900 MPa (65 to 130 ksi). As with the wrought alloys, the cast aluminum-bronze alloys commonly contain an iron addition (0.8 to 5.0%) to provide iron-rich particles for grain refinement and added strength. In addition, at aluminum levels in the 9.5 to 10.5% range (or 8.0 to 9.5% Al with nickel or manganese additions) the alloys are heat treatable for added strength. Depending on the section thickness and cooling rate of the casting, as well as the alloy composition and heat treatments, the microstructures can be rather complex. The aluminum-bronzes can be annealed completely or partially in the  $\beta$  field and quenched to form  $\beta$  martensite with  $\alpha$  needles. Aging these alloys will temper the martensite by precipitation fine  $\alpha$  needles. One of the aluminum-bronze alloys, Cu-10.5Al-5Fe-5Ni, for example, is used for the combination of high strength and good corrosion resistance. Through heat treatment, the intermetallic  $\kappa$ -phase, with a complex composition (iron, nickel, copper) aluminum and CsCl crystal structure, provides a strengthening component in any of the morphologies: as globular particles, fine precipitates, or as a component of cellular eutectoid colonies.

Table 8 lists the chemical compositions, uses, and characteristics of copper alloy castings. Additional information, including mechanical property data, is found in the article "Copper Alloy Castings" in this Section.

### Table 8 Compositions, uses, and characteristics of copper alloy castings

UNS No.	Other designations, descriptive names (former SAE No.)	Applicable casting processes <sup>(a)</sup>	Composition <sup>(b)</sup> , wt%

Manganese bronze and leaded manganese bronze alloys (high strength and leaded high strength yellow brasses):Alloys with high mechanical strength, good corrosion resistance and favorable castability. Can be machined, but with the exception of C86400 and C86700, are less readily machined than leaded compositions. Alloy C86300 can attain tensile strengths exceeding 115 ksi (793 MPa). Used for mechanical devices:gears, levers, brackets, and valve and pump components for fresh and seawater service. When used for high strength bearings, alloys C86300 and C86400 require hardened shafts.

Copper-tin-lead alloys (high leaded tin bronzes): <b>Most commonly used bearing alloys, found in bearings operating at moderate-to-high speeds, as in electric motors and appliances. Alloy C93200 is considered the workhorse alloy of the series. Alloy C93600 has improved machining and anti-seizing properties. C93800 noted for good corrosion resistance against concentrations of sulfuric acid below 78%. Alloy C94100 is especially good under boundary lubricated conditions.</b>

Copper-aluminum-iron and copper-aluminum-iron-nickel alloys (aluminum bronzes): <b>The aluminum bronzes are characterized by high strength and excellent corrosion resistance. Alloys containing more than 9.5% Al can be heat treated, some to tensile strengths exceeding 120 ksi (827 MPa). Uses include a variety of heavy duty mechanical and structural products including gears, worm drives, valve guides, and seats. Excellent heavy duty bearing alloys, but do not tolerate misalignment or dirty lubricants, and generally should be used against hardened steel shafts, with both shaft and bearing machined to fine surface finishes.</b>

# Copper Tubular Products

## Introduction

TUBE AND PIPE made of copper or copper alloys are used extensively for carrying potable water in buildings and homes. These products also are used throughout the oil, chemical, and process industries to carry diverse fluids, ranging from various natural and process waters, to seawater, to an extremely broad range of strong and dilute organic and inorganic chemicals. In the automotive and aerospace industries, copper tube is used for hydraulic lines, heat exchangers (such as automotive radiators), air conditioning systems, and various formed or machined fittings. In marine service, copper tube and pipe are used to carry potable water, seawater, and other fluids, but their chief application is in tube bundles for condensers, economizers, and auxiliary heat exchangers. Copper tube and pipe are used in food and beverage industries to carry process fluids for beet and cane sugar refining, for brewing of beer, and for many other food-processing operations. In the building trades, copper tube is used widely for heating and air conditioning systems in homes, commercial buildings, and industrial plants and offices. Table 1 summarizes selected copper alloys that are standard tube alloys, and gives ASTM specifications and typical uses for each of the alloys.

Table 1 Copper tube alloys and typical applications

UNS No.	Alloy type	ASTM specifications	Type uses
C10200	Oxygen-free copper	B 68, B 75, B 88, B 111, B 188, B 280, B 359, B 372, B 395, B 447	Bus tube, conductors, wave guides
C12200	Phosphorus deoxidized copper	B 68, B 75, B 88, B 111, B 280, B 306, B 359, B 360, B 395, B 447, B 543	Water tubes; condenser, evaporator and heat-exchanger tubes; air conditioning and refrigeration, gas, heater and oil burner lines; plumbing pipe and steam tubes; brewery and distillery tubes; gasoline, hydraulic and oil lines; rotating heads
C19200	Copper	B 111, B 359, B 395, B 469	Automotive hydraulic brake lines; flexible hose
C23000	Red brass, 85%	B 111, B 135, B 359, B 395, B 543	Condenser and heat-exchanger tubes, flexible hose; plumbing pipe; pump lines
C26000	Cartridge brass, 70%	B 135	Plumbing brass goods

<b>C33000</b>	Low-leaded brass (tube)	B 135	Pump and power cylinders and liners; plumbing brass goods
<b>C36000</b>	Free-cutting brass	. . .	Screw machine parts; plumbing goods
<b>C43500</b>	Tin brass	. . .	Bourdon tubes; musical instruments
<b>C44300, C4400, and C44500</b>	Inhibited admiralty metal	B 111, B 359, B 395	Condenser, evaporator, and heat-exchanger tubes; distiller tubes
<b>C 46400, C46500, C46600, and C46700</b>	Naval brass	. . .	Marine hardware, nuts
<b>C60800</b>	Aluminum bronze, 5%	B 111, B 359, B 395	Condenser, evaporator and heat-exchanger tubes; distiller tubes
<b>C65100</b>	Silicon bronze B	B 315	Heat-exchanger tubes; electrical conduits
<b>C65500</b>	Silicon bronze A	B 315	Chemical equipment, heat-exchanger tubes; piston rings
<b>C68700</b>	Arsenical aluminum brass	B 111, B 359, B 395	Condenser, evaporator and heat-exchanger tubes; distiller tubes
<b>C70600</b>	Copper-nickel, 10%	B 111, B 359, B 395, B 466, B 467, B 543, B 552	Condenser, evaporator and heat-exchanger tubes; salt water piping; distiller tubes
<b>C71500</b>	Copper-nickel, 30%	B 111, B 359, B 395, B 446, B 467, B543, B552	Condenser, evaporator and heat-exchanger tubes; distiller tubes; salt water piping

Frequently, resistance to corrosion is a critical factor in selecting a tube alloy for a specific application. Information that can help determine the alloy(s) most suitable for a given type of service is found in the article "Corrosion Characteristics of Copper and Copper Alloys" in this Section.

**Joints** in copper tube and pipe are made in various ways. Permanent joints can be made by brazing or welding. Semipermanent joints are made most often by soldering, usually in conjunction with standard socket-type solder fittings, but threaded joints also can be considered semipermanent joints for pipe. Detachable joints are almost always some form of mechanical joint--flared joints, flange-and-gasket joints, and joints made using any of a wide variety of specially designed compression fittings are all common.

**Properties of Tube.** As with most wrought products, the mechanical properties of copper tube depend on prior processing. With copper, it is not so much the methods used to produce tube, but rather the resulting metallurgical condition that has the greatest bearing on properties. Table 2 summarizes tensile properties for selected tube alloys in their most widely used conditions.

## Production of Tube Shells

Copper tubular products are typically produced from shells made by extruding or piercing copper billets.

**Extrusion** of copper and copper alloy tube shells is done by heating a billet of material above the recrystallization temperature, and then forcing material through an orifice in a die and over a mandrel held in position with the die orifice. The clearance between mandrel and die determines the wall thickness of the extruded tube shell.

In extrusion, the die is located at one end of the container section of an extrusion press; the metal to be extruded is driven through the die by a ram, which centers the container from the end opposite the die. Tube shells are produced either by starting with a hollow billet or by a two-step operation in which a solid billet is first pierced and then extruded.

Extrusion pressure varies with alloy composition. C36000 (61.5Cu-3Pb-35.5Zn) requires a relatively low pressure, whereas C26000 (70Cu-30Zn) and C44300 (71.5Cu-1Sn-27.5Zn-0.06As) require the highest pressure of all brasses. Most of the coppers require an extrusion pressure intermediate between those for C26000 and C36000. C71500 (70Cu-30Ni) requires a very high extrusion pressure.

Extrusion pressure also depends on billet temperature, extrusion ratio (the ratio of the cross-sectional area of the billet to that of the extruded section), speed of extrusion, and degree of lubrication. The flow of metal during extrusion depends on many factors, including copper content of the metal, amount of lubricant, and die design.

**Rotary piercing** on a Mannesmann mill is another method commonly used to produce seamless pipe and tube from copper and certain copper alloys. Piercing is the most severe forming operation customarily applied to metals. The process takes advantage of tensile stresses that develop the center of a billet when it is subjected to compressive forces around the periphery. In rotary piercing, one end of a heated cylindrical billet is fed between rotating work rolls that lie in a horizontal plane and are inclined at an angle to the axis of the billet (Fig. 1). Guide rolls beneath the billet prevent it from dropping from between the work rolls. Because the work rolls are set at an angle to each other as well as to the billet, the billet is simultaneously rotated and driven forward toward the piercing plug, which is held in position between the work rolls.

**Fig. 1** Schematic diagram of metal piercing. Arrows indicate direction of motion.

The opening between work rolls is set smaller than the billet, and the resultant pressure acting around the periphery of the billet opens up tensile cracks, and then a rough hole, at the center of the billet just in front of the piercing plug. The piercing plug assists in further opening the axial hole in the center of the billet, smooths the wall of the hole, and controls the wall thickness of the formed tube.

Coppers and plain alpha brasses can be pierced, provided the lead content is held to <0.01%. Alpha-beta brasses can tolerate higher levels of lead without adversely affecting their ability to be pierced.

When piercing brass, close temperature control must be maintained because the range in which brass can be pierced is narrow. Each alloy has a characteristic temperature range within which it is sufficiently plastic for piercing to occur. Below this range, the central hole does not open up properly under the applied peripheral forces. Overheating can lead to cracked surfaces. Suggested piercing temperatures for various alloys are given in the following table:

UNS number	Piercing temperature	
	°C	°F
<b>C11000</b>	815-870	1500-1600
<b>C12200</b>	815-870	1500-1600
<b>C22000</b>	815-870	1500-1600

<b>C23000</b>	815-870	1500-1600
<b>C26000</b>	760-790	1400-1450
<b>C28000</b>	705-760	1300-1400
<b>C46400</b>	730-790	1350-1450

## Production of Finished Tubes

**Welded tube** is made from clean strip in either cold-rolled or annealed tempers. The strip is formed into a tubular shape on a precision forming mill.

For forge-welded tube, the edges of the strip are heated to the required welding temperature, usually by high-frequency electric current, and are pressed firmly together causing a forge-type joint to be formed with internal and external flash or bead. The external flash is always removed, providing a smooth external surface. The internal flash is also removed by scarfing, providing a smooth, clean internal surface.

For fusion-welded tube, the edges of the strip are brought together and welded, usually by a gas tungsten arc welding process, without the addition of filler metal, causing a fusion-type joint to be formed with no internal or external flash or bead.

Welded tube can be used in the as-welded condition or, subsequent to welding, can be further processed by the standard cold drawing, reducing, and annealing processes.

**Cold drawing** of extruded or pierced tube shells to smaller sizes is done on draw blocks for coppers and on draw benches for brasses and other alloys. With either type of machine, the metal is cold worked by pulling the tube through a die that reduces the diameter. Concurrently, wall thickness is reduced by drawing over a plug or mandrel that can be either fixed or floating. Cold drawing increases the strength of the material and simultaneously reduces ductility. Tube size is reduced--outside diameter, inside diameter, wall thickness, and cross-sectional area all are smaller after drawing. Because the metal work hardens, tubes can be annealed at intermediate stages when drawing to small sizes. However, coppers are so ductile that they frequently can be drawn to finished size without intermediate annealing.

**Tube reducing** is an alternative process for cold sizing of the tube. In tube reducing, semicircular grooved dies are rolled or rocked back and forth along the tube while a tapered mandrel inside the tube controls the inside diameter and wall thickness. The process yields tube having very accurate dimensions and better concentricity than can be achieved by tube drawing.

The grooves in the tube-reducing dies are tapered, with one end of the grooved section being somewhat larger than the outside diameter of the tube to be sized. As the dies are rocked, the tube is pinched against the tapered mandrel, which reduces wall thickness and increases tube length. The tube is fed longitudinally, and rotated on its axis to distribute the cold work uniformly around the circumference. Feeding and rotating are synchronized with die motion and occur after the dies have completed their forward stroke.

Tube reducing can be used for all alloys that can be drawn on draw benches. Slight changes in die design and operating conditions may be required to accommodate different alloys. Small-diameter tube may be produced by block or bench drawing following tube reducing.

## Product Specifications

Copper tube and pipe are available in a wide variety of nominal diameters and wall thicknesses, from small-diameter capillary tube to 300 mm (12 in.) nominal-diameter pipe. To a certain extent, dimensions and tolerances for copper tube and pipe depend on the type of service for which they are intended. The standard dimensions and tolerances for several

kinds of copper tube and pipe are given in the ASTM specifications listed in Table 3, along with other requirements for the tubular products. Seamless copper tube for automotive applications ( $\frac{1}{8}$  to  $\frac{3}{4}$  in. in nominal diameter) is covered by SAE J528. Requirements for copper tube and pipe to be used in condensers, heat exchangers, economizers, and similar unfired pressure vessels are also given in the ASME specifications listed in Table 3. (ASME materials specifications are almost always identical to ASTM specifications having the same numerical designation; for example, ASME SB111 is identical to ASTM B 111.) Certain tube alloys are covered in AMS specifications, which apply to materials for aerospace applications. Typical examples include:

AMS specification	Product	Copper alloy
<b>4555</b>	Seamless brass tube, light annealed	C26000 C33000
<b>4558</b>	Seamless brass tube drawn	C33200

# Copper Wire and Cable

## Introduction

WIRE made from copper and copper alloys has been used since about 2000 to 3000 B.C. According to archaeological evidence, the ancient Assyrians, Babylonians, and Egyptians were skilled in producing copper wire for ornamental purposes. Drawing wire through a die is a much more modern development. Development of wiredrawing processes during the Middle Ages concentrated to a large extent on drawing iron and steel wires to make pins and instrument strings. But with the invention of the electric telegraph in 1847 came the requirement for long continuous lengths of electric conductor wire made of copper. In 1850, copper wire was used to make a submarine cable connecting England and France.

At the beginning of the twentieth century, wire was still being drawn through single dies--a process commonly known as "bull-block" drawing. Dies were made by punching a series of holes in a steel plate.

Multiple wiredrawing machines were introduced around 1900. As a result, chilled cast iron plates and dies that could be reamed to size replaced the punch-sized, steel-plate dies. Lubricants were introduced because of the considerable heat

generated by friction between the wire-and-draw capstan and by successive reductions through progressively smaller dies. In turn, use of lubricants permitted wire to be drawn at faster speeds.

The prime development during the 1920s was the introduction of drawing dies made of tungsten carbide. High hardness and lack of porosity make tungsten carbide dies ideal for high-speed wire-drawing. Tungsten carbide dies are standard today. For very fine wire sizes, below ~1.6 mm (0.064 in.), diamond dies are used.

### Classification of Copper for Conductors

Copper metals used for electrical conductors fall into three general categories: high-conductivity coppers, high-copper alloys, and electrical bronzes.

High-conductivity coppers are covered by ASTM specifications B 4, B 5, B 170, B 442, and B 623. ASTM B 4 covers both high-resistance lake copper and low-resistance lake copper. Lake copper is fire refined from local Lake Superior ore deposits. ASTM B 5 covers copper electrolytically refined from blister copper, converter copper, black copper, or lake copper. ASTM B 170 covers oxygen-free electrical copper.

Some specialty coppers are produced by adding minimal amounts of hardening agents (such as chromium, tellurium, beryllium, cadmium, or zirconium). These are used in applications where high-anneal resistance is required.

A series of bronzes have been developed for use as conductors; these alloys are covered by ASTM B 105. These bronzes are intended to provide better corrosion resistance and higher tensile strengths than standard conductor coppers.

### Classification of Wire and Cable

**Round Wire.** Standard nominal diameters and cross-sectional areas of solid round copper wires used as electrical conductors are prescribed in ASTM B 258. Wire sizes have almost always been designated in the American Wire Gauge (AWG) system. This system is based on fixed diameters for two wire sizes (4/0 and 36 AWG, respectively) with a geometric progression of wire diameters for the thirty-eight intermediate gages and for gages smaller than 36 AWG (see Table 1). This is an inverse series in which a high number denotes a smaller wire diameter. Each increase of one AWG number is approximately equivalent to a 20.7% reduction in cross-sectional area.

**Table 1 Sizes of round wire in the American Wire Gauge (AWG) system and the properties of solid annealed copper wire (ASTM B 3)**

Conductor AWG	size,	Conductor diameter		Conductor area at 20 °C (68 °F)		Annealed copper (ASTM B 3)

(a) Based on a density of 8.89 g/cm<sup>3</sup> at 20 °C (68 °F).

(b) Minimum elongation in 250 mm (10 in.).

(c) Based on a resistivity value of 0.017241  $\Omega \cdot \text{mm}^2/\text{m}$  ( $875 \cdot 20 \Omega \cdot \text{lb}/\text{mile}^2$ ), which is the resistivity for the International Annealed Copper Standard (IACS) of electrical conductivity.

(d) Elongation not specified in ASTM B 3

Hard-drawn copper wire and hard-drawn copper alloy wire for electrical purposes are specified in ASTM B 1 and B 105, respectively. ASTM B 3 specifies soft (or annealed) copper wire. Tables 1 and 2 give the sizes and properties of wire specified in ASTM B 1, B 3, and B 105.

Table 2 Tensile properties of hard-drawn copper and copper alloy round wire

Conductor size, AWG	Hard-drawn copper wire (ASTM B 1)					Minimum tensile strength of hard-drawn copper alloy wire (ASTM B 105)												ASTM B 105 minimum elongation, %

(a) Tensile strengths cannot always be met if wire is drawn into coils of less than 480 mm (19 in.).

(b) Elongation in 250 mm (10 in.)

**Square and Rectangular Wire.** ASTM B 48 specifies soft (annealed) square and rectangular copper wire.

**Stranded wire** is normally used in electrical applications where some degree of flexing is encountered either in service or during installation. In order of increasing flexibility, the common forms of stranded wire are concentric lay, unilay, rope lay, and bunched.

Concentric-lay stranded wire and cable are composed of a central wire surrounded by one or more layers of helically laid wires, with the direction of lay reversed in successive layers, and with the length of lay increased for each successive layer. The outer layer usually has a left-hand lay.

ASTM B 8 establishes five classes of concentric-lay stranded wire and cable, from AA (the coarsest) to D (the finest). Table 3 gives details of concentric-lay constructions.

**Table 3 Characteristics of concentric-lay stranded copper conductors specified in ASTM B 8**

Conductor size, circular mils or AWG	Nominal weight, lb/1000 ft <sup>(a)</sup>	Nominal resistance, $\Omega$ /1000 ft <sup>(a)</sup>	Class AA		Class A		Class B		Class C		Class D	
			Number of wires	Diameter of individual wires, mils <sup>(a)</sup>	Number of wires	Diameter of individual wires, mils <sup>(a)</sup>	Number of wires	Diameter of individual wires, mils <sup>(a)</sup>	Number of wires	Diameter of individual wires, mils <sup>(a)</sup>	Number of wires	Diameter of individual wires, mils <sup>(a)</sup>

Nominal resistance is for uncoated wire.

(a) Units used in ASTM B 8 specification

Unilay stranded wire is composed of a central core surrounded by more than one layer of helically laid wires, all layers having a common lay length and direction. This type of wire sometimes is referred to as "smooth bunch". The layers usually have a left-hand lay.

Rope-lay stranded wire and cable are composed of a stranded member (or members) as a central core, around which are laid one or more helical layers of similar stranded members. The members can be concentric or bunch stranded. ASTM B 173 and B 172 establish five classes of rope-lay stranded conductors: classes G and H, which have concentric members and classes I, K, and M, which have bunched members. Tables 4 and 5 show construction details. These cables are normally used to make large, flexible conductors for portable service, such as mining cable or apparatus cable.

**Table 4 Characteristics of rope-lay stranded copper conductors having uncoated or tinned concentric members specified in ASTM B 173**

Bunch stranded wire is composed of any number of wires twisted together in the same direction without regard to geometric arrangement of the individual strands. ASTM B 174 provides for five classes (I, J, K, L, and M); these conductors are commonly used in flexible cords, hookup wires, and special flexible welding conductors. Table 6 gives typical construction details.

**Table 6 Characteristics of bunch stranded copper conductors having uncoated or tinned members specified in ASTM B 174**

**Tin-Coated Wire.** Solid and stranded wires are available with tin coatings. These are manufactured to the latest revisions of ASTM B 33, which covers soft or annealed tinned-copper wires, and B 246, which covers hard-drawn or medium-hard-drawn tinned-copper wires. Table 7 gives characteristics of tinned, round, solid wire.

**Table 7 Characteristics of tinned solid round copper wire specified in ASTM B 33, B 246, and B 258**

(a) In 250 mm (10 in.)

## Fabrication of Wire Rod

Wire rod is the intermediate product in the manufacture of wire. Although wire rod is the term used in the U.S. for the intermediate product, the term drawing stock is used in international standards and customs documents.

**Rolling.** The traditional process for converting prime copper into wire rod involves hot rolling of cast wirebar. Almost all drawing stock is rolled to 8 mm (0.32 in.) diameter. Larger sizes, up to 22 mm (0.87 in.) or more in diameter, are available on special order.

Some special oxygen-free copper wirebar is produced by vertical casting, but most wirebar is produced by horizontal casting of tough-pitch copper into open molds. The oxygen content is controlled at 0.03 to 0.06% to give a level surface. Cast wirebars weigh  $\sim 110$  to 135 kg (250 to 300 lb) each. The ends are tapered to facilitate entry into the first pass of the hot rolling mill.

Prior to rolling, bars are heated to  $\sim 925$  °C (1700 °F) in a neutral atmosphere and then rolled on a continuous mill through a series of reductions to yield round rod  $\sim 6$  to 22 mm ( $\frac{1}{4}$  to  $\frac{7}{8}$  in.) in diameter. The hot-rolled rod is coiled, water quenched, and then pickled to remove the black cupric oxide that forms during rolling. This method can produce rod at rates up to 7.5 kg/s (30 tons/h).

Disadvantages of this process include:

- High capital investment to achieve low operating cost
- Relatively small coils that must be welded together for efficient production, where the welded junctions present potential sources of weakness in subsequent wiredrawing operations
- Unsuitability of rod rolled from cast wirebars for certain specialized wire applications

**Continuous Casting.** Because of the disadvantages inherent in producing rolled rod from conventionally cast wirebars, processes have been developed for continuously converting liquid metal directly into wire rod, thus avoiding the intermediate wirebar stage. Continuously cast wire rod has come to dominate the copper wire rod market and now accounts for more than 50% of the total amount of wire rod produced.

Advantages of continuous casting and rolling include:

- Large coil weights, up to 10 Mg (11 tons)
- Ability to reprocess scrap at considerable savings
- Improved rod quality and surface condition
- Homogeneous metallurgical conditions and close process control
- Low capital investment and low operating costs for moderate production rates

## Wiredrawing and Wire Stranding

**Preparation of Rod.** In order to provide a wire of good surface quality, it is necessary to have a clean wire rod with a smooth, oxide-free surface. Conventional hot-rolled rod must be cleaned in a separate operation, but with the advent of continuous casting, which provides better surface quality, a separate cleaning operation is not required. Instead, the rod passes through a cleaning station as it exits from the rolling mill.

The standard method for cleaning copper wire rod is pickling in hot 20% sulfuric acid followed by rinsing in water. When fine wire is being produced, it is necessary to provide rod of even better surface quality. This can be achieved in a number of ways. One method is open-flame annealing of cold-drawn rod--that is, heating to 700 °C (1300 °F) in an oxidizing atmosphere. This eliminates shallow discontinuities. A more common practice, especially for fine magnet-wire applications, is die shaving, where rod is drawn through a circular cutting die made of steel or carbide to remove approximately 0.13 mm (0.005 in.) from the entire surface of the rod. A further refinement of this cleaning operation for rod made from conventionally cast wirebar involves scalping the top surface of cast wirebar and subsequently die shaving the hot-rolled bar.

**Wiredrawing.** Single-die machines called bull blocks are used for drawing special heavy sections such as trolley wire. Drawing speeds range from  $\sim 1$  to 2.5 m/s (200 to 500 ft/min). Tallow is generally used as the lubricant, and the wire is drawn through hardened steel or tungsten carbide dies. In some instances, multiple-draft tandem bull blocks (in sets of 3 or 5 passes) are used instead of single-draft machines.

Tandem drawing machines having 10 to 12 dies for each machine are used for break-down of hot-rolled or continuous-cast copper rod. The rod is reduced in diameter from 8.3 mm (0.325 in.) to  $\sim 2$  mm (0.08 in.) by drawing it through dies at speeds up to 25 m/s (5000 ft/min). The drawing machine operates continuously; the operator merely welds the end of each rod coil to the start of the next coil.

Intermediate and fine wires are drawn on smaller machines that have 12 to 20 or more dies each. The wire is reduced in steps of 20 to 25% in cross-sectional area. Intermediate machines can produce wire as small as 0.5 mm (0.020 in.) in diameter, and fine wire machines can produce wire in diameters from 0.5 mm (0.020 in.) to less than 0.25 mm (0.010 in.). Drawing speeds are typically 25 to 30 m/s (5000 to 6000 ft/min) and may be even higher.

All drawing is performed with a copious supply of lubricant to cool the wire and prevent rapid die wear. Traditional lubricants are soap and fat emulsions, which are fed to all machines from a central reservoir. Breakdown of rod usually requires a lubricant concentration of  $\sim 7\%$ , drawing of intermediate and fine wires, and concentrations of 2 to 3%. Today, synthetic lubricants are becoming more widely accepted.

Drawn wire is collected on reels or stem packs, depending on the next operation. Fine wire is collected on reels carrying as little as 4.5 kg (10 lb); large-diameter wire, on stem packs carrying up to 450 kg (1000 lb). To ensure continuous operation, many drawing machines are equipped with dual take-up systems. When one reel is filled, the machine automatically flips the wire onto an adjacent empty reel and simultaneously cuts the wire. This permits the operator to unload the full reel and replace it with an empty one without stopping the wiredrawing operation.

**Production of Flat or Rectangular Wire.** Depending on size and quantity, flat or rectangular wire is drawn on bull block machines or Turk's head machines, or is rolled on tandem rolling mills with horizontal and vertical rolls. Larger quantities are produced by rolling and smaller quantities are produced by drawing.

**Annealing.** Wiredrawing, like any other cold-working operation, increases tensile strength and reduces ductility of copper. Although it is possible to cold work copper up to 99% reduction in area, copper wire usually is annealed after 90% reduction.

In some plants, electrical-resistance heating methods are used to fully anneal copper wire as it exits from the drawing machines. Wire coming directly from drawing passes over suitably spaced contact pulleys that carry the electrical current necessary to heat the wire above the recrystallization temperature in less than a second.

In plants where batch annealing is practiced, drawn wire is treated either in a continuous tunnel furnace, where reels travel through a neutral or slightly reducing atmosphere and are annealed during transit, or in batch bell furnaces under a similar protective atmosphere. Annealing temperatures range from 400 to 600 °C (750 to 1100 °F) depending chiefly on wire diameter and reel weight.

**Wire Coating.** Four basic coatings are used on copper conductors for electrical applications:

- Lead, or lead alloy (80Pb-20Sn), ASTM B 189
- Nickel, ASTM B 355
- Silver, ASTM B 298
- Tin, ASTM B 33

Coatings are applied to:

- Retain solderability for hookup-wire applications
- Provide a barrier between the copper and insulation materials, such as rubber, that would react with the copper and adhere to it (thus making it difficult to strip insulation from the wire to make an electrical connection)
- Prevent oxidation of the copper during high-temperature service

Tin-lead alloy coatings and pure tin coatings are the most common; nickel and silver are used for specialty and high-temperature applications.

Copper wire can be coated by hot dipping in a molten metal bath, electroplating, or cladding. With the advent of continuous processes, electroplating has become the dominant process, especially because it can be completed "on line" following the wire-drawing operation.

**Stranded wire** is produced by twisting or braiding several wires together to provide a flexible cable. Different degrees of flexibility for a given current-carrying capacity can be achieved by varying the number, size, and arrangement of individual wires. Solid wire, concentric strand, rope strand, and bunched strand provide increasing degrees of flexibility; within the last three categories, a larger number of finer wires provides greater flexibility.

Stranded copper wire and cable are made on machines known as bunchers or stranders. Conventional bunchers are used for stranding small-diameter wires (34 AWG up to 10 AWG). Individual wires are payed off reels located alongside the equipment and are fed over flyer arms that rotate around the take-up reel to twist the wires. The rotational speed of the arm relative to the take-up speed controls the length of lay in the bunch. For small, portable, flexible cables, individual wires are usually 30 to 34 AWG, and there can be as many as 150 wires in each cable.

A tubular buncher has up to 18 wire-payoff reels mounted inside the unit. Wire is taken off each reel while it remains in a horizontal plane, is threaded along a tubular barrel, and is twisted together with other wires by a rotating action of the barrel. At the take-up end, the strand passes through a closing die to form the final bunch configuration. The finished strand is wound onto a reel that also remains within the machine.

Supply reels in conventional stranders for large-diameter wire are fixed onto a rotating frame within the equipment and revolve around the axis of the finished conductor. There are two basic types of machines. In one, known as a rigid frame strander, individual supply reels are mounted in such a way that each wire receives a full twist for every revolution of the strander. In the other, known as a planetary strander, the wire receives no twist as the frame rotates.

These types of stranders are comprised of multiple bays, with the first bay carrying six reels and subsequent bays carrying increasing multiples of six. The core wire in the center of the strand is payed off externally. It passes through the machine center and individual wires are laid over it. In this manner, strands with up to 127 wires are produced in one or two passes through the machine, depending on the capacity for stranding individual wires.

Normally, hard-drawn copper is stranded on a planetary machine so that the strand will not be as springy and will tend to stay bunched rather than spring open when it is cut off. The finished product is wound onto a power-driven external reel that maintains a prescribed amount of tension on the stranded wire.

## Insulation and Jacketing

Of the three broad categories of insulation--polymeric, enamel, and paper-and-oil--polymeric insulation is the most widely used.

**Polymeric Insulation.** The most common polymers are polyvinyl chloride (PVC), polyethylene, ethylene propylene rubber (EPR), silicon rubber, polytetrafluoroethylene (PTFE), and fluorinated ethylene propylene (FEP). Polyimide coatings are used where fire resistance is of prime importance, such as in wiring harnesses for manned space vehicles. Until a few years ago, natural rubber was used, but this has now been supplanted by synthetics such as butyl rubber and EPR. Synthetic rubbers are used wherever good flexibility must be maintained, such as in welding or mining cable.

Many varieties of PVC are made, including several that are flame resistant. PVC has good dielectric strength and flexibility, and is one of the least expensive conventional insulating and jacketing materials. It is used mainly for communication wire, and low-voltage power cables. PVC insulation is normally selected for applications requiring continuous operation at temperatures up to 75 °C (165 °F).

Polyethylene, because of low and stable dielectric constant, is specified when better electrical properties are required. It resists abrasion and solvents. It is used chiefly for hookup wire, communication wire, and high-voltage cable. Cross-linked polyethylene (XLPE), which is made by adding organic peroxides to polyethylene and then vulcanizing the mixture, yields better heat resistance, better mechanical properties, better aging characteristics, and freedom from environmental stress cracking. Special compounding can provide flame resistance in cross-linked polyethylene. Typical

uses include building wire, control cables, and power cables. The usual maximum sustained operating temperature is 90 °C (200 °F).

Polytetrafluoroethylene and fluorinated ethylene propylene are used to insulate jet aircraft wire, electronic equipment wire, and specialty control cables, where heat resistance, solvent resistance, and high reliability are important. These electrical cables can operate at temperatures up to 250 °C (480 °F).

All of the polymeric compounds are applied over copper conductors by hot extrusion. The extruders are machines that convert pellets or powders of thermoplastic polymers into continuous covers. The insulating compound is loaded into a hopper that feeds into a long, heated chamber. A continuously revolving screw moves the pellets into the hot zone where the polymer softens and becomes fluid. At the end of the chamber, molten compound is forced out through a small die over the moving conductor, which also passes through the die opening. As the insulated conductor leaves the extruder it is water cooled and taken up on reels. Cables jacketed with EPR and XLPE go through a vulcanizing chamber prior to cooling to complete the cross-linking process.

**Enamel Film Insulation.** Film-coated wire, usually fine magnet wire, is composed of a metallic conductor coated with a thin, flexible enamel film. These insulated conductors are used for electromagnetic coils in electrical devices and must be capable of withstanding high breakdown voltages. Temperature ratings range from 105 to 220 °C (220 to 425 °F), depending on enamel composition. The most commonly used enamels are based on polyvinyl acetals, polyesters, and epoxy resins.

Equipment for enamel coating of wire is often custom built, but standard lines are available. Basically, systems are designed to insulate large numbers of wire simultaneously. Wires are passed through an enamel applicator that deposits a controlled thickness of liquid enamel onto the wire. Then the wire travels through a series of ovens to cure the coating, and finished wire is collected on spools. In order to build up a heavy coating of enamel, it may be necessary to pass wires through the system several times. In recent years, some manufacturers have experimented with powder-coating methods. These avoid evolution of solvents, which is characteristic of curing conventional enamels, and thus make it easier for the manufacturer to meet Occupational Safety and Health Administration and Environmental Protection Agency standards. Electrostatic sprayers, fluidized beds, and other experimental devices are used to apply the coatings.

**Paper-and-Oil Insulation.** Cellulose is one of the oldest materials for electrical insulation and is still used for certain applications. Oil-impregnated cellulose paper is used to insulate high-voltage cables for critical power-distribution applications. The paper, which can be applied in tape form, is wound helically around the conductors using special machines in which six to twelve paper-filled pads are held in a cage that rotates around the cable. Paper layers are wrapped alternately in opposite directions, free of twist. Paper-wrapped cables then are placed inside special impregnating tanks to fill the pores in the paper with oil and to ensure that all air has been expelled from the wrapped cable.

The other major use of paper insulation is for flat magnet wire. In this application, magnet-wire strip (with a width-to-thickness ratio greater than 50 to 1) is helically wrapped with one or more layers of overlapping tapes. These may be bonded to the conductor with adhesives or varnishes. The insulation provides highly reliable mechanical separation under conditions of electrical overload.

# Copper Alloy Castings

## Introduction

COPPER ALLOY CASTINGS are used in applications that require superior corrosion resistance, high thermal or electrical conductivity, good bearing surface qualities, or other special properties. Casting makes it possible to produce parts with shapes that cannot be easily obtained by fabrication methods such as forming or machining. Often, it is more economical to produce a part as a casting than to fabricate it by other means.

## Types of Copper Alloys

Because pure copper is extremely difficult to cast and is prone to surface cracking, porosity problems, and the formation of internal cavities, small amounts of alloying elements (such as beryllium, silicon, nickel, tin, zinc, and chromium) are

used to improve the casting characteristics of copper. Larger amounts of alloying elements are added for property improvement.

As described in the "Introduction and Overview" article in this Section, the copper-base castings are designated by the united number system (UNS) with numbers ranging from C80000 to C99999. Also, copper alloys in the cast form are sometimes classified according to their freezing range (that is, the temperature range between the liquidus and solidus temperatures). The freezing range of various copper alloys is discussed in the subsection "Control of Solidification" in this article.

**Compositions** of copper casting alloys differ from those of their wrought counterparts for various reasons. Generally, casting permits greater latitude in the use of alloying elements, because the effects of composition on hot or cold working properties are not important. However, imbalances among certain elements, and trace amounts of certain impurities in some alloys, will diminish castability and can result in castings of questionable quality.

Many of the casting alloys have lead contents of 5% or more. Alloys containing such high percentages of lead are not suited to hot working, but are ideal for low- to medium-speed bearings, where the lead prevents galling and excessive wear under boundary-lubrication conditions.

The tolerance for impurities is normally greater in castings than in their wrought counterparts--again because of the adverse effects certain impurities have on hot or cold workability. On the other hand, impurities that inhibit response to heat treatment must be avoided in both castings and wrought products. The choice of an alloy for any casting usually depends on five factors: metal cost, castability, machinability, properties, and final cost.

### Castability

Castability should not be confused with fluidity, which is only a measure of the distance to which a metal will flow before solidifying. Fluidity is thus one factor determining the ability of a molten alloy to completely fill a mold cavity in every detail. Castability, on the other hand, is a general term relating to the ability to reproduce fine detail on a surface. Colloquially, good castability refers to the ease with which an alloy responds to ordinary foundry practice without requiring special techniques for gating, risering, melting, sand conditioning, or any of the other factors involved in making good castings. High fluidity often ensures good castability, but it is not solely responsible for that quality in a casting alloy.

Foundry alloys generally are classified as high-shrinkage or low-shrinkage alloys. The former class includes the manganese bronzes, aluminum bronzes, silicon bronzes, silicon brasses, and some nickel silvers. They are more fluid than the low-shrinkage red brasses, more easily poured, and give high-grade castings in the sand, permanent mold, plaster, die, and centrifugal casting processes. With high-shrinkage alloys, careful design is necessary to promote directional solidification, avoid abrupt changes in cross section, avoid notches (by using generous fillets), and properly place gates and risers; all of these design precautions help avoid internal shrinks and cracks. Turbulent pouring must be avoided to prevent the formation of dross becoming entrapped in the casting. Liberal use of risers or exothermic compounds ensures adequate molten metal to feed all sections of the casting. Table 1 presents foundry characteristics of selected standard alloys, including a comparative ranking of both fluidity and overall castability for sand casting; number 1 represents the highest castability or fluidity ranking.

**Table 1 Foundry properties of the principal copper alloys for sand casting**

- (a) Relative rating for casting in sand molds. The alloys are ranked from 1 to 8 in both overall castability and fluidity; 1 is the highest or best possible rating.

All copper alloys can be successfully cast in sand. Sand casting allows the greatest flexibility in casting size and shape and is the most economical casting method if only a few castings are made (die casting is more economical above ~ 50,000 units). Permanent mold casting is best suited for tin, silicon, aluminum, and manganese bronzes, and yellow brasses. Die casting is well suited for yellow brasses, but increasing amounts of permanent mold alloys are also being die cast. Size is a definite limitation for both methods, although large slabs weighing as much as 4500 kg (10,000 lb) have been cast in permanent molds. Brass die castings generally weigh less than 0.2 kg (0.5 lb) and seldom exceed 0.9 kg (2 lb). The limitation of size is due to the reduced die life with larger castings.

Virtually all copper alloys can be cast successfully by the centrifugal casting process. Castings of almost every size from less than 100 g to more than 22,000 kg (<0.25 to >50,000 lb) have been made.

Because of their low lead contents, aluminum bronzes, yellow brasses, manganese bronzes, low-nickel bronzes, and silicon brasses and bronzes are best adapted to plaster mold casting. For most of these alloys, lead should be held to a minimum because it reacts with the calcium sulfate in the plaster, resulting in discoloration of the surface of the casting and increased cleaning and machining costs. Size is a limitation on plaster mold casting, although aluminum bronze castings that weigh as little as 100 g (0.25 lb) have been made by the investment (lost-wax) process, and castings that weigh more than 150 kg (330 lb) have been made by conventional plaster molding.

**Control of Solidification.** Production of consistently sound castings requires an understanding of the solidification characteristics of the alloys as well as knowledge of relative magnitudes of shrinkage. The actual amount of contraction during solidification does not differ greatly from alloy to alloy. The distribution, however, is a function of the freezing range and the temperature gradient in critical sections. Manganese and aluminum bronzes are similar to steel in that their freezing ranges are quite narrow--about 40 and 14 °C (70 and 25 °F), respectively. Large castings can be made by the same conventional methods used for steel, as long as proper attention is given to placement of gates and risers--both those for controlling directional solidification and those for feeding the primary central shrinkage cavity.

Tin bronzes have wider freezing ranges (~165 °C or 300 °F for C83600). Alloys with such wide freezing ranges form a mushy zone during solidification, resulting in interdendritic shrinkage or microshrinkage. Because feeding cannot occur properly under these conditions, porosity results in the affected sections. In overcoming this effect, design and riser placement, plus the use of chills, are important. Another means of overcoming interdendritic shrinkage is to maintain close temperature control of the metal during pouring and to provide for rapid solidification. These requirements limit section thickness and pouring temperatures, and this practice requires a gating system that will ensure directional solidification. Sections up to 25 mm (1 in.) in thickness are routinely cast. Sections up to 50 mm (2 in.) thick can be cast, but only with difficulty and under carefully controlled conditions. A bronze with a narrow solidification (freezing) range and good directional solidification characteristics is recommended for castings having section thicknesses greater than about 25 mm (1 in.).

It is difficult to achieve directional solidification in complex castings. The most effective and most easily used device is the chill. For irregular sections, chills must be shaped to fit the contour of the section of the mold in which they are placed. Insulating pads and riser sleeves sometimes are effective in slowing down the solidification rate in certain areas to maintain directional solidification.

Mechanical Properties

Most copper-base casting alloys containing tin, lead, or zinc have only moderate tensile and yield strengths, low-to-medium hardness, and high elongation. When higher tensile or yield strength is required, the aluminum bronzes, manganese bronzes, silicon brasses, silicon bronzes, beryllium coppers, and some nickel-silvers are used instead. Most of the higher-strength alloys have better-than-average resistance to corrosion and wear. Table 2 presents mechanical and physical properties of copper-base casting alloys. (Throughout this discussion, as well as in Table 2, the mechanical properties quoted are for sand cast test bars. Properties of the castings themselves may be lower, depending on section size and process-design variables.)

Note: HT indicates alloy in heat-treated condition.

(a) At 0.5% extension under load.

(b) At a permanent set of 0.025 mm (0.001 in.).

(c) 500 kgf (1100 lbf) load.

(d) 3000 kgf (6600 lbf load).

(e) Heat treated at 900 °C (1650 °F), water quenched, tempered at 590 °C (1100 °F), and water quenched.

(f) At 0.2% offset.

(g) Solution anneal of 760 °C (1400 °F) for 4 h, water quench, and then aged at 315 °C (600 °F) for 5 h and air cooled.

Tensile strengths for cast test bars of aluminum bronzes and manganese bronzes range from 450 to 900 MPa (65 to 130 ksi), depending on composition; some aluminum bronzes attain maximum tensile strength only after heat treatment.

Although manganese and aluminum bronzes are often used for the same applications, the manganese bronzes are handled more easily in the foundry. As-cast tensile strengths as high as 800 MPa (115 ksi) and elongations of 15 to 20% can be obtained readily in sand castings; slightly higher values are possible in centrifugal castings. Stresses can be relieved at 175 to 200 °C (350 to 400 °F). Lead can be added to the lower-strength manganese bronzes to increase machinability, but at the expense of tensile strength and elongation. Lead content should not exceed 0.1% in high-strength manganese bronzes. Although manganese bronzes range in hardness from 125 to 250 HB, they are readily machined.

Tin is added to low-strength manganese bronzes to enhance resistance to dezincification, but it should be limited to 0.1% in high-strength manganese bronzes unless sacrifices in strength and ductility can be accepted.

Manganese bronzes are specified for marine propellers and fittings, pinions, ball bearing races, worm wheels, gear shift forks, and architectural work. Manganese bronzes are also used for rolling mill screw-down nuts and slippers, bridge trunnions, gears, and bearings, all of which require high strength and hardness.

Various cast aluminum bronzes contain 9 to 14% Al and lesser amounts of iron, manganese, or nickel. They have a very narrow solidification range; therefore, they have a greater need for adequate gating and risering than do most other copper casting alloys and thus are more difficult to cast. A wide range of properties can be obtained with these alloys, especially after heat treatment, but close control of composition is necessary. Like the manganese bronzes, aluminum bronzes can develop tensile strengths well over 700 MPa (100 ksi).

Most aluminum bronzes contain from 0.75 to 4% Fe to refine grain structure and increase strength. Alloys containing from 8 to 9.5% Al cannot be heat treated unless other elements (such as nickel or manganese) in amounts over 2% are added. They have higher tensile strengths and greater ductility and toughness than any of the ordinary tin bronzes. Applications include valve nuts, cam bearings, impellers, hangers in pickling baths, agitators, crane gears, and connecting rods.

The heat-treatable aluminum bronzes contain from 9.5 to 11.5% Al; they also contain iron, with or without nickel or manganese. These castings are quenched in water or oil from temperatures between 760 and 925 °C (1400 and 1700 °F) and tempered at 425 to 650 °C (800 to 1200 °F), depending on the exact composition and the required properties.

From the range of properties shown in Table 2, it can be seen that all the maximum properties cannot be obtained in any one aluminum bronze. In general, alloys with higher tensile strengths, yield strengths, and hardnesses have lower values of elongation. Typical applications of the higher-hardness alloys are rolling mill screw-down nuts and slippers, worm gears, bushings, slides, impellers, nonsparking tools, valves, and dies.

Aluminum bronzes resist corrosion in many substances, including pickling solutions. When corrosion occurs, it often proceeds by preferential attack of the aluminum-rich bronzes. Duplex alpha-plus-beta aluminum bronzes are more susceptible to preferential attack of the aluminum-rich phases than are the all-alpha aluminum bronzes.

Aluminum bronzes have fatigue limits that are considerably greater than those of manganese bronze or any other cast copper alloy. Unlike Cu-Zn and Cu-Sn-Pb-Zn alloys, the mechanical properties of aluminum and manganese bronzes do not decrease with increases in casting cross section. This is because these alloys have narrow freezing ranges, which result in denser structures when castings are properly designed and properly fed.

Whereas manganese bronzes experience hot shortness above 230 °C (450 °F), aluminum bronzes can be used at temperatures as high as 400 °C (750 °F) for short periods of time without an appreciable loss in strength. For example, a room-temperature tensile strength of 540 MPa (78 ksi) declines to 529 MPa (76.7 ksi) at 260 °C (500 °F), 460 MPa (67 ksi) at 400 °C (750 °F), and 400 MPa (58 ksi) at 540 °C (1000 °F). Corresponding elongation values change from 28% to 32, 35, and 25%, respectively.

Unlike manganese bronzes, many aluminum bronzes increase in yield strength and hardness but decrease in tensile strength and elongation upon slow cooling in the mold. Whereas some manganese bronzes precipitate a relatively soft phase during slow cooling, aluminum bronzes precipitate a hard constituent rather rapidly within the narrow temperature range of 565 to 480 °C (1050 to 900 °F). Therefore, large castings, or smaller castings that are cooled slowly, will have properties different from those of small castings cooled relatively rapidly. The same phenomenon occurs upon heat treating the hardenable aluminum bronzes. Cooling slowly through the critical temperature range after quenching, or tempering at temperatures within this range, will decrease elongation. An addition of 2 to 5% Ni greatly diminishes this effect.

Nickel brasses, silicon brasses, and silicon bronzes, although generally high in strength than red metal alloys, are used more for their corrosion resistance.

Cast beryllium coppers achieve variations in properties principally by varying heat treatment conditions. The "red" beryllium copper alloys are exemplified by C82000 and C82200; the "gold" alloys include C82400, C82500, C82600, and C82800. The casting alloys typically contain large amounts of beryllium than their wrought counterparts. The "gold" casting alloys, in particular, have excellent casting characteristics and can be poured at relatively low temperatures into molds with intricate shapes and fine detail.

Figure 1 shows distributions of hardness and tensile-strength data for separately cast test bars of three different alloys.

**Fig. 1** Distribution of hardness over 100 tests for three copper casting alloys of different tensile strengths. (a) C83600. Tensile strength, 235 to 260 MPa (34 to 38 ksi); 500 kg (1100 lbf) load. (b) C90300. Tensile strength, 275 to 325 MPa (40 to 47 ksi); 500 kg (1100 lbf) load. (c) C87500. Tensile strength, 420 to 500 MPa (61 to 72 ksi); 1500 kg (3300 lbf) load

**Properties of Test Bars.** The mechanical properties of separately cast test bars often differ widely from those of production castings poured at the same time, particularly when the thickness of the casting differs markedly from that of the test bar.

The mechanical properties of tin bronzes are particularly affected by variations in casting section size. With increasing section sizes up to  $\sim 50$  mm (2 in.), the mechanical properties--both strength and elongation--of the casting themselves are progressively lower than the corresponding properties of separately cast test bars. Elongation is particularly affected; for some tin bronzes, elongation of a 50 mm (2 in.) section may be as little as  $\frac{1}{10}$  that of a 10 mm (0.4 in.) section or of a separately cast test bar.

The metallurgical behavior of many copper alloy systems is complex. The cooling rate (a function of casting section size) directly influences grain size, segregation, and interdendritic shrinkage; these factors, in turn, affect the mechanical properties of the cast metal. Therefore, molding and casting techniques are based on metallurgical characteristics as well as on casting shape.

## Dimensional Tolerances

Typical dimensional tolerances are different for castings produced by different molding methods. A molding process involving two or more mold parts requires greater tolerances for dimensions that cross the parting line than for dimensions wholly within one mold part. For castings made in green sand molds, tolerances across the parting line depend on the accuracy of pins and bushings that align the cope with the drag.

Figure 2 shows variations in two important dimensions for 50 production castings of red brass. The larger dimension presented the greatest difficulty; none of the 50 production castings had an actual dimension as large as the nominal design value. Figure 3 shows dimensional variations in two similar cored valve castings. For each design, both the cores and the corresponding cavities in the castings were measured for approximately 100 castings. For both designs, the castings had actual dimensions less than those of the cores. This indicates that cores may need to have a slightly larger nominal size than is desired in the finished casting in order to ensure proper as-cast hole sizes.

Fig. 2 Variations from design dimensions for a typical red brass casting. Parts were cast in green sand molds made using the same pattern. All dimensions are given in inches.

Fig. 3 Variations from design dimensions for two typical cast red brass valve bodies. Valve bodies, similar in design but of different sizes, were made using dry sand cores to shape the internal cavities. The upper histograms indicate dimensional variations for the castings; the lower histograms indicate variations for the corresponding cores. All dimensions are given in inches.

### Machinability

Machinability ratings of copper casting alloys are similar to those of their wrought counterparts. The cast alloys can be separated into three groups. Table 3 shows the relative machinability of alloys belonging to the three groups.

Table 3 Machinability ratings of several copper casting alloys

UNS No.	Common name	Machinability rating, % <sup>(a)</sup>
---------	-------------	--

Group 1: free-cutting alloys		
<b>C83600</b>	Leaded red brass	90
<b>C83800</b>	Leaded red brass	90
<b>C84400</b>	Leaded semired brass	90
<b>C84800</b>	Leaded semired brass	90

<b>C95300</b>	Aluminum bronze	35

<b>C86500</b>	High-strength manganese bronze	30
<b>C82500</b>	Beryllium copper	30
Group 3: hard-to-machine alloys		
<b>C86300</b>	High-strength manganese bronze	20
<b>C95200</b>	9% aluminum bronze	20
<b>C95400</b>	11% aluminum bronze	20
<b>C95500</b>	Nickel-aluminum bronze	20

- (a) Expressed as a percentage of the machinability of C36000, free-cutting brass. The rating is based on relative speed for equivalent tool life. For example, a material having a rating of 50 should be machined at about half the speed that would be used to make a similar cut in C36000.

The first group includes only those containing a single copper-rich phase plus lead. Whether present merely to improve machinability or for some other purpose, lead facilitates chip breakage, thus allowing higher machining speeds with decreased tool wear and improved surface finishes.

Alloys of the second group contain two or more phases. Generally, the secondary phases are harder or more brittle than the matrix. Silicon bronzes, several aluminum bronzes, and the high-tin bronzes belong to this group. Hard and brittle secondary phases act as internal chip breakers, resulting in short chips and easier machining. Manganese bronzes produce a long spiral chip that is smooth on both sides and that does not break. Some aluminum bronzes, on the other hand, produce a long spiral chip that is smooth on both sides and that does not break. Some aluminum bronzes, on the other hand, produce a long spiral chip that is rough on the underside and that breaks, thus acting like a short chip. Some of the alloys in the second group are classified as moderately machinable because tools wear more rapidly when these alloys are machined, even though chip formation is entirely adequate.

The third group, the most difficult to machine, is composed mainly of the high-strength manganese bronzes and aluminum bronzes that are high in iron or nickel content.

## General Purpose Alloys

General-purpose copper casting alloys are often classified as either red or yellow alloys. Table 2 show general properties of these alloys.

The leaded red and leaded semired brasses respond readily to ordinary foundry practice and are rated very high in castability. Alloy C83600 is the best known of this group and usually is referred to by a common name--85-5-5-5 or ounce metal. Alloy C83600 and the modification, C83800 (83-4-6-7), constitute the largest tonnage of copper-base foundry alloys. They are used where moderate corrosion resistance, good machinability, moderate strength and ductility, and good castability are required. C83800 has lower mechanical properties but better machinability and lower initial metal cost than C83600.

Both C83600 and C83800 are used for plumbing goods, flanges, feed pumps, meter casings and parts, general household and machinery hardware and fixtures, papermaking machinery, hydraulic and steam valves, valve disks and seats, impellers, injectors, memorial markers, plaques, statuary, and similar products.

Alloys C84400 and C84800 are higher in lead and zinc and lower in copper and tin than C83600 and C83800. They are lower in price, and they have lower tensile strengths and hardnesses. Their widest application is in the plumbing industry.

The leaded yellow brasses C85200 and C85700 are even lower in price and mechanical properties. Their main applications are die castings for plumbing goods and accessories, low-pressure valves, air and gas fittings, general hardware, and ornamental castings. In general, they are best suited for small parts; larger parts with thick sections should be avoided. Aluminum (0.15 to 0.25%) is added to yellow brasses to increase fluidity and to give a smoother surface.

All of the red and yellow general-purpose alloys, when properly made and cleaned, can be plated with nickel or chromium.

Alloys that do not contain lead, such as the tin bronzes C90500 (Navy G bronze) and C90300 (modified Navy G bronze), are considerably more difficult to machine than leaded alloys. Alloys containing 10 to 12% Sn, 1 to 2% Ni, and 0.1 to 0.3% P are known as gear bronzes. Up to 1.5% Pb frequently is added to increase machinability. The addition of lead to C90300 increases machinability, but a concurrent decrease in tin is needed to maintain elongation. The leaded tin bronzes include C92200 (known as steam bronze, valve bronze, or Navy M bronze) and C92300 (commercial G bronze).

All of the tin bronzes are suitable wherever corrosion resistance, leak tightness, or greater strength is required at higher operating temperatures than can be tolerated with leaded red or semired brasses. The limiting temperature for long-time operation of C92200 is 290 °C (550 °F); for C90300, C90500, and C92300, it is 260 °C (500 °F) because of the embrittlement caused by the precipitation of a high-tin phase. This reaction does not occur in tin bronze with tin contents less than ~8%. For elevated-temperature service in handling fluids and gases, Table UNF-23 of the ASME Boiler and Pressure Vessel Code defines allowable working stresses for C92200 (leaded tin bronze, ASTM B 61) and C83600 (leaded red brass, ASTM B 62) at different temperatures (Table 4).

**Table 4 Allowable working stresses for C92200 and C83600 castings**

Temperature		Working stress			
		ASTM B 61 <sup>(a)</sup>		ASTM B 62 <sup>(b)</sup>	
°C	°F	MPa	ksi	MPa	ksi
38	100	47	6.8	41	6.0
65	150	47	6.8	41	6.0
93	200	47	6.8	40	5.8
120	250	47	6.8	38	5.5
150	300	45	6.5	34	5.0
175	350	41	6.0	31	4.5
205	400	38	5.5	24	3.5
230	450	34	5.0	24	3.5

<b>260</b>	500	28	4.0	24	3.5
<b>290</b>	550	23	3.3	24	3.5

Source: ASME Boiler and Pressure Vessel Code, Table UNF-23

- (a) A minimum tensile strength of 235 MPa (34 ksi) is specified for C92200 in ASTM B 61.
- (b) A minimum tensile strength of 250 MPa (30 ksi) is specified for C83600 in ASTM B 62.

Nickel frequently is added to tin bronzes to increase density and leak tightness. Alloys containing more than 3% Ni are heat treatable, but they must contain less than 0.01% Pb for optimum properties; one example of such an alloy is C94700 (88Cu-5Sn-2Zn-5Ni).

## Bearing and Wear Properties

Copper alloys have long been used for bearings because of their combination of moderate-to-high strength, corrosion resistance, and self-lubrication properties. The choice of an alloy depends on the required corrosion resistance and fatigue strength, the rigidity of the backing material, lubrication, the thickness of bearing material, load, the speed of rotation, atmospheric conditions, and other factors. Copper alloys can be cast into plain bearings, cast on steel backs, cast on rolled strip, make into sintered powder metallurgy shapes, or pressed and sintered onto a backing material.

Three groups of alloys are used for bearing and wear-resistant applications: phosphor bronzes (Cu-Sn); copper-tin-lead (low-zinc) alloys; and manganese, aluminum, and silicon bronzes.

Phosphor bronzes (Cu-Sn-P or Cu-Sn-Pb-P alloys) have residual phosphorus ranging from a few hundredths of 1% (for deoxidation and slight hardening) to a maximum of 1%, a level that imparts great hardness. Nickel often is added to refine grain size and disperse the lead. Copper-tin bearings have high resistance to wear, high hardness, and moderately high strength. Alloy C90700 is so widely used for gears that it is commonly called gear bronze.

Phosphor bronzes of higher tin content, such as C91100 and C91300, are used in bridge turntables, where loads are high and rotational movement is slow. The maximum load permitted for C91100 (16% Sn) is 17 MPa (2500 psi); for C91300 (19% Sn) it is 24 MPa (3500 psi). These bronzes are high in phosphorus (1% max) to impart high hardness, and low in zinc (0.25% max) to prevent seizing. They are very brittle, and because of this brittleness are sometimes replaced by manganese bronzes or aluminum bronzes.

High-lead tin bronzes are used where a softer metal is required at slow-to-moderate speeds and at loads not exceeding 5.5 MPa (800 psi). Alloys of this type include C93200 and C93700. The former, also known as 83-7-7-3, is an excellent general bearing alloy; it is especially well suited for applications where lubrication may be deficient. Alloy C93200 is widely used in machine tools, electrical and railroad equipment, steel mill machinery, and automotive applications. Alloy C93200 is produced by the continuous casting process and has replaced sand castings for mass-produced bearings of high quality. Alloys C93800 (15% Pb) and C94300 (24% Pb) are used where high loads are encountered under conditions of poor or nonexistent lubrication; under corrosive conditions, such as in mining equipment (pumps and car bearings); or in dusty atmospheres, as in stone-crushing and cement plants. These alloys replace the tin bronzes or low-lead tin bronzes where operating conditions are unsuitable for alloys containing little or no lead. They also are produced by the continuous casting process.

High-strength manganese bronzes have high tensile strength, hardness, and resistance to shock. Large gears, bridge turntables (slow motion and high compression), roller tracks for anti-aircraft guns, and recoil parts of cannons are typical applications.

Aluminum bronzes with 8 to 9% Al are widely used for bushings and bearings in light-duty or high-speed machinery. Aluminum bronzes containing 11% Al, either as-cast or heat treated, are suitable for heavy-duty service (such as valve guides, rolling mill bearings, screw-down nuts, and slippers) and precision machinery. As aluminum content increases above 11%, hardness increases and elongation decreases to low values. Such bronzes are well suited for guides and aligning plates, where wear would be excessive. Aluminum bronzes that contain more than 13% Al exceed 300 HB in hardness but are brittle. Such alloys are suitable for dies and other parts not subjected to impact loads.

Aluminum bronze generally has a considerably higher fatigue limit and freedom from galling than manganese bronze. On the other hand, manganese bronze has great toughness for equivalent tensile strength and does not need to be heat treated.

## Electrical and Thermal Conductivity

Electrical and thermal conductivity of any casting will invariably be lower than for wrought metal of the same composition. Copper castings are used in the electrical industry for their current-carrying capacity, and they are used for water-cooled parts of melting and refining furnaces because of their high thermal conductivity. However, for a copper casting to be sound and have electrical or thermal conductivity of at least 85%, care must be taken in melting and casting. The ordinary deoxidizers (silicon, tin, zinc, aluminum, and phosphorus) cannot be used because small residual amounts lower electrical and thermal conductivity drastically. Calcium boride or lithium help to produce sound castings with high conductivity.

Cast copper is soft and low in strength. Increased strength and hardness and good conductivity can be obtained with heat-treated alloys containing silicon, cobalt, chromium, nickel, and beryllium in various combinations. These alloys, however, are expensive and less readily available than the standardized alloys. Table 5 presents some of the properties of these alloys after heat treatment.

**Table 5 Composition and typical properties of heat-treated copper casting alloys of high strength and conductivity**

UNS No.	Nominal composition	Tensile strength		Yield strength		Elongation, %	Hardness	Electrical conductivity, % IACS
		MPa	ksi	MPa	ksi			
<b>C81400</b>	99Cu-0.8Cr-0.06Be	365	53	250	36	11	69 HRB	70
<b>C81500</b>	99Cu-1Cr	350	51	275	40	17	105 HB	85
<b>C81800</b>	97Cu-1.5Co-1Ag-0.4Be	705	102	515	75	8	96 HRB	48
<b>C82000</b>	97Cu-2.5Co-0.5Be	660	96	515	75	6	96 HRB	48

## Cost Considerations

During the design of a copper alloy casting, foundry personnel or the design engineer must choose a method of producing internal cavities. There is no general rule for choosing between cored and coreless designs. A cost analysis will determine

which is the more economical method of producing the castings, although frequently the choice can be decided by experience.

For example, costs were compared for producing a small (13 mm, or  $\frac{1}{2}$  in.) valve disk both as a cored casting and as a machined casting (internal cavities made without cores). The machined casting could be produced for about 78% of the cost of making the identical casting using dry sand cores--a savings of 22% in favor of machined casting. In a similar instance, producing a larger (38 mm, or  $1\frac{1}{2}$  in.) valve disk as a cored casting that required only a minimal amount of machining saved more than 8% in overall cost compared to producing the same valve disk without cores. Thus, for two closely related parts, a difference in manufacturing economy may exist when all cost factors are taken into account.

# Copper Powder Metallurgy Products

## Introduction

COPPER-BASE POWDER METALLURGY (P/M) products rank second after iron and steel products in terms of volume. According to the Metal Powder Industries Federation (MPIF), the estimated shipments of copper and copper-base alloy powders in 1996 were ~20,500 Mg (23,000 short tons) in North America. The shipments in Europe were estimated to be ~14,000 Mg (15,600 short tons), while the shipments in Japan were estimated at ~6,200 Mg (7,000 short tons).

The use of copper in the P/M industry dates back to the 1920s, when commercial porous bronze bearings were developed independently in the research laboratories of General Motors Corp. and Bound-Brook Oilless Bearing Co. These self-lubricating bearings still account for the major portion of P/M copper and copper alloy applications. Other important applications for copper and copper-base P/M materials include friction materials, brushes, filters, structural parts, electrical parts, additives to iron powders (alloying as well as infiltration), catalysts, paints, and pigments.

In general, physical and mechanical properties of near full (theoretical) density copper and copper alloy P/M structural parts are comparable to cast and wrought copper-base materials of similar composition. However, P/M copper parts vary in density from the low density typical of self-lubricating bearings or filters to the near full density of electrical parts. The physical and mechanical properties depend greatly on the density as a percentage of theoretical density.

## Powder Production and Properties

### *Copper Powders*

Copper powders of 99+ % purity are commercially available. The four major methods of producing such copper powders are:

- Atomization
- Oxide reduction
- Hydrometallurgy
- Electrolysis

Of the previous methods, atomization and oxide reduction are presently practiced on a large scale globally. Hydrometallurgical and electrolytic copper powders have not been manufactured in the United States since the early 1980s, and will not be described further. Information on copper powders produced by hydrometallurgy or electrolysis can, however, be found in Volume 7, *Powder Metallurgy*, of the *ASM Handbook*.

Table 1 shows a comparison of some of the typical fundamental powder characteristics of commercial copper powders made by the four production processes. Each process produces a unique particle shape and surface area.

### Table 1 Characteristics of commercial copper powders

Type of powder	Composition, %			Particle shape	Surface area
	Copper	Oxygen	Acid insolubles		
<b>Electrolytic</b>	99.1-99.8	0.1-0.8	0.03 max	Dendritic	Medium to high
<b>Oxide reduced</b>	99.3-99.6	0.2-0.6	0.03-0.1	Irregular; porous	Medium
<b>Water atomized</b>	99.3-99.7	0.1-0.3	0.01-0.03	Irregular to spherical; solid	Low
<b>Hydrometallurgical</b>	97-99.5	0.2-0.8	0.03-0.8	Irregular agglomerates	Very high

**Atomization.** In this process, molten copper flows through a refractory nozzle, and the liquid stream is disintegrated into droplets by an impinging jet of water or gas. The droplets solidify into powder particles. The size and shape of these particles are governed by the atomizing medium, pressure, and flow rate. Gas atomization produces spherical particles while the shape of water-atomized powder particles can be controlled from almost spherical to irregular by controlling the interaction between the water jet and the metal stream (Fig. 1). Higher pressures and lower flow rates favor finer powders; average particle sizes less than 325 mesh (45  $\mu\text{m}$ ) are feasible.

**Fig. 1** Scanning electron micrographs of gas- and water-atomized copper powders. (a) Nitrogen atomized. (b) Water atomized, apparent density of 3.04 g/cm<sup>3</sup>. (c) Water atomized, apparent density of 4.60 g/cm<sup>3</sup>

Water is the preferred atomizing medium for producing copper powder. The atomized powder is often subjected to an elevated temperature reduction (to reduce any oxides formed during atomization) and agglomeration treatment to improve the compacting properties. Table 2 shows the typical properties of commercial water-atomized copper powders.

**Table 2** Properties of commercial grades of water-atomized copper powders

Copper, %	Chemical properties, %		Physical properties						
	Hydrogen loss	Acid insolubles	Hall flow rate, s/50 g	Apparent density, g/cm <sup>3</sup>	Tyler sieve analysis, %

(a) Water atomized plus reduced.

(b) Contains magnesium

**Oxide Reduction.** This process involves oxidizing copper (particulate copper scrap, electrolytic copper, atomized copper, etc.) and milling the oxide into powder. The oxide powder is reduced at elevated temperature by solid or gaseous reducing agents, and the resulting sintered cake is milled into powder. The particle size is controlled through milling of the starting oxide and the reduced sinter cake. The milled copper powder particles are irregular and porous (Fig. 2). A broad range of pore characteristics can be obtained by controlling the reduction conditions.

Fig. 2 Oxide-reduced copper powder. 500×

The particle size, shape, and pore characteristics determine the compacting properties of the powder and the part produced. Table 3 shows the typical properties of a commercial copper powder produced by the oxide-reduction process.

**Table 3 Properties of commercial grades of copper powder produced by the oxide reduction process**

## Copper Alloy Powders

Alloy powders are available in various compositions, including brasses, nickel silvers, tin bronzes, aluminum bronzes, and beryllium bronzes. Alloy powders are produced by one of two methods:

- Preblending copper powders with other elemental powders such as tin, zinc, or nickel
- Prealloying during powder production

**Preblending.** Preblended powders are mixtures of selected compositions, with or without lubricant, that form the desired alloy during sintering. The most common P/M copper alloy made with preblended powders is tin bronze used in self-lubricating bearings. Typical bronze composition is 90Cu-10Sn, often containing up to 1.5% graphite. Some "dilute" bronze bearings contain various amounts of iron replacing some of the copper and tin. Copper-lead and steel-backed copper-lead-tin materials, used to replace solid bronze bearings, also use preblended powders because lead is virtually insoluble in copper and cannot be prealloyed. Friction materials used in brakes and clutches contain disparate materials such as copper with several other components including lead, tin, iron, graphite, molybdenum disulfide, oxides, etc. These can only be made using preblended powders.

**Prealloying.** Prealloyed powders are generally produced by melting the constituents to form a homogeneous alloy and atomizing the alloy melt by the methods similar to those used for the production of copper powder. They can also be produced by sintering preblended powders and grinding the materials to attain the desired powder characteristics.

**Brass and Nickel Silver.** Air atomization is generally used for making prealloyed powders of brass and nickel silver for use in high-density ( $>7.0 \text{ g/cm}^3$ ) components. The low-surface tension of the molten alloys of these compositions renders the particle shape sufficiently irregular to make the powders compactible (Fig. 3). Reduction of oxides is not necessary for the standard P/M grades of brass and nickel-silver powders.

**Fig. 3** Prealloyed air-atomized, nickel-silver powder (63Cu-18Ni-17Zn-2Pb). 165×

Commercial prealloyed brass and nickel-silver powders are available in leaded and nonleaded compositions. Commercial brass alloys range from 90Cu-10Zn to 65Cu-35Zn. Leaded versions of 80Cu-20Zn and 70Cu-30Zn are most commonly used for the manufacture of sintered structural parts that may require secondary machining operations. The only commercially available nickel-silver powder has a nominal composition of 65Cu-18Ni-17Zn, which is modified by addition of lead when improved machinability is required.

**Bronze.** Prealloyed bronze powders are not used widely for structural parts fabrication because their modular particle form and high apparent density result in low green strength. However, blends of such powders with irregular copper powders and phosphorus-copper yield sintered parts with good mechanical properties.

Table 4 shows typical properties of commercial grades of prealloyed brass, bronze, and nickel-silver powders.

**Table 4 Physical properties of typical brass, bronze, and nickel-silver alloy compositions**

Property	Brass <sup>(a)</sup>	Bronze <sup>(a)</sup>	Nickel silver <sup>(a)(b)</sup>

## Production of Parts

### *Powder Consolidation*

Copper and copper alloy powders are generally cold compacted in closed dies with top and bottom punches used to apply the desired pressure. During cold compaction the powder particles mechanically interlock with each other. Typical compacted densities are 80 to 90% of the theoretical density of the material. When higher densities are required, consolidation methods such as hot pressing, extrusion, hot isostatic pressing, and hot forging are used.

### *Sintering*

The compacted parts are sintered at elevated temperatures under protective conditions to avoid oxidation. During this process the powder particles are metallurgically bonded to each other. Typical sintering times and temperatures for copper P/M parts production are given in the following paragraphs.

### **Pure Copper P/M Parts**

Pure copper P/M parts are used mainly in electrical and electronic applications because of their high-electrical conductivity. It is essential to use very pure copper powders ( $\geq 99.95\%$  purity) or to bring about the precipitation of soluble impurities during sintering. As little as 0.023% Fe in solid solution in copper lowers the conductivity to 86% of that of pure copper. Small amounts of iron mechanically mixed with the copper powder lower the conductivity much less, unless the iron dissolves in the copper during sintering. If high-purity copper is used, or if soluble impurities are precipitated during sintering, it is possible to obtain the strength and conductivity values shown in Fig. 4.

**Fig. 4** Effect of density on electrical conductivity and tensile properties of P/M copper

Conductivity is directly related to porosity; the greater the void content (lower the density), the lower the conductivity. Electrical conductivity of pure copper parts pressed at moderate pressures of 205 to 250 MPa (15 to 18 tsi) and sintered at 800 to 900 °C (1500 to 1650 °F) varies from 80 to 90% International Annealed Copper Standard (IACS) on a scale where conductivity of solid annealed copper is 100% IACS. The conductivity of solid copper can be reached or approached in P/M copper parts by sintering the pressed parts at higher temperatures, such as 930 to 1030 °C (1700 to 1900 °F), followed by repressing, coining, or forging.

Typical applications of pure copper parts in which high electrical conductivity is required include commutator rings, contacts, shading coils, nose cones, and electrical twist-type plugs. Copper powders also are used in copper-graphite compositions that have low contact resistance, high current-carrying capacity, and high-thermal conductivity. Typical applications include brushes for motors and generators and moving parts for rheostats, switches, and current-carrying washers.

### **Bronze P/M Parts**

Powder metallurgy bronzes typically originate as premixes consisting of elemental copper and tin powders plus 0.5 to 0.75% dry organic lubricants such as stearic acid or zinc stearate. Some structural parts, however, requiring densities  $>7.0$  g/cm<sup>3</sup> are fabricated from prealloyed powders. Prealloyed powders have higher yield strengths and work hardening rates than premixed powders. Therefore, pressing loads required to achieve given green densities in prealloyed powders are higher than the pressure required for elemental powders. Differences in pressing characteristics of premixed and prealloyed powders are compared in Fig. 5.

**Fig. 5** Pressing characteristics of premixed and prealloyed 90Cu-10Sn powders

Typical sintering furnace temperatures for bronze range from 815 to 870 °C (1500 to 1600 °F); total sintering time within the hot zone can range from 15 to 30 min depending on the furnace temperature selected, required dimensional change, and most importantly, the presence of an optimum alpha-bronze grain structure. Sintering atmospheres should be protective and reducing to facilitate sintering. Reduction of the copper oxides that may surround each copper powder particle and of tin oxide allow for increased diffusion rates. Figure 6 shows typical strength/density data for 90Cu-10Sn sintered bronzes with and without graphite additions. Control of sintered dimensions in premix systems is achieved by manipulating sintering time and/or temperature.

**Fig. 6** Effect of density on the strength of copper-tin and copper-tin-graphite compacts

Generally, copper-tin blends composed of relatively coarser powders sinter to high-growth values than a blend composed of finer powders. After powder blends have been tested and adjusted to provide an approximation of target dimensions, final adjustments are made during production sintering to obtain dimensional precision. Factors affecting the ultimate dimensional values include physical characteristics of the constituents and compacted density.

**Bearings.** Self-lubricating porous bronze bearings continue to consume the major portion of the copper powder produced each year. These bearings are made by pressing elemental powder blends of copper and tin, followed by sintering. The most widely used bearing material is 90Cu-10Sn bronze, often with the addition of up to 1.5% graphite. So-called dilute bronze bearings contain various amounts of iron. Dilution with iron reduces the cost of a bearing at the expense of some loss in performance.

Compaction pressures for the bronze powders range from  $\sim$ 140 to 415 MPa (20 to 60 ksi). Sintering is typically completed in a continuous mesh-belt furnace at temperatures between 815 and 870 °C (1500 and 1600 °F) for  $\sim$ 3 to 8 min at temperature. Typical furnace atmospheres are dissociated ammonia or endothermic gas. To obtain reproducible sintering results it is important to carefully control time and temperature because of their influence on the kinetics of the homogenization process, which in turn determines the dimensional changes occurring during sintering. Most bearings are sized for improved dimensional accuracy; typical sizing pressure can range from  $\sim$ 200 to 550 MPa (30 to 80 ksi). Bearings are sold either dry or saturated with oil. The pores are filled with oil by a vacuum impregnation process. Most

common bearings range in density from 5.8 to 6.6 g/cm<sup>3</sup> dry or 6.0 to 6.8 g/cm<sup>3</sup> oil impregnated. This range corresponds to ~25 to 35% pore volume.

The most common shapes for bronze bearings are simple or flanged bushings, but some have spherical external surfaces. Sizes range from about 0.8 to 75 mm (<sup>1</sup>/<sub>32</sub> to 3 in.) in diameter. Sintered bronze bearings are used in automotive components, home appliances, farm, lawn and garden equipment, consumer electronics, business machines, industrial equipment, and portable power tools.

**Filters.** Filters constitute one of the major applications for porous P/M parts. The ability to achieve close control of porosity and pore size is the main reason filters are made from metal powders. Most producers of nonferrous filters prefer atomized spherical powders with closely controlled particle size to allow production of filters within the desired pore size range. The effective pore size of filters generally ranges from 5 to 125 μm.

Tin bronze is the most widely used P/M filter material, but nickel silver, stainless steel, copper-tin-nickel alloys, and nickel-base alloys also are used. The major advantage of P/M bronze materials over other porous metals is cost. Porous P/M bronze filters can be obtained with tensile strengths ranging from 20 to 140 MPa (3 to 20 ksi) and appreciable ductility, up to 20% elongation. P/M bronze also has the same corrosion resistance as cast bronze of the same composition and thus can be used in a wide range of environments.

Bronze filters usually are made by gravity sintering of spherical bronze powders, which are generally made by atomization of molten prealloyed bronze. These powders typically contain 90 to 92% Cu and 8 to 10% Sn. Filters made from atomized bronze have sintered densities ranging from 5.0 to 5.2 g/cm<sup>3</sup>. To produce filters with the highest permeability for a given maximum pore size, powder particles of a uniform particle size must be used.

Powder metallurgy bronze filters are commonly used to filter gases, oils, refrigerants, and chemical solutions. They have been used in fluid systems of space vehicles to remove particles as small as 1 μm . Bronze diaphragms can be used to separate air from liquid or mixtures of liquids that are not emulsified. Only liquids capable of wetting the pore surface can pass through the porous metal part.

Bronze filter materials can also be used as flame arrestors on electrical equipment operating in flammable atmospheres, where the high-thermal conductivity of the bronze prevents ignition. They can also be used as vent pipes on tanks containing flammable liquids. In these applications, heat is conducted away rapidly so that the ignition temperature is not reached.

**Structural Parts.** Powder metallurgy bronze parts for structural applications frequently are selected because of corrosion and wear resistance of bronze. They are generally produced by methods similar to those used for self-lubricating bearings and are generally used in automobile clutches, copiers, outboard motors, and paint-spraying equipment. Typical compositions of bronze structural parts (CT-1000) are included in Table 5 and the typical properties are shown in Table 6.

## ***Brass and Nickel Silver P/M Parts***

In contrast to bronze structural parts, parts made from brass, leaded brass, and nickel silver are produced from prealloyed atomized powder. Table 5 shows compositions of some common brass and nickel-silver alloys. The leaded compositions are used whenever secondary machining operations are required.

The alloy powders are usually blended with lubricants in amounts from 0.5 to 1.0 wt%. Lithium stearate is the preferred lubricant because of cleansing and scavenging action during sintering. However, bilubricant systems are common, such as lithium stearate and zinc stearate, which minimize the surface staining attributed to excessive lithium stearate. Lubricated powders are typically compacted to 75% of theoretical density at 207 MPa (30 ksi) and to 85% of theoretical density at 415 MPa (60 ksi).

Sintering of brass and nickel-silver compacts is normally performed in protective atmospheres. Dissociated ammonia, endothermic gas, and nitrogen-base atmospheres are most common. Temperatures range from 815 to 925 °C (1500 to 1700 °F) depending on alloy composition. To avoid distortion and/or blistering of the compacts, sintering temperatures should not exceed the solidus temperature of the alloy. Through multiple pressing and sintering operations, yield strength and hardness approaching those of the wrought alloy counterparts can be achieved. To minimize zinc losses during sintering, yet allow for adequate lubricant removal, protective-sintering-tray arrangements are used. Table 6 shows the typical properties of common brass and nickel-silver P/M parts.

Next to bronze bearings, brasses and nickel silvers are the most widely used materials for structural P/M parts. Typical applications include hardware for latch bolts and cylinders for locks; shutter components for cameras; gears, cams, and actuator bars in timing assemblies and in small generator drive assemblies; and decorative trim and medallions. In many of these applications, corrosion resistance, wear resistance, and aesthetic appearance play important roles.

## ***Copper-Nickel P/M Parts***

Copper-nickel P/M alloys containing 75Cu-25Ni and 90Cu-10Ni have been developed for coinage and corrosion-resistance applications. The 75Cu-25Ni alloy powder pressed at 772 MPa (112 ksi) has a green density 89% of the theoretical density. After sintering at 1090 °C (2000 °F) in dissociated ammonia, elongation is 14%, and apparent hardness is 20 HRB. Repressing at 772 MPa (112 ksi) increases density to 95%. This alloy has the color of stainless steel and can be burnished to a high luster. The 90Cu-10Ni alloy has a final density of 99.4% under similar pressing and sintering conditions. It has a bright bronze color and also can be burnished to a high luster.

In one method of producing coins, medals, and medallions, a mixture containing 75% Cu and 25% Ni powders is blended with zinc stearate lubricant and compressed, sintered, coined, and re-sintered to produce blanks suitable for striking. These blanks are softer than rolled blanks because they are produced from high-purity materials. Therefore, they can be coined at relatively low pressures, and it is possible to achieve greater relief depth with reduced die wear.

In another procedure, an organic binder is mixed with copper or copper-nickel powders and rolled into "green" sheets. Individual copper and copper-nickel sheets are pressed together to form a laminate, and blanks are punched from it. Blanks are heated in hydrogen to remove the organic binder and sinter the material. The density of the "green" blanks is low (45% of theoretical), but coining increases density to 97%. After pressing, the blanks are annealed to improve ductility and coinability.

## ***Copper-Lead P/M Parts***

Copper and lead, which have limited solubilities in each other, are difficult to alloy by conventional ingot metallurgy. Copper-lead powder mixtures have excellent cold pressing properties; they can be compacted at pressures as low as 76 MPa (11 ksi) to densities as high as 80% of theoretical density. After sintering, they can be repressed at pressures as low as 152 MPa (22 ksi) to produce essentially nonporous bearings.

Steel-backed copper or copper-lead-tin P/M materials are sometimes used to replace solid bronze bearings. They are produced by spreading the powder in a predetermined thickness on a steel strip, sintering, rolling to theoretical density, resintering, and annealing. The end product has a residual porosity of  $\sim 0.25\%$ . Blanks of suitable size are cut from the bimetallic strip, formed, and drilled with oil holes or machined to form suitable grooves. These materials include Cu-25Pb-0.5Sn, Cu-25Pb-3.5Sn, Cu-10Pb-10Sn, and Cu-50P-1.5Sn alloys.

## Copper-Base P/M Friction Materials

Sintered metal-based friction materials are used in applications involving the transmission of motion through friction (clutches), and for deceleration and stopping (brakes). In these applications, mechanical energy is converted into frictional heat, which is absorbed and dissipated by the friction material. Copper-base materials are preferred because of their high thermal conductivity; however, low cost iron-base materials have been developed for moderate to severe duty dry applications.

Most friction materials contain copper powders blended with other metal powders, solid lubricants, oxides, and other compounds. These constituents are immiscible in each other, and therefore, can only be made by powder metallurgy. Table 7 shows compositions of some common copper-base friction materials.

**Table 7 Compositions of some common copper-base friction materials**

Composition, wt%							Use <sup>(a)</sup>
Cu	Sn	Fe	Pb	Graphite	MoS <sub>2</sub>	Other	
60-75	4-10	5-10	...	3-10	3-12	2-7 SiO <sub>2</sub>	D
52.5	...	...	7.5	...	...	5 SiO <sub>2</sub> ; 15 Bi	W
72	4.7	3.3	3.5	8.7	1.4	1.9 SiO <sub>2</sub> ; 0.2 Al <sub>2</sub> O <sub>3</sub>	W, D
72	7	3	6	6	...	3 SiO <sub>2</sub> ; 4 MoO <sub>3</sub>	D
62	7	8	12	7	...	4 sand	D
74	3.5	...	...	16	...	2 Sb; 4.5 SiO <sub>2</sub>	D

(a) W, wet; D, dry. See Fig. 7.

Mixtures of the appropriate powders are carefully blended to minimize segregation of the constituents. Fine metal powders with high-surface area are necessary to provide a strong and thermally conductive matrix. The blended powders are compacted at pressures ranging from 165 to 275 MPa (24 to 40 ksi).

Bell-type sintering furnaces are used where the friction facing is bonded to a supporting steel backing plate such as in clutch disks. The green disks are placed on the copper-plated steel plates and stacked. Pressure is applied on the vertical stack of disks. Sintering temperatures range from 550 to 950 °C (1020 to 1740 °F) in a protective atmosphere. Typical sintering times are 30 to 60 min. The sintered parts are typically machined for dimensional accuracy and surface parallelism.

The friction elements are usually brazed, welded, riveted, or mechanically fastened to the supporting steel members. They may also be pressure bonded directly to the assembly.

## Copper-Base P/M Electrical Contact Materials

Copper-base materials are used in electrical contacts because of their high electrical and thermal conductivities, low cost, and ease of fabrication. Their main drawbacks are poor resistance to oxidation and corrosion. Therefore, copper-base

contacts are used in applications where the voltage drop resulting from the oxide film is acceptable or where it is possible to protect the contact, such as by immersion in oil or by enclosing the contact in a protective gas or vacuum.

Common copper alloys used in contacts include yellow brass (C27000), phosphor bronze (C51000), and copper-beryllium alloys (C17200 and C17500). These are made by the melt-cast process and are limited to lower current applications where arcing and welding are not severe.

Composites of copper with refractory metals (Cu-W) or their carbides (Cu-WC) are used in applications in which limited oxidation of the copper is acceptable or where oxidation is prevented by one of the methods mentioned previously. The properties of the contacts depend on the manufacturing method used. The specific method used depends on the composition of the composite. As a general rule-of-thumb, materials with 40% or less tungsten or tungsten carbide are manufactured by the conventional pressing, sintering (generally below the melting point of copper), and repressing technique. Materials containing more than 40% tungsten are generally made by infiltrating the copper into either loose tungsten powder or pressed-and-sintered tungsten compacts. Their counterparts using tungsten carbide are made by infiltrating the copper into loose powder because the tungsten carbide powder cannot be pressed into compacts. Additional information on copper-base electrical contact materials can be found in the Section "Special-Purpose Materials" in this Handbook.

### ***Copper-Base P/M Brush Materials***

Brushes are components that transfer electrical current between the stationary and rotating elements in electric motors and generators. Most common brushes are made from composites of graphite and a conductive metal. The graphite provides the required lubrication and the metal provides the current-carrying capability; copper and silver are preferred metals because of their high-electrical conductivity.

The copper content in typical copper-graphite brush materials varies from  $\sim 20$  to 75%, with the balance being graphite. Powder metallurgy is the only way to produce these materials because of the immiscibility of the two components. Copper powder used in the brushes could be made by oxide reduction, electrodeposition, atomization, or flaking.

The manufacture of brushes involves blending the copper and graphite powders. These are molded into brushes or large blocks, typically at pressures ranging from 100 to 200 MPa (15 to 30 ksi), providing green densities of 2 to 4 g/cm<sup>3</sup>. The molded parts are sintered at 500 to 800 °C (950 to 1500 °F) in a protective atmosphere. Machining is performed if necessary to achieve the final dimensional tolerances.

Copper-graphite brushes are widely used in battery-powered tools that require high power outputs in small, lightweight packages. Typically, input voltage influences the metal content required. High voltages require a low-metal content whereas low voltages require a high-metal content. Below 9 V, the metal content is usually higher than 80% while above 18 V, the metal content is generally below 50%.

Copper-graphite brushes are also used extensively in automotive applications including starter motors, blower motors, doorlocks, and windshield wiper motors. The starter motors generally used high-copper content grades to enable them to handle extremely high-current densities for short periods of time. Blower motors use lower-copper content grades to extend service life to several thousand hours. The doorlocks and windshield wiper motors use grades that are between the blower and starter motor grades.

### ***Infiltrated Parts***

Iron-base P/M parts can be infiltrated with copper or a copper alloy by placing a slug of the infiltrant on the part and then sintering above the melting point of the infiltrant. The molten infiltrant is completely absorbed in the pores by capillary action and a composite structure is created. The amount of infiltrant used is limited by the pore volume in the starting iron part and typically ranges between 15 and 25%.

Infiltration increases the density of the part, resulting in improved mechanical properties, corrosion resistance, electrical and thermal conductivities, machinability, and brazeability. Tensile strengths ranging from 480 to 620 MPa (70 to 90 ksi) can be achieved in iron-base parts infiltrated with 15 to 25% copper.

Infiltration is used for iron-base structural parts that much have densities  $>7.4$  g/cm<sup>3</sup>. Typical examples include gears, automatic transmission components, valve seat inserts, automobile door hinges, etc.

## **Oxide-Dispersion-Strengthened Copper P/M Materials**

Copper is widely used in industry because of high electrical and thermal conductivities, but it has low strength, particularly when heated to high temperatures. It can be strengthened by using finely dispersed particles of stable oxides such as alumina, titania, beryllia, thoria, or yttria in the matrix. Because these oxides are immiscible in liquid copper, dispersion-strengthened copper cannot be made by conventional ingot metallurgy; powder metallurgy techniques must be used.

### ***Manufacture***

Oxide-dispersion-strengthened (ODS) copper can be made by simple mechanical mixing of the copper and oxide powders, by coprecipitation from salt solutions, by mechanical alloying, or by selective or internal oxidation. Dispersion quality and cost vary substantially among these methods; internal oxidation produces the finest and most uniform dispersion. Aluminum oxide is a common dispersoid used in the manufacture of ODS copper.

In internal oxidation, an atomized copper-aluminum alloy is internally oxidized at elevated temperature. This process converts the aluminum into aluminum oxide. Size and uniformity of dispersion of the aluminum oxide depend on several process parameters. Consolidation of the powder to full density and/or various mill forms is accomplished by various techniques. Mill forms, such as rod and bar, are made by canning the powder in a suitable metal container (generally copper) and hot extruding it to the desired size. Wire is made by cold drawing coils of rod. Strip is made either by rolling coils of extruded rectangular bar or by directly rolling powder with or without a metal container. Large shapes that cannot be made by hot extrusion are made by hot isostatic pressing of canned powder; alternatively, such shapes can be made by hot forging canned powder or partially dense compacted preforms.

Properties of the consolidated material depend on the amount of deformation introduced into the powder particles. Consequently, low-deformation processes such as hot isostatic pressing and, to a lesser extent, hot forging develop materials with lower strengths and ductilities than those produced by extrusion.

Finished parts can be made from consolidated shapes by machining, brazing, and soldering. Fusion welding is not recommended because it causes the aluminum oxide to segregate from the liquid copper matrix, resulting in a loss of dispersion strengthening. However, flash welding, in which the liquid metal is squeezed out of the weld joint, and electron beam welding, in which a small heat-affected zone is created, have been used successfully. Solid-state welding (with multiple cold upsets in a closed die) has also been used with success to join smaller coils into a large coil for wire drawing.

### ***Properties***

Oxide-dispersion-strengthened copper offers a unique combination of high-strength and high-electrical and thermal conductivities. More important, it retains a larger portion of these properties during and after exposure to elevated temperatures than any other copper alloy.

The properties of ODS copper can be modified to meet a wide range of design requirements by varying the aluminum oxide content and/or the amount of cold work. Figure 7 shows the ranges in tensile strength, elongation, hardness, and electrical conductivity obtained as a function of aluminum/aluminum oxide contents. These properties are typical for rod stock in the hot extruded condition. Cold work can be used to broaden the ranges in tensile strength, elongation, and hardness; the effect on electrical conductivity is minimal.

Fig. 7 Properties of three ODS coppers

Three grades of ODS copper are commercially available. They are designated as C15715, C15725, and 15760 by the Copper Development Association Inc. The nominal compositions of these three grades are:

Grade	Copper		Aluminum oxide	
	wt%	vol%	wt%	vol%
<b>C15715</b>	99.7	99.3	0.3	0.7
<b>C15725</b>	99.5	98.8	0.5	1.2
<b>C15760</b>	98.9	97.3	1.1	2.7

The free or reducible oxygen content of the three ODS coppers, generally  $\sim 0.02$  to  $0.05$  wt%, is present in the form of dissolved oxygen and cuprous oxide. Alloys in this state are prone to hydrogen embrittlement at high temperatures. Low-oxygen (LOX) compositions are available in all of these grades, at which the reducible oxygen is converted to nonreducible oxide by adding up to  $0.020$  wt% boron as the oxygen getter. These grades are then immune to hydrogen embrittlement and must be specified for applications in which the components are likely to be subjected to reducing atmospheres during manufacture or use.

**Physical Properties.** Because ODS copper contains small amounts of aluminum oxide as discrete particles in an essentially pure copper matrix, the physical properties closely resemble those of pure copper. Table 8 shows physical properties of the three commercial ODS coppers comparing them with oxygen-free (OF) copper. The melting point is essentially the same for copper because the matrix melts and the aluminum oxide separates from the melt. Density, modulus of elasticity, and coefficient of thermal expansion are similar to those of pure copper.

**Table 8 Physical properties of three oxide-dispersion-strengthened (ODS) coppers and oxygen-free (OF) copper**

Property	Material			
	C15715	C15725	C15760	OF Copper
<b>Melting point, °C (°F)</b>	1083 (1981)	1083 (1981)	1083 (1981)	1083 (1981)
<b>Density, g/cm<sup>3</sup> (lb/in.)</b>	8.90 (0.321)	8.86 (0.320)	8.81 (0.318)	8.94 (0.323)
<b>Electrical resistivity at 20 °C (68 °F), <math>\Omega \cdot \text{mm}^2/\text{m}</math> (<math>\Omega \cdot \text{circular mil/ft}</math>)</b>	0.0186 (11.19)	0.0198 (11.91)	0.0221 (13.29)	0.017 (10.20)
<b>Electrical conductivity at 20 °C (68 °F), %IACS</b>	92	87	78	101
<b>Thermal conductivity at 20 °C (68 °F), W/m · K (Btu/ft · h · °F)</b>	365 (211)	344 (199)	322 (186)	391 (226)
<b>Linear coefficient of thermal expansion for 20 to 1000 °C (68 to 1830 °F), ppm/°C (ppm/°F)</b>	16.6 (9.2)	16.6 (9.2)	16.6 (9.2)	17.7 (9.8)
<b>Modulus of elasticity, GPa (10<sup>6</sup> psi)</b>	130 (19)	130 (19)	130 (19)	115 (17)

High-electrical and thermal conductivities are particularly interesting to design engineers in the electrical and electronics industries. At room temperature, these range from 78 to 92% of those for pure copper. Coupled with the high strengths of these materials, they enhance the current-carrying or heat-dissipating capabilities for given section size and structural strength. Alternatively, they enable reduction of section sizes for component miniaturization without sacrificing structural strength or current and heat-carrying capabilities. At elevated temperatures, the decrease in electrical and thermal conductivities of ODS coppers closely parallel those of pure copper.

**Room-Temperature Mechanical Properties.** Table 9 shows the room-temperature mechanical properties of ODS C15715 in available mill forms. These cover a wide range of sizes, typified by various amounts of cold work by drawing and rolling, for example. Oxide-dispersion-strengthened copper has strength comparable to many steels and conductivity comparable to copper.

**Table 9 Typical room-temperature mechanical properties of C15715**

Shapes	Thickness or diameter		Temper or condition <sup>(a)</sup>	Tensile strength		Yield strength		Elongation, %	Hardness, HRB

(a) A-C, as consolidated; CW, cold work/% reduction in area; HT, heat treatment for 1 h

Oxide-dispersion-strengthened copper has excellent resistance to softening even after exposure to temperatures close to the melting point of copper because the aluminum oxide particles are stable at these temperatures and retain their original size and spacing. These particles block dislocation and grain boundary motion and thus prevent recrystallization, which is normally associated with softening. Figure 8 compares the softening behavior of C15715 strip with OF Copper (C10200) and a copper-zirconium (C15000) alloy. At common brazing and glass-to-metal sealing temperatures (above 600 °C, or 1110 °F) encountered in practice, ODS coppers retain much of their strength while OF copper and copper-zirconium lose most of their strength. Therefore, ODS copper is used in applications in which the component manufacture involves high-temperature operations such as brazing, glass-to-metal sealing, hot isostatic pressing, diffusion bonding, etc.

**Fig. 8** Softening behavior of oxide-dispersion-strengthened (ODS) coppers compared to oxygen-free (OF) copper and copper-zirconium alloy

**Elevated-Temperature Mechanical Properties.** ODS copper has excellent strength at elevated temperatures. Figure 9 shows the 100 h stress-rupture strengths of C15760 and C15715 at temperatures up to 870 °C (1600 °F). Other high-conductivity copper-base materials are shown for comparison. Ranging from pure copper on the low end to precipitation-hardened alloys on the high end, there is a sharp drop in stress-rupture strength in the 200 to 450 °C (400 to 850 °F) temperature range. Above 400 °C (750 °F), the ODS coppers are superior to any of the other alloys. Above 600 °C (1100 °F), the ODS coppers have rupture strengths comparable or superior to some stainless steels. Oxide-dispersion-strengthened copper has excellent thermal stability at high temperatures because the aluminum oxide particles retain their original particle size and spacing even after prolonged heating and do not allow recrystallization of the matrix. Cold work significantly enhance the stress-rupture properties of ODS copper; the higher the temperature, the more noticeable the enhancement.

**Fig. 9** Elevated-temperature stress-rupture properties of oxide-dispersion-strengthened copper compared to several high-conductivity copper alloys

## Applications

The combination of high-electrical and thermal conductivity, outstanding corrosion resistance, ease of fabrication, and retainment of high strength at elevated temperatures make ODS copper useful in many applications. Dispersion-strengthened copper enhances the current-carrying or heat-dissipating capabilities for a given section size and structural strength. Alternatively, it enables reduction of section sizes for component miniaturization. Major application areas include:

- Resistance welding electrodes
- Metal inert gas (MIG) welding contact tips
- Lead wires for incandescent lamps
- X-ray and microwave tube components
- Relay blades and contact supports
- Sliding electrical contacts
- Particle accelerator components used for physics and materials research
- Hybrid circuit package components
- Electrodes for electrical discharge machining (EDM) operations

# Thermal Softening and Stress Relaxation in Copper

## Introduction

COPPER AND COPPER ALLOYS are used extensively in structural applications in which they are subject to moderately elevated temperatures. Examples include automotive radiators, solar heating panels, communications cable, and electrical connectors. At relatively low operating temperatures, these alloys can undergo thermal softening (degradation of strength/hardness) or stress relaxation (decrease in stress resulting from transformation of elastic strain into plastic strain in a constrained solid), which can lead to service failures. Because of the wide variations in composition and processing among commercial copper alloys, resistance to thermal softening and stress relaxation varies considerably. Of course, selection of an alloy for a given application is based not only on stress-time temperature response but also on such factors as cost, basic mechanical and physical properties, operating temperature, service environment, and formability. For many applications, electrical conductivity is a primary consideration.

## Thermal Softening Data

At temperatures lower than those inducing recrystallization in commercial heat treatments, thermal softening can occur over extended periods. If resistance to softening at slightly elevated temperature is required, C11100 is often specified. This copper contains a small amount of cadmium, which raises the temperature at which recovery and recrystallization occur. Oxygen-free copper, electrolytic tough pitch copper, and fire-refined tough pitch copper are available as silver-bearing coppers having specific minimum silver contents. The silver, which may be present as an impurity in anode copper or may be intentionally alloyed to molten cathode copper, also imparts resistance to softening to cold-worked metal. Silver-bearing coppers and cadmium-bearing coppers are used for applications such as automotive radiators and electrical conductors that must operate at temperatures above about 200 °C (400 °F).

Adding small amounts of elements such as silver, cadmium, iron, cobalt, and zirconium to deoxidized copper imparts resistance to softening at the times and temperatures encountered in soldering operations, such as those used to join components of automobile and truck radiators, and those used in semiconductor packaging operations. Thermal and electrical conductivities and room-temperature mechanical properties are unaffected by small additions of these elements. However, cadmium-copper and zirconium-copper work harden at higher rates than either silver-bearing copper or electrolytic tough pitch copper.

Cold-rolled silver-bearing copper is used extensively for automobile radiator fins. Usually such strip is only moderately cold rolled because heavy cold rolling makes silver-bearing copper more likely to soften during soldering or baking

operations. Some manufacturers prefer cadmium-copper C14300 because it can be severely cold rolled without making it susceptible to softening during soldering. Figure 1 illustrates the softening characteristics of C14300 and C11400 as measured for several temperatures and two tempers. As shown in Fig. 1(b), C14300 cold rolled to a tensile strength of 400 MPa (64 ksi) retains 91% strength after a typical core bake of 3 min at 345 °C (650 °F). Silver-bearing copper C11400 given the same cold reduction retains only 60% tensile strength after the same baking schedule.

**Fig. 1** Softening characteristics of cadmium-bearing copper (C14300 represented by solid curves) and silver-bearing tough pitch copper (C11400 represented by dashed curves). (a) Softening curves for material cold reduced 21% in area, from 0.1 to 0.075 mm (0.0038 to 0.0030 in.) in thickness. (b) Softening curves for material cold reduced 90% in area, from 0.75 to 0.075 mm (0.0300 to 0.0030 in.) in thickness

Another application in which softening resistance is of paramount importance is lead frames for electronic devices, such as plastic dual-in-line packages. During packaging and assembly, lead frames may be subjected to temperatures up to 350 °C (660 °F) for several minutes and up to 500 °C (930 °F) for several seconds. The leads must maintain good strength because they are pressed into socket connectors, often by automated assembly machines; softened leads collapse, causing spoilage.

Alloy C15100 (copper-zirconium), alloy C15500 (copper-silver-magnesium-phosphorus), alloy C19400 (copper-iron-phosphorus-zinc), and alloy C19500 (copper-iron-cobalt-tin-phosphorus) are popular for these applications because they have good conductivity, good strength, and good softening resistance. Figures 2 and 3 compare the softening resistance of these alloys with electrolytic copper C11000.

Fig. 2 Softening resistance of lead frame materials at the upper temperature limit (500 °C, or 930 °F)

Fig. 3 Softening resistance of lead frame materials at an intermediate temperature level (350 °C, or 660 °F)

## Stress-Relaxation Data

When an external stress is applied to a piece of metal, it reacts by developing an equal and opposite internal stress. If the metal is held in this strained position, the internal stress will decrease as a function of time. This phenomenon is called stress relaxation and happens because of the transformation of elastic strain in the material to plastic, or permanent strain. The reduction-of-stress rate will be a function of alloy, temper, temperature, and time.

Unalloyed copper C11000 (electrolytic tough pitch) is probably the most inexpensive high-conductivity copper and is used extensively because of the ease of fabrication. The stress-relaxation behavior of this material is rather poor, as demonstrated in Fig. 4, in which relaxed stress is plotted as a function of time and temperature for 0.25 mm (0.010 in.) C11000 wire initially stressed in tension to 89 MPa (13 ksi). Comparison of stress values at a given time for different temperatures illustrated the very sharp dependence of stress relaxation on temperature for this copper. At 93 °C (200 °F), for example, no tension remains after  $10^5$  h (11.4 years), whereas 40% of the initial stress remains after 40 years at room temperature. For C11000 and for many other copper metals, stress relaxation in a given time period is inversely proportional to absolute temperature (Ref 1).

Fig. 4 Tensile-stress-relaxation characteristics of C11000. Data are for tinned 30 AWG (0.25 mm diam) annealed ETP copper wire; initial elastic stress, 89 MPa (13 ksi).

The stress-relaxation behavior of C10200 (oxygen-free copper) is somewhat better than that of C11000, as shown in Table 1, which also presents stress-relaxation data for other high-conductivity copper metals. A more extensive comparison of the mechanical behavior of C10200 and C11000 is presented in Ref 2.

**Table 1 10,000 h tensile-stress-relaxation data for selected types of tinned copper wire**

Alloy	Temper	Temperature		Initial stress <sup>(a)</sup>		Stress remaining, %
		°C	°F	MPa	ksi	
C10200	O61	27	80	82	11.9	69
C11000	O61	23	73	89	12.9	60
C15000	H04 <sup>(b)</sup>	23	73	203	29.5	93

(a) Initial stress set at ~55% of 0.2% offset yield strength.

(b) In-process strand anneal.

(c) Batch annealed.

Among the high-conductivity coppers, relaxation is greatest in very-high-purity copper (99.999+%)--a material used mainly in research. Improvement in the stress-relaxation behavior of high-conductivity copper can be achieved by adding alloying elements that cause solid-solution strengthening, age hardening, or dispersion hardening (Ref 3). For example, minute additions of silver significantly reduce stress relaxation in copper (Ref 4, 5).

Lower-conductivity alloys, which are strengthened by alloy additions or precipitation hardening, exhibit improved resistance to stress relaxation, compared to pure copper. Figure 5 gives stress-relaxation data for a precipitation-hardened beryllium copper alloy (C17200). The performance of any particular material will be dependent on the chemical composition, condition, and temperature at which it is tested. For materials that are strengthened by cold rolling, several general comments can be made. First, the amount of relaxation that will occur during a given time at a certain temperature will increase with increasing amounts of prior cold work. Second, the performance of these materials can vary depending on the orientation of the test sample to the rolling direction. Finally, the performance of heavily cold-rolled materials can be improved by stress-relief annealing (Ref 6 and 7). Figure 6 illustrates these effects for copper alloyed with 5% Sn (C51000).

**Fig. 5** Stress relaxation in C17200 at two levels of initial stress. Data are for beryllium copper (1.9% Be) strip, 0.38 mm (0.015 in.) thick. Open symbols represent initial test stress equal to 80% of the monotonic bending yield stress; solid symbols represent initial stress 50% of the bending yield stress. This alloy has adequate resistance to stress relaxation at temperatures up to 120 °C (250 °F), provided the initial stress is below the elastic limit.

**Fig. 6** Anisotropic stress-relaxation behavior in bending for highly cold-worked C51000 strip. Data are for 5% Sn phosphor bronze cold rolled 93% (reduction in area) to 0.25 mm (0.01 in.) and heat treated 2 h at 260 °C (500 °F). Graphs at left are for stress relaxation transverse to the rolling direction; graphs at right, for stress relaxation parallel to the rolling direction. Initial stresses: as rolled, parallel orientation, 607 MPa (88 ksi); as rolled, transverse orientation, 634 MPa (92 ksi); heat treated, parallel orientation, 641 MPa (93 ksi); heat treated, transverse orientation, 738 MPa (107 ksi)

Table 2 provides bending stress-relaxation data at 75 °C (165 °F) for solid-solution and dispersion hardened copper alloys commonly used in electrical and electronic spring applications. Tensile strength and electrical conductivity values also are tabulated. In general, the resistance to stress relaxation, as measured by percentage of stress remaining, increases with solute hardening additions but with some sacrifice in electrical conductivity. It should be noted that stress relaxation resistance can be expected to decrease with increasing tensile strength (temper) for a given alloy.

**Table 2 Bending-stress-relaxation data at 75 °C for commonly used electronic spring materials**

Alloy	Conductivity, % IACS	Tensile strength		Stress remaining <sup>(a)</sup> , %	
		MPa	ksi	1000 h	10 <sup>5</sup> h
<b>C15100</b>	90	434	63	81	74
<b>C19400</b>	65	448	65	88	83
<b>C19500</b>	50	586	85	79	72

<b>C26000</b>	28	565	82	74	63
<b>C42500</b>	28	565	82	87	80
<b>C51000</b>	15	483	70	92	86
<b>C65400</b>	7	779	113	87	80
<b>C68800</b>	18	800	116	82	73
<b>C72500</b>	11	613	89	90	87
<b>C75200</b>	9	620	90	93	90

(a) The values for percentage of stress remaining at  $10^5$  h are extrapolated from 1000 h test data. Initial stress level was  $\sim 80\%$  of the 0.2% offset yield stress.

# Corrosion Characteristics of Copper and Copper Alloys

## Introduction

COPPER AND COPPER ALLOYS are widely used in many environments and applications because of their excellent corrosion resistance, which is coupled with combinations of other desirable properties, such as superior electrical and thermal conductivity, ease of fabricating and joining, wide range of attainable mechanical properties, and resistance to biofouling. Copper corrodes at negligible rates in unpolluted air, water, and deaerated nonoxidizing acids. Copper alloy

artifacts have been found in nearly pristine condition after having been buried in the earth for thousands of years, and copper roofing in rural atmospheres has been found to corrode at rates of less than 0.4 mm (15 mils) in 200 years. Copper alloys resist many saline solutions, alkaline solutions, and organic chemicals. However, copper is susceptible to more rapid attack in oxidizing acids, oxidizing heavy-metal salts, sulfur, ammonia (NH<sub>3</sub>), and some sulfur and NH<sub>3</sub> compounds. Resistance to acid solution depends mainly on the severity of oxidizing conditions in the solution. Reaction of copper with sulfur and sulfides to form copper sulfide (CuS or Cu<sub>2</sub>S) usually precludes the use of copper and copper alloys in environments known to contain certain sulfur species.

Copper and copper alloys provide superior service in many of the applications included in the following general classifications:

- Applications requiring resistance to atmospheric exposure, such as roofing and other architectural uses, hardware, building fronts, grille work, hand rails, lock bodies, doorknobs, and kick plates
- Freshwater supply lines and plumbing fittings, for which superior resistance to corrosion by various types of waters and soils is important
- Marine applications--most often freshwater and seawater supply lines, heat exchangers, condensers, shafting, valve stems, and marine hardware--in which resistance to seawater, hydrated salt deposits, and biofouling from marine organisms is important
- Heat exchangers and condensers in marine service, steam power plants, and chemical process applications, as well as liquid-to-gas or gas-to-gas heat exchangers in which either process stream may contain a corrosive contaminant
- Industrial and chemical plant process equipment involving exposure to a wide variety of organic and inorganic chemicals
- Electrical wiring, hardware, and connectors; printed circuit boards; and electronic applications that require demanding combinations of electrical, thermal, and mechanical properties, such as semiconductor packages, lead frames, and connectors

## Forms of Corrosion

Coppers and copper alloys, like most other metals and alloys, are susceptible to several forms of corrosion, depending primarily on environmental conditions. Table 1 lists the identifying characteristics of the forms of corrosion that commonly attack copper metals as well as the most effective means of combating each.

**Table 1 Guide to corrosion of copper alloys**

Form of attack	Characteristics	Preventive measures
<b>General thinning</b>	Uniform metal removal	Select proper alloy for environmental conditions based on weight loss data
<b>Galvanic corrosion</b>	Corrosion preferentially near a more cathodic metal	Avoid electrically coupling dissimilar metals; maintain optimum ratio of anode to cathode area; maintain optimum concentration of oxidizing constituent in corroding medium
<b>Pitting</b>	Localized pits, tubercles; water line pitting; crevice corrosion; pitting under foreign objects or dirt	Alloy selection; design to avoid crevices; keep metal clean
<b>Impingement: erosion-corrosion cavitation</b>	Erosion attack from turbulent flow plus dissolved gases, generally as lines of pits in direction of fluid flow	Design for streamlined flow; keep velocity low; remove gases from liquid phase; use erosion-resistant alloy

<b>Fretting</b>	Chafing or galling, often occurring during shipment	Lubricate contacting surfaces; interleave sheets of paper between sheets of metal; decrease load on bearing surfaces
<b>Intergranular corrosion</b>	Corrosion along grain boundaries without visible signs of cracking	Select proper alloy for environmental conditions based on metallographic examination of corrosion specimens
<b>Dealloying</b>	Preferential dissolution of zinc or nickel, resulting in a layer of sponge copper	Select proper alloy for environmental conditions based on metallographic examination of corrosion specimens
<b>Corrosion fatigue</b>	Several transgranular cracks	Select proper alloy based on fatigue tests in service environment; reduce mean or alternating stress
<b>Stress-corrosion cracking (SCC)</b>	Cracking, usually intergranular but sometimes transgranular, that is often fairly rapid	Select proper alloy based on stress-corrosion tests; reduce applied or residual stress; remove mercury compounds or $\text{NH}_3$ from environment

### ***General Corrosion***

General corrosion is the well-distributed attack of an entire surface with little or no localized penetration. It is the least damaging of all forms of attack. General corrosion is the only form of corrosion for which weight loss data can be used to estimate penetration rates accurately.

General corrosion of copper alloys results from prolonged contact with environments in which the corrosion rate is very low, such as fresh, brackish, and salt water; many types of soil; neutral, alkaline, and acid salt solutions, organic acids; and sugar juices. Other substances that cause uniform thinning at a faster rate include oxidizing acids, sulfur-bearing compounds,  $\text{NH}_3$ , and cyanides.

### ***Galvanic Corrosion***

An electrochemical potential almost always exists between two dissimilar metals when they are immersed in a conductive solution. If two dissimilar metals are in electrical contact with each other and immersed in a conductive solution, a potential results that enhances the corrosion of the more electronegative member of the couple (the anode) and partly or completely protects the more electropositive member (the cathode). Copper metals are almost always cathodic to other common structural metals, such as steel and aluminum. When steel or aluminum is put in contact with a copper metal, the corrosion rate of the steel or aluminum increases, but that of the copper metal decreases. The common grades of stainless steel exhibit variable behavior; that is, copper metals may be anodic or cathodic to the stainless steel, depending on conditions of exposure. Copper metals usually corrode preferentially when coupled with high-nickel alloys, titanium, or graphite.

Corrosion potentials of copper metals generally range from -0.2 to -0.4 V when measured against a saturated calomel electrode (SCE); the potential of pure copper is about -0.3 V. Alloying additions of zinc or aluminum move the potential toward the anodic (more electronegative) end of the range; additions of tin or nickel move the potential toward the cathodic (less electronegative) end. Galvanic corrosion between two copper metals is seldom a significant problem, because the potential difference is so small.

Table 2 lists a galvanic series of metals and alloys valid for dilute aqueous solutions, such as seawater and weak acids. The metals that are grouped together can be coupled to each other without significant galvanic damage. However, the connecting of metals from different groups leads to damage of the more anodic metal; the larger the difference in galvanic potential between groups, the greater the corrosion. Accelerated damage due to galvanic effects is usually greatest near the junction, where the electrochemical current density is the highest.

Cathodic end

Another factor that affects galvanic corrosion is area ratio. An unfavorable area ratio exists when the cathodic area is large and the anodic area is small. The corrosion rate of the small anodic area may be several hundred times greater than if the anodic and cathodic areas were equal in size. Conversely, when a large anodic area is coupled to a small cathodic area, current density and damage due to galvanic corrosion are much less. For example, copper rivets (cathodic) used to fasten steel plates together lasted longer than 1.5 years in seawater, but steel rivets used to fasten copper plates were completely destroyed during the same period.

Five principal methods are available for eliminating or significantly reducing galvanic corrosion:

- Select dissimilar metals that are as close as possible to each other in the galvanic series
- Avoid coupling small anodes to large cathodes
- Insulate dissimilar metals completely wherever practicable
- Apply coatings and keep them in good repair, particularly on the cathodic member
- Use a sacrificial anode; that is, couple the system to a third metal that is anodic to both structural metals

## ***Pitting***

As with most commercial metals, corrosion of copper metals results in pitting under certain conditions. Pitting is sometimes general over the entire surface, giving the metal an irregular and roughened appearance. In other cases, pits are concentrated in specific areas and are of various sizes and shapes.

**Localized pitting** is the most damaging form of corrosive attack because it reduces load-carrying capacity and increases stress concentration by creating depressions or holes in the metal. Pitting is the usual form of corrosive attack at surfaces on which there are incomplete protective films, nonprotective deposits of scale, or extraneous deposits of dirt or other foreign substances.

In seawater, pitting tends to occur more often under conditions of relatively low water velocity, typically less than 0.6 to 0.9 m/s (2 to 3 ft/s). The occurrence of pitting is somewhat random regarding the specific location of a pit on the surface as well as whether it will even occur on a particular metal sample. Long-term tests of copper alloys show that the average pit depth does not continually increase with extended times of exposure. Instead, pits tend to reach a certain limit beyond which little apparent increase in depth occurs. Of the copper alloys, the most pit resistant are the aluminum bronzes with less than 8% Al and the low-zinc brasses. Copper nickels and tin bronzes tend to have intermediate pitting resistance, but the high-copper alloys and silicon bronzes are somewhat more prone to pitting.

**Crevice corrosion** is a form of localized corrosion that occurs near a crevice formed either by two metal surfaces or a metal and a nonmetal surface. Like pitting, crevice attack is a random occurrence, the precise location of which cannot always be predicted. Also, like pitting, the depth of attack appears to level off rather than to increase continually with time. This depth is usually less than that from pitting, and for most copper alloys, it will be less than 400  $\mu\text{m}$  (15.8 mils).

For most copper alloys, the location of the attack will be outside but immediately adjacent to the crevice due to the formation of metal ion concentration cells. Classic crevice corrosion resulting from oxygen depletion and attack within crevices is less common in copper alloys. Aluminum- and chromium-bearing copper alloys, which form more passive surface films, are susceptible to differential oxygen cell attack, as are aluminum alloys and stainless steels.

Local cell action similar to crevice attack can also result from the presence of foreign objects or debris, such as dirt, pieces of shell, or vegetation, or it may result from rust, permeable scales, or uneven accumulation of corrosion product on the metallic surface. This type of attack can sometimes be controlled by cleaning the surfaces. For example, condensers and heat exchangers are cleaned periodically to prevent deposit attack.

**Water line attack** is a term used to describe pitting due to a differential oxygen cell functioning between the well-aerated surface layer of a liquid and the oxygen-starved layer immediately beneath it. The pitting occurs immediately below the water line.

### ***Impingement***

Various forms of impingement attack occur where gases, vapors, or liquids impinge on metal surfaces at high velocities, such as in condensers or heat exchangers. Rapidly moving turbulent water can strip away the protective films from copper alloys. When this occurs, the metal corrodes at a more rapid rate in an attempt to reestablish this film, but because the films are being swept away as rapidly as they are being formed, the corrosion rate remains constant and high.

**Erosion-corrosion** is characterized by undercut grooves, waves, ruts, gullies, and rounded holes; it usually exhibits a directional pattern. Pits are elongated in the direction of flow and are undercut on the downstream side. When the corrosion becomes severe, it may result in a pattern of horseshoe-shaped grooves or pits with their open ends pointing downstream. As attack progresses, the pits may join, forming fairly large patches of undercut pits. When this form of corrosion occurs in a condenser tube, it is usually confined to a region near the inlet end of the tube where fluid flow is rapid and turbulent. If some of the tubes in a bundle become plugged, the velocity is increased in the remaining tubes; therefore, the unit should be kept as clean as possible. Erosion-corrosion is most often found with waters containing low levels of sulfur compounds and with polluted, contaminated, or silty salt water or brackish water. The erosive action locally removes protective films, thus contributing to the formation of concentration cells and to localized pitting of anodic sites.

**Cavitation** is a phenomenon that occurs in moving water when the flow is disturbed so as to create a local pressure drop. Under these conditions, a vapor bubble will form and then collapse, applying a momentary stress of up to 1379 MPa (200 ksi) to the surface. This repeated mechanical working of the surface creates a local fatigue situation that aids the removal of the metal. The harder alloys tend to have greater resistance to cavitation and there is often an incubation period before the onset of cavitation attack. Of the copper alloys, aluminum bronze has the best cavitation resistance.

Impingement attack can be reduced, and the life of the unit extended, by decreasing fluid velocity, streamlining the flow, and removing entrained air. This is usually accomplished by redesigning water boxes, injector nozzles, and piping to reduce or eliminate low-pressure pockets, obstructions to smooth flow, abrupt changes in flow direction, and other features that cause local regions of high-velocity or turbulent flow. Condensers and heat exchangers are less susceptible to impingement attack if they are made of one of the aluminum brasses or copper nickels, which are more erosion resistant than the brasses or tin brasses. Erosion-resistant inserts at tube inlets and epoxy-type coatings are often effective repair methods in existing shell and tube heat exchangers. When contaminated waters are involved, filtering or screening the liquids and cleaning the surfaces can be very effective in minimizing impingement attack. The use of cathodic protection can lessen all forms of localized attack except cavitation.

### ***Fretting***

Another form of attack, called fretting or fretting corrosion, appears as pits or grooves in the metal surface that are surrounded or filled with corrosion product. Fretting is sometimes referred to as chafing, road burn, friction oxidation, wear oxidation, or galling.

The basic requirements for fretting are as follows:

- Repeated relative (sliding) motion between two surfaces must occur. The relative amplitude of the motion may be very small--motion of only a few tenths of a millimeter is typical
- The interface must be under load
- Both load and relative motion must be sufficient to produce deformation of the interface
- Oxygen and/or moisture must be present

Fretting does not occur on lubricated surfaces in continuous motion, such as axle bearings, but instead on dry interfaces subject to repeated, small relative displacements. A classic type of fretting occurs during shipment of bundles of mill products having flat faces. Fretting is not confined to coppers and copper alloys, but has been recognized on almost every kind of surface--steel, aluminum, noble metals, mica, and glass.

Fretting can be controlled, and sometimes eliminated, by:

- Lubricating with low-viscosity high-tenacity oils to reduce friction at the interface between the two metals and to exclude oxygen from the interface
- Separating the faying surfaces by interleaving an insulating material
- Increasing the load to reduce motion between faying surfaces; this may be difficult in practice, because only a minute amount of relative motion is necessary to produce fretting
- Decreasing the load at bearing surfaces to increase the relative motion between parts

### ***Intergranular Corrosion***

Intergranular corrosion is an infrequently encountered form of attack that occurs most often in applications involving high-pressure steam. This type of corrosion penetrates the metal along grain boundaries--often to a depth of several grains--which distinguishes it from surface roughening. Mechanical stress is apparently not a factor in intergranular corrosion. The alloys that appear to be the most susceptible to this form of attack are Muntz metal, admiralty metal, aluminum brasses, and silicon bronzes.

### ***Dealloying***

Dealloying is a corrosion process in which the more active metal is selectively removed from an alloy, leaving behind a weak deposit of the more noble metal. Copper-zinc alloys containing more than 15% Zn are susceptible to a dealloying process called dezincification. In the dezincification of brass, selective removal of zinc leaves a relatively porous and weak layer of copper and copper oxide. Corrosion of a similar nature continues beneath the primary corrosion layer, resulting in gradual replacement of sound brass by weak, porous copper. Unless arrested, dealloying eventually penetrates the metal, weakening it structurally and allowing liquids or gases to leak through the porous mass in the remaining structure.

The term *plug-type dealloying* refers to the dealloying that occurs in local areas; surrounding areas are usually unaffected or only slightly corroded (Fig. 1). In *uniform-layer dealloying*, the active component of the alloy is leached out over a broad area of the surface (Fig. 2). Dezincification is the usual form of corrosion for uninhibited brasses in prolonged contact with waters high in oxygen and carbon dioxide, CO<sub>2</sub>. It is frequently encountered with quiescent or slowly moving solutions. Slightly acidic water, low in salt content and at room temperature, is likely to produce uniform attack, but neutral or alkaline water, high in salt content and above room temperature, often produces plug-type attack.

**Fig. 1** Plug-type dezincification in an  $\alpha$ -brass (70Cu-30Zn) exposed for 79 days in 1 N NaCl at room temperature. Note porous structure within the plug. The dark line surrounding the plug is an etching artifact. 160×

**Fig. 2** Uniform-layer dezincification in an admiralty brass heat-exchanger tube. The top layer of the micrograph, which consists of porous, disintegrated particles of copper, was from the inner surface of the tube that was exposed to water at pH 8.0, 31 to 49 °C (87 to 120 °F), and 207 kPa (30 psi). Below the dezincified layer is the bright yellow, intact, admiralty brass outer tube wall. 35×

Brasses with copper contents of 85% or more resist dezincification. Dezincification of brasses with two-phase structures is generally more severe, particularly if the second phase is continuous; it usually occurs in two stages: the high-zinc  $\beta$  phase, followed by the lower-zinc  $\alpha$  phase.

Tin tends to inhibit dealloying, especially in cast alloys. Alloys C46400 (naval brass) and C67500 (manganese bronze) which are  $\alpha$ - $\beta$  brasses containing  $\sim 1\%$  Sn, are widely used for naval equipment and have reasonably good resistance to dezincification. Addition of a small amount of phosphorus, arsenic, or antimony to admiralty metal (an all- $\alpha$  71Cu-28Zn-1Sn brass) inhibits dezincification. Inhibitors are not entirely effective in preventing dezincification of the  $\alpha$ - $\beta$  brasses, because they do not prevent dezincification of the  $\beta$  phase.

Where dezincification is a problem, red brass, commercial bronze, inhibited admiralty metal, and inhibited aluminum brass can be successfully used. In some cases, the economic penalty of avoiding dealloying by selecting a low-zinc alloy may be unacceptable. Low-zinc alloy tubing requires fittings that are available only as sand castings, but fittings for high-zinc tube can be die cast or forged much more economically. Where selection of a low-zinc alloy is unacceptable, inhibited yellow brasses are generally preferred.

Dealloying has been observed in other alloys. Dealloying of aluminum occurs in some copper-aluminum alloys, particularly with those having more than 8% Al. It is especially severe in alloys with continuous  $\gamma$  phase and usually occurs as plug-type dealloying. Nickel additions exceeding 3.5% or heat treatment to produce an  $\alpha$ + $\beta$  microstructure prevents dealloying. Dealloying of nickel in C71500 is rare, having been observed at temperatures over 100 °C (212 °F), low flow conditions, and high local heat flux. Dealloying of tin in cast tin bronzes has been observed as a rare occurrence in hot brine or steam. Cathodic protection generally protects all but the two-phase, copper-zinc alloys from dealloying.

## ***Corrosion Fatigue***

The combined action of corrosion (usually pitting corrosion) and cyclic stress may result in corrosion fatigue cracking. Like ordinary fatigue cracks, corrosion fatigue cracks generally propagate at right angles to the maximum tensile stress in the affected region. However, cracks resulting from simultaneous fluctuating stress and corrosion propagate much more rapidly than cracks caused solely by fluctuating stress. Also, corrosion fatigue failure usually involves several parallel cracks, but it is rare for more than one crack to be found in a part that has failed by simple fatigue. The cracks shown in Fig. 3 are characteristic of service failures resulting from corrosion fatigue.

**Fig. 3** Typical corrosion fatigue cracking of a copper alloy. Transgranular cracks originate at the base of corrosion pits on the roughened inner surface of a tube. Etched. Approximately 150×

Ordinarily, corrosion fatigue can be readily identified by the presence of several cracks emanating from corrosion pits. Cracks not visible to the unaided eye or at low magnification can be made visible by deep etching or plastic deformation or can be detected by eddy-current inspection. Corrosion fatigue cracking is often transgranular, but there is evidence that certain environments induce intergranular cracking in copper metals.

In addition to effective resistance to corrosion, copper and copper alloys also resist corrosion fatigue in many applications involving repeated stress and corrosion. These applications include such parts as springs, switches, diaphragms, bellows, aircraft and automotive gasoline and oil lines, tubes for condensers and heat exchangers, and fourdrinier wire for the paper industry.

Copper alloys that are high in fatigue limit and resistance to corrosion in the service environment are more likely to have good resistance to corrosion fatigue. Alloys frequently used in applications involving both cyclic stress and corrosion include beryllium coppers, phosphor bronzes, aluminum bronzes, and copper nickels.

### ***Stress-Corrosion Cracking***

Stress-corrosion cracking (SCC) and season cracking describe the same phenomenon--the apparently spontaneous cracking of stressed metal. Stress corrosion cracking is often intergranular (Fig. 4), but transgranular cracking may occur in some alloys in certain environments. Stress-corrosion cracking occurs only if a susceptible alloy is subjected to the combined effects of sustained stress and certain chemical substances.

**Fig. 4** Typical stress-corrosion cracking in a copper alloy. Intergranular cracking in an etched specimen. Approximately 60×

**Conditions Leading to SCC.** Ammonia and ammonium compounds are the corrosive substances most often associated with SCC of copper alloys. These compounds are sometimes present in the atmosphere; in other cases, they are in

cleaning compounds or in chemicals used to treat boiler water. Both oxygen and moisture must be present for  $\text{NH}_3$  to be corrosive to copper alloys; other compounds, such as  $\text{CO}_2$  are thought to accelerate SCC in  $\text{NH}_3$  atmospheres. Moisture films on metal surfaces will dissolve significant quantities of  $\text{NH}_3$ , even from atmospheres with low  $\text{NH}_3$  concentrations.

A specific corrosive environment and sustained stress are the primary causes of SCC; microstructure and alloy composition may affect the rate of crack propagation in susceptible alloys. Microstructure and composition can be most effectively controlled by selecting the correct combination of alloy, forming process, thermal treatment, and metal-finishing process. Although test results may indicate that a finished part is not susceptible to SCC, such an indication does not ensure complete freedom from cracking, particularly where service stresses are high.

Applied and residual stresses can both lead to failure by SCC. Susceptibility is largely a function of stress magnitude. Stresses near the yield strength are usually required, but parts have failed under much lower stresses. In general, the higher the stress, the weaker the corroding medium must be to cause SCC. The reverse is also true; the stronger the corroding medium, the lower the required stress.

**Sources of Stress.** Applied stresses result from ordinary service loading or from fabricating techniques, such as riveting, bolting, shrink fitting, brazing, and welding. Residual stresses are of two types: differential-strain stresses, which result from nonuniform plastic strain during cold forming, and differential-thermal-contraction stresses, which result from nonuniform heating and/or cooling.

Residual stresses induced by nonuniform straining are primarily influenced by the method of fabrication. In some fabricating processes, it is possible to cold work a metal extensively and yet produce only a low level of residual stress. For example, residual stress in a drawn tube is influenced by die angle and amount of reduction. Wide-angle dies (about  $32^\circ$ ) produce higher residual stresses than narrow-angle dies (about  $8^\circ$ ). Light reductions yield high residual stresses because only the surface of the alloy is stressed; heavy reductions yield low residual stresses because the region of cold working extends deeper into the metal. Most drawing operations can be planned so that residual stresses are low and susceptibility to SCC is negligible.

Residual stresses resulting from upsetting, stretching, or spinning are more difficult to evaluate and to control by varying tooling and process conditions. For these operations, SCC can be prevented more effectively by selecting a resistant alloy or by treating the metal after fabrication.

**Alloy Composition.** Brasses containing less than 15% Zn are highly resistant to SCC. Phosphorus-deoxidized copper and tough pitch copper rarely exhibit SCC, even under severe conditions. On the other hand, brasses containing 20 to 40% Zn are highly susceptible. Susceptibility increases only slightly as zinc content is increased from 20 to 40%.

There is no indication that the other elements commonly added to brasses increase the probability of SCC. Phosphorus, arsenic, magnesium, tellurium, tin, beryllium, and manganese are thought to decrease susceptibility under some conditions. Addition of 1.5% Si is known to decrease the probability of cracking.

Altering the microstructure cannot make a susceptible alloy totally resistant to SCC. However, the rapidity with which susceptible alloys crack appears to be affected by grain size and structure. All other factors being equal, the rate of cracking increases with grain size. The effects of structure on SCC are not sharply defined, primarily because they are interrelated with effects of both composition and stress.

**Control Measures.** Stress-corrosion cracking can be controlled, and sometimes prevented, by selecting copper alloys that have high resistance to cracking (notably those with less than 15% Zn); by reducing residual stress to a safe level by thermal stress relief, which can usually be applied without significantly decreasing strength; or by altering the environment, such as by changing the predominant chemical species present or introducing a corrosion inhibitor.

Residual and assembly stresses can be eliminated by recrystallization annealing after forming or assembly. Recrystallization annealing cannot be used when the integrity of the structure depends on the higher strength of strain-hardened metal, which always contains a certain amount of residual stress. Thermal stress relief (sometimes called relief annealing) can be specified when the higher strength of a cold-worked temper must be retained. Thermal stress relief consists of heating the part for a relatively short time at low temperature. Specific times and temperatures depend on alloy composition, severity of deformation, prevailing stresses, and the size of the load being heated. Usually, time is from 30 min to 1 h and temperature is from 150 to  $425^\circ\text{C}$  (300 to  $795^\circ\text{F}$ ). Table 3 lists typical stress-relieving times and temperatures for some of the more common copper alloys.

**Table 3 Typical stress-relieving parameters for some common copper alloys**

Common name	UNS No.	Temperature		Time, h
		°C	°F	
<b>Commercial bronze</b>	C22000	205	400	1
<b>Cartridge brass</b>	C26000	260	500	1
<b>Muntz metal</b>	C28000	190	375	$\frac{1}{2}$
<b>Admiralty metal</b>	C44300, C44400, C44500	300	575	1
<b>Phosphor bronze, 5 or 10%</b>	C51000, C52400	190	375	1
<b>Silicon bronze</b>	C65500	370	700	1
<b>Aluminum bronze</b>	C61300, C61400	400	750	1
<b>Copper nickel, 30%</b>	C71500	425	800	1

The exact thermal treatment should be established by examining specific parts for residual stress. If such examination indicates that a thermal treatment is insufficient, temperature and/or time should be adjusted until satisfactory results are obtained. Parts in the center of a furnace load may not reach the desired temperature as soon as parts around the periphery. Therefore, it may be necessary to compensate for furnace loading when setting process controls or to limit the number of parts that can be stress relieved together.

Mechanical methods, such as stretching, flexing, bending, straightening between rollers, peening, and shot blasting, can also be used to reduce residual stresses to a safe level. These methods depend on plastic deformation to decrease dangerous tensile stresses or to convert them to less objectionable compressive stresses.

## Effects of Alloy Compositions

**Coppers and high-copper alloys** have similar corrosion resistance. They have excellent resistance to seawater corrosion and biofouling, but are susceptible to erosion-corrosion at high water velocities. The high-copper alloys are primarily used in applications that require enhanced mechanical performance, often at slightly elevated temperature, with good thermal or electrical conductivity. Processing for increased strength in the high-copper alloys generally improves their resistance to erosion-corrosion. A number of alloys in this category have been developed for electronic applications--such as contact clips, springs, and lead frames--that require specific mechanical properties, relatively high electrical conductivity, and atmospheric-corrosion resistance.

**Brasses** are basically copper-zinc alloys and are the most widely used group of copper alloys. The resistance of brasses to corrosion by aqueous solutions does not change markedly as long as the zinc content does not exceed ~15%; above 15% Zn, dezincification may occur. Quiescent or slowly moving saline solutions, brackish waters, and mildly acidic solutions are environments that often lead to the dezincification of unmodified brasses.

Susceptibility to SCC is significantly affected by zinc content; alloys that contain more zinc are more susceptible. Resistance increases substantially as zinc content decreases from 15 to 0%. Stress-corrosion cracking is practically unknown in commercial copper.

Elements such as lead, tellurium, beryllium, chromium, phosphorus, and manganese have little or no effect on the corrosion resistance of coppers and binary copper-zinc alloys. These elements are added to enhance such mechanical properties as machinability, strength, and hardness.

**Tin Brasses.** Tin additions significantly increase the corrosion resistance of some brasses, especially resistance to dezincification. Examples of this effect are two tin-bearing brasses, especially resistance to dezincification. Examples of this effect are two tin-bearing brasses: uninhibited admiralty metal (no active UNS number) and naval brass (C46400). Uninhibited admiralty metal was once widely used to make heat-exchanger tubes; it has largely been replaced by inhibited grades of admiralty metal (C44300, C44400, and C44500), which have even greater resistance to dealloying. Admiralty metal is a variation of cartridge brass (C26000) that is produced by adding ~1% Sn to the basic 70Cu-30Zn composition. Similarly, naval brass is the alloy resulting from the addition of 0.75% Sn to the basic 60Cu-40Zn composition of Muntz metal (C28000).

**Aluminum Brasses.** An important constituent of the corrosion film on a brass that contains a few percent aluminum in addition to copper and zinc is aluminum oxide ( $\text{Al}_2\text{O}_3$ ), which markedly increases resistance to impingement attack in turbulent high-velocity saline water. For example, the arsenical aluminum brass C68700 (76Cu-22Zn-2Al) is frequently used for marine condensers and heat exchangers in which impingement attack is likely to pose a serious problem. Aluminum brasses are susceptible to dezincification unless they are inhibited, which is usually done by adding 0.02 to 0.10% As.

**Inhibited Alloys.** Addition of phosphorus, arsenic, or antimony (typically 0.02 to 0.10%) to admiralty metal, naval brass, or aluminum brass effectively produces high resistance to dezincification. Inhibited alloys have been extensively used for such components as condenser tubes, which must accumulate years of continuous service between shutdowns for repair or replacement.

**Phosphor Bronzes.** Addition of tin and phosphorus to copper produces good resistance to flowing seawater and to most nonoxidizing acids except hydrochloric (HCl). Alloys containing 8 to 10% Sn have high resistance to impingement attack. Phosphor bronzes are much less susceptible to SCC than brasses and are similar to copper in resistance to sulfur attack.

**Tin bronzes**, which are used primarily in cast form, are modified by further alloy additions of lead, zinc, and nickel. This group of alloys has fair resistance to impingement and good resistance to biofouling.

**Copper Nickels.** Alloy C71500 (Cu-30Ni) has the best general resistance to aqueous corrosion of all the commercially important copper alloys, but C70600 (Cu-10Ni) is often selected because it offers good resistance at lower cost. Both of these alloys, although well suited to applications in the chemical industry, have been most extensively used for condenser tubes and heat-exchanger tubes in recirculating steam systems. They are superior to coppers and to other copper alloys in resisting acid solutions and are highly resistant to SCC and impingement corrosion.

**Nickel Silvers.** The two most common nickel silvers are C75200 (65Cu-18Ni-17Zn) and C77000 (55Cu-18Ni-27Zn). They have good resistance to corrosion in both fresh and salt waters. Primarily because their relatively high nickel contents inhibit dezincification, C75200 and C77000 are usually much more resistant to corrosion in saline solutions than brasses of similar copper content.

**Copper-silicon alloys** generally have the same corrosion resistance as copper, but they have higher mechanical properties and superior weldability. These alloys appear to be much more resistant to SCC than the common brasses. Silicon bronzes are susceptible to embrittlement by high-pressure steam and should be tested for suitability in the service environment before being specified for components to be used at elevated temperature.

**Aluminum bronzes** containing 5 to 12% Al have excellent resistance to impingement corrosion and high-temperature oxidation. Aluminum bronzes are used for beater bars and for blades in wood pulp machines because of their ability to withstand mechanical abrasion and chemical attack by sulfite solutions.

In most practical commercial applications, the corrosion characteristics of aluminum bronzes are primarily related to aluminum content. Alloys with up to 8% Al normally have completely face-centered cubic (fcc)  $\alpha$  structures and good resistance to corrosion attack. As aluminum content increases above 8%,  $\alpha$ - $\beta$  duplex structures appear. The  $\beta$  phase is a high-temperature phase retained at room temperature upon fast cooling from 565 °C (1050 °F) or above. Slow cooling for long exposure at temperatures from 320 to 565 °C (610 to 1050 °F) tends to decompose the  $\beta$  phase into a brittle  $\alpha$ + $\gamma_2$  eutectoid having either a lamellar or a nodular structure. The  $\beta$  phase is less resistant to corrosion than the  $\alpha$  phase, and eutectoid structures are even more susceptible to attack.

Depending on specific environmental conditions,  $\beta$  phase or eutectoid structure in aluminum bronze can be selectively attacked by a mechanism similar to the dezincification of brasses. Proper quench-and-temper treatment of duplex alloys, such as C62400 and C95400, produces a tempered  $\beta$  structure with reprecipitated acicular  $\alpha$  crystals, a combination that is often superior in corrosion resistance to the normal annealed structures.

Iron-rich particles are distributed as small round or rosette particles throughout the structures of aluminum bronzes containing more than about 0.5% Fe. These particles sometimes impart a rusty tinge to the surface, but have no known effect on corrosion rates.

Nickel-aluminum bronzes are more complex in structure with the introduction of the  $\kappa$  phase. Nickel appears to alter the corrosion characteristics of the  $\beta$  phase to provide greater resistance to dealloying and cavitation erosion in most liquids. For C63200 and perhaps C95800, quench-and-temper treatments may yield even greater resistance to dealloying. Alloy C95700, a high-manganese cast aluminum bronze, is somewhat inferior in corrosion resistance to C95500 and C95800, which are low in manganese and slightly higher in aluminum.

Aluminum bronzes are generally suitable for service in nonoxidizing mineral acids, such as phosphoric ( $\text{H}_3\text{PO}_4$ ), sulfuric ( $\text{H}_2\text{SO}_4$ ), and HCl; organic acids, such as lactic, acetic ( $\text{CH}_3\text{COOH}$ ), or oxalic; neutral saline solutions, such as sodium chloride (NaCl) or potassium chloride (KCl); alkalis, such as sodium hydroxide (NaOH), potassium hydroxide (KOH), and anhydrous ammonium hydroxide ( $\text{NH}_4\text{OH}$ ); and various natural waters including sea, brackish, and potable waters. Environments to be avoided include nitric acid ( $\text{HNO}_3$ ); some metallic salts, such as ferric chloride ( $\text{FeCl}_3$ ) and chromic acid ( $\text{H}_2\text{CrO}_4$ ); moist chlorinated hydrocarbons; and moist  $\text{NH}_3$ . Aeration can result in accelerated corrosion in many media that appear to be compatible.

Exposure under high tensile stress to moist  $\text{NH}_3$  can result in SCC. In certain environments, corrosion can lower the fatigue limit to 25 to 50% of the normal atmospheric value.

## Selection for Specific Environments

Selection of a suitably resistant material requires consideration of the many factors that influence corrosion including stress, velocity, galvanic coupling, concentration cells, initial surface conditions, and contamination of the surrounding medium. Over the years, experience has been the best criterion for selecting the most suitable alloy for a given environment. The Copper Development Association (CDA) has compiled much field experience in the form of the ratings shown in Table 4. The table should be used only as a guide; small changes in the environmental conditions sometimes degrade the performance of a given alloy from "suitable" to "not suitable."

### Table 4 Corrosion ratings of wrought copper alloys in various corrosive media

This table is intended to serve only as a general guide to the behavior of copper and copper alloys in corrosive environments. It is impossible to cover in a simple tabulation the performance of a material for all possible variations of temperature, concentration, velocity, impurity content, degree of aeration, and stress. The ratings are based on general performance; they should be used with caution, and then only for the purpose of screening candidate alloys. The letters E, G, F, and P have the following significance: E, excellent: resists corrosion under almost all conditions of service. G, good: some corrosion will take place, but satisfactory service can be expected under all but the most severe conditions. F, fair: corrosion rates are higher than for the G classification, but the metal can be used if needed for a property other than corrosion resistance and if either the amount of corrosion does not cause excessive maintenance expense or the effects of corrosion can be lessened, such as by use of coatings or inhibitors. P, poor: corrosion rates are high, and service is generally unsatisfactory.

- (a) Copper and copper alloys are resistant to corrosion by most food products. Traces of copper may be dissolved and affect taste or color of the products. In such cases, copper alloys are often tin coated.
- (b) Acetylene forms an explosive compound with copper when moisture or certain impurities are present and the gas is under pressure. Alloys containing less than 65% Cu are satisfactory; when the gas is not under pressure, other copper alloys are satisfactory.
- (c) Precautions should be taken to avoid stress-corrosion cracking (SCC).
- (d) At elevated temperatures, hydrogen will react with tough pitch copper, causing failure by embrittlement.
- (e) Where air is present, corrosion rate may be increased.
- (f) Below 150 °C (300 °F), corrosion rate is very low; above this temperature, corrosion is appreciable and increases rapidly with temperature.
- (g) Aeration and elevated temperature may increase corrosion rate substantially.

- (h) Excessive oxidation may begin above 120 °C (250 °F). If moisture is present, oxidation may begin at lower temperatures.
- (i) Use of high-zinc brasses should be avoided in acids because of the likelihood of rapid corrosion by dezincification. Copper, low-zinc brasses, phosphor bronzes, silicon bronzes, aluminum bronzes, and copper nickels offer good resistance to corrosion by hot and cold dilute H<sub>2</sub>SO<sub>4</sub> and to corrosion by cold concentrated H<sub>2</sub>SO<sub>4</sub>. Intermediate concentrations of H<sub>2</sub>SO<sub>4</sub> are sometimes more corrosive to copper alloys than either concentrated or dilute acid. Concentrated H<sub>2</sub>SO<sub>4</sub> may be corrosive at elevated temperatures due to breakdown of acid and formation of metallic sulfides and sulfur dioxide, which cause localized pitting. Tests indicate that copper alloys may undergo pitting in 90 to 95% H<sub>2</sub>SO<sub>4</sub> at about 50 °C (122 °F), in 80% acid at about 70 °C (160 °F), and in 60% acid at about 100 °C (212 °F).
- (j) Wetting agents may increase corrosion rates of copper and copper alloys slightly to substantially when carbon dioxide or oxygen is present by preventing formation of a film on the metal surface and by combining (in some instances) with the dissolved copper to produce a green, insoluble compound.

Whenever there is a lack of operating experience, whenever reported test conditions do not closely match the conditions for which alloy selection is being made, and whenever there is doubt as to the applicability of published data, it is always best to conduct an independent test. Field tests are the most reliable. Laboratory tests can be equally valuable, but only if operating conditions are precisely defined and then accurately simulated in the laboratory. Long-term tests are generally preferred because the reaction that dominates the initial stages of corrosion may differ significantly from the reaction that dominates later on. If short-term tests must be used as the basis for alloy selection, the test program should be supplemented with field tests so that the laboratory results can be reevaluated in light of true operating experience.

Erroneous conclusions based on laboratory results can also be reached by measuring corrosion damage inaccurately, especially when corrosion is slight. It is common practice to express test results in terms of penetration or average reduction in metal thickness, even when corrosion was actually measured by weight loss. Weight loss or average-penetration data are valid only when corrosion is uniform. When corrosion occurs predominantly by pitting or some other localized form or when corrosion is intergranular or involves the formation of a thick, adherent scale, direct measurement of the extent of corrosion provides the most reliable information. A common technique is to measure the maximum depth of penetration observed on a metallographic cross section through the region of interest. Statistical averaging of repeated measurements on one or more specimens may or may not be warranted. Despite the deficiencies in laboratory testing, information gained in this manner serves as a useful starting point for alloy selection.

### ***Atmospheric Exposure***

Comprehensive tests conducted over a 20-year period under the supervision of the American Society for Testing and Materials (ASTM), as well as many service records, have confirmed the suitability of copper and copper alloys for atmospheric exposure (Table 5). Copper and copper alloys resist corrosion by industrial, marine, and rural atmospheres except atmospheres containing NH<sub>3</sub> or certain other agents where SCC has been observed in high-zinc alloys (>20% Zn). The copper metals most widely used in atmospheric exposure are C11000, C22000, C23000, C38500, and C75200. Alloy C11000 is an effective material for roofing, flashings, gutters, and downspouts.

(a) Derived from 20-year exposure tests. Types of atmospheres: Altoona, industrial; New York City, industrial marine; Key West, tropical rural marine; La Jolla, humid marine; State College, northern rural; Phoenix, dry rural.

(b) Although obsolete, this alloy indicates the corrosion resistance expected of C71500.

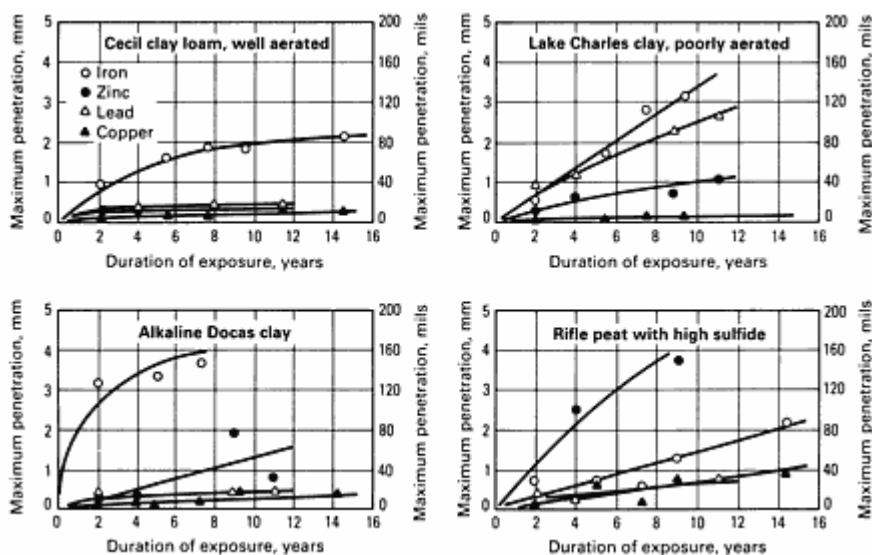

The colors of different copper alloys are often important in architectural applications, and color may be the primary criterion for selecting a specific alloy. After surface preparation, such as sanding or polishing, different copper alloys vary in color from silver to yellow to gold to reddish shades. Different alloys having the same initial color may show differences in color after weathering under similar conditions. Therefore, alloys having the same or nearly the same composition are usually used together for consistency of appearance in a specific structure.

Copper alloys are often specified for marine atmosphere exposures because of the attractive and protective patina they form during the exposure. In marine atmospheric exposures, this patina consists of a film of basic copper chloride or carbonate, sometimes with an inner layer of  $\text{Cu}_2\text{O}$ . The severity of the corrosion attack in marine atmospheres is somewhat less than that in industrial atmospheres but greater than that in rural atmospheres. However, these rates decrease with time.

### ***Soils and Groundwater***

**Soils.** Copper, zinc, lead, and iron are the metals most commonly used in underground construction. Data compiled by the former National Bureau of Standards (NBS) compare the behavior of these materials in soils of the following four types: well-aerated acid soils low in soluble salts (Cecil clay loam), poorly aerated soils (Lake Charles clay), alkaline soils high in soluble salts (Docas clay), and soils high in sulfides (Rifle peat).

Corrosion data as a function of time for copper, iron, lead, and zinc exposed to these four types of soil are given in Fig. 5. Copper exhibits high resistance to corrosion by these soils, which are representative of most soils found in the United States. Where local soil conditions are unusually corrosive, it may be necessary to use some means of protection, such as cathodic protection, neutralizing backfill (limestone, for example), protective coating, or wrapping.

**Fig. 5** Corrosion of copper, iron, lead, and zinc in four different soils

For many years, NBS (now the National Institute of Standards and Technology, or NIST) has conducted studies on the corrosion of underground structures to determine the specific behavior of metals and alloys when exposed for long periods in a wide range of soils. Results indicate that tough pitch coppers, deoxidized coppers, silicon bronzes, and low-zinc brasses behave essentially alike. Soils containing cinders with high concentrations of sulfides, chlorides, or hydrogen ions ( $H^+$ ) corrode these materials. In this type of contaminated soil, the corrosion rates of copper-zinc alloys containing more than about 22% Zn increase with zinc content. Corrosion generally results from dezincification. In soils that contain only sulfides, corrosion rates of the copper-zinc alloys decrease with increasing zinc content, and no dezincification occurs. Although not included in these tests, inhibited admiralty metals would offer significant resistance to dezincification.

**Groundwater.** Naturally occurring saline waters are also found deep underground. Although the composition and concentration of these groundwaters vary from site to site, the concentration of dissolved species generally increases with depth. Such groundwaters are encountered in mines, during oil drilling, and in deep boreholes. The waters have a complex composition, often being mixtures of sodium ( $Na^+$ ), calcium ( $Ca^{2+}$ ), magnesium ( $Mg^{2+}$ ), chloride ( $Cl^-$ ), sulfate ( $SO_4^{2+}$ ) and bicarbonate ( $HCO_3^-$ ) ions as well as trace amounts of other ions. Iron minerals in the bedrock react with dissolved oxygen in the groundwater and produce less oxidizing conditions than are found in waters nearer the surface.

For both copper and copper alloys, corrosion rate depends strongly on the amount of dissolved oxygen present. The data in Table 6 illustrate this point for both pure copper and Cu-10Ni in various synthetic groundwaters. These data are derived from experiments lasting from 2 to 4 weeks; therefore, they include the high initial rates of corrosion and do not represent long-term corrosion rates. However, they do serve to show that deoxygenation of the solution results in at least an order of magnitude decrease in the short-term corrosion rate. It is also apparent from these data that, in aerated solutions at least, the addition of nickel decreases the uniform corrosion rate of copper. This is due to the formation of a more highly protective surface film.

**Table 6 Short-term corrosion rates of copper alloys in saline groundwaters**

Alloy	Type of groundwater	Oxygen concentration, $\mu\text{g/g}$	Temperature		Corrosion rate	
			$^{\circ}\text{C}$	$^{\circ}\text{F}$	$\mu\text{m/yr}$	mils/yr

(a) TDS, total dissolved solids

## Water

**Freshwater.** Copper is extensively used for handling freshwater. Copper tubing in the K-gage range with flared fittings was designed for underground water service and, along with type L tubing, has now become standard for this application. The largest single application of copper tubing is for hot- and cold-water distribution lines in homes and other buildings, although considerable quantities are also used in heating lines (including radiant heating lines for homes), drain tubes, and fire safety systems.

**Steam.** Copper and copper alloys resist attack by pure steam, but if much  $\text{CO}_2$ , oxygen, or  $\text{NH}_3$  is present, the condensate is corrosive. Even though wet steam at high velocities can cause severe impingement attack, copper alloys are extensively used in condensers and heat exchangers. Copper alloys are also used for feedwater heaters, although their use in such applications is somewhat limited because of their rapid decline in strength and creep resistance at moderately elevated temperatures. Copper nickels are the preferred copper alloys for the higher temperatures and pressures.

Use of copper in systems handling hot water and steam is limited by the working pressures of tubes and joints. For example, copper tubing of 6.4 to 25 mm ( $\frac{1}{4}$  to 1 in.) nominal diameter joined with 50Sn-50Pb solder can be used at temperatures to  $120^{\circ}\text{C}$  ( $250^{\circ}\text{F}$ ) and pressures to 585 kPa (85 psi). The working pressure at this temperature in tubing of

the same size can be increased to 1380 kPa (200 psi) when the system is joined with 95Sn-5Sb solder. When the joining material is a silver-base brazing alloy with a melting point above 540 °C (1000 °F), the working pressure at 120 °C (250 °F) for tubing in this size range can be increased to 2070 kPa (300 psi). A few copper alloys have shown a tendency to fail by SCC when they are highly stressed and exposed to steam. Alpha aluminum bronzes that do not contain tin are among the susceptible alloys.

**Steam condensate** that has been properly treated so that it is relatively free of noncondensate gases, as in a power-generating station, is relatively noncorrosive to copper and copper alloys. Rates of attack in such exposures are less than 25  $\mu\text{m}/\text{year}$  (0.1 mil/year). Copper and copper alloys are not attacked by condensate that contains a significant amount of oil, such as condensate from a reciprocating steam engine.

Dissolved  $\text{CO}_2$ , oxygen, or both significantly increase the rate of attack. For example, condensate with a 4.6 ppm O, and 14 ppm  $\text{CO}_2$ , and a pH of 5.5 at 68 °C (155 °F) caused an average penetration of 175 to 350  $\mu\text{m}/\text{year}$  (6.9 to 13.8 mils/year) when in contact with C12200 (phosphorus-deoxidized copper), C14200 (arsenical copper), C23000 (red brass), C44300 to C44500 (admiralty metal), and C71000 (copper nickel, 20%). Steel tested under the same conditions was penetrated at about twice the rate given for the copper alloys listed above, but tin-coated copper proved to be much more resistant and was attacked at a rate of less than 25  $\mu\text{m}/\text{year}$  (1 mil/year). To attain the optimum service life in condensate systems, it is necessary to ensure that the tubes are installed with enough slope to allow proper drainage, to reduce the quantity of corrosive agents (usually  $\text{CO}_2$  and oxygen) at the source by mechanical or chemical treatment of feedwater, or to treat the steam chemically.

**Salt Water.** An important use of copper alloys is in handling seawater in ships and tidewater power stations. Copper itself, although fairly useful, is usually less resistant to general corrosion than C44300 to C44500, C61300, C68700, C70600, or C71500. The superior performance to these alloys results from the combination of insolubility in seawater, erosion resistance, and biofouling resistance. The corrosion rates of copper and copper alloys in relatively quiescent seawater are typically less than 50  $\mu\text{m}/\text{year}$  (2 mils/year).

In the laboratory and in service, copper-nickel alloys C70600, C71500, C72200, and C71640 exhibit excellent corrosion resistance in seawater. Average corrosion rates for both C70600 and C71500 range from 2 to 12  $\mu\text{m}/\text{year}$  (0.08 to 0.5 mil/year). Long-term evaluations have revealed corrosion rates under 2.5  $\mu\text{m}/\text{year}$  (0.1 mil/year) for both alloys after 14 years of exposure to quiescent and low-velocity seawater.

**Polluted cooling waters**, particularly in coastal harbors and estuaries, have caused premature failures of power station and shipboard condensers using copper-base alloys, including the copper-nickels. Although enforcement of strict pollution standards has dramatically reduced pollution in many harbors in recent years, accelerate attack of condenser tubes and seawater piping materials by polluted waters is still reported.

The primary causes of accelerated attack of copper-base alloys in polluted seawater are (1) the action of sulfate-reducing bacteria, under anaerobic conditions (for example, in bottom muds or sediments), on the natural sulfates present in seawater and (2) the putrefaction of organic sulfur compounds from decaying plant and animal matter within seawater systems during periods of extended shutdown. Corrosion resistance can be enhanced by proper design, the use of inhibitors, or by adding iron to the seawater (by additions of ferrous sulfate or sacrificial iron anodes).

**Biofouling.** Copper alloys, including the copper-nickels, have long been recognized for their inherent resistance to marine fouling. This fouling resistance is usually associated with microbiological fouling, such as barnacles, mussels, and marine invertebrates of corresponding size. Service experience with shrimp trawlers and private yachts fabricated with C70600 or C71500 hulls has demonstrated excellent resistance to hard-shell fouling and an accompanying reduction in hull maintenance costs. Copper-nickel alloys have also performed successfully as seawater intake screens by virtue of their mechanical strength, corrosion resistance, and resistance to biofouling.

**Heat Exchangers and Condensers.** The selection of material for condenser and heat-exchanger tubes necessitates a survey of service conditions, an examination of tubes previously used and evaluation of its service life, and a review of the type, form, and location of corrosion experience in the unit or in similar units. Types of water and operating conditions vary widely, and any estimate of probable tube performance must be based on specific operating factors. Tubes of various alloys, inhibited admiralty metal (C44300, C44400, and C44500), inhibited aluminum brass (C68700), aluminum bronzes (C61300 and C63200), copper nickels (C70600 and C71500) and phosphorus-deoxidized coppers (C12000 to C12300), have all been found to give satisfactory and economical performance in these applications.

## Acids

Copper is widely employed for industrial equipment used to handle acid solutions. A fairly definite separation exists between those acids that can be handled by copper and those that cannot. In general, copper alloys are successfully used with nonoxidizing acids, such as acetic ( $\text{CH}_3\text{COOH}$ ), sulfuric ( $\text{H}_2\text{SO}_4$ ), hydrochloric ( $\text{HCl}$ ), and phosphoric ( $\text{H}_3\text{PO}_4$ ), as long as the concentration of oxidizing agents, such as dissolved oxygen (air) and ferric ( $\text{Fe}^{3+}$ ) or dichromate ions, is low. Broadly speaking, a thoroughly agitated or stirred solution or one into which a stream of air has been bubbled approaches air saturation and is therefore not a suitable acid medium for copper. Acids that are oxidizing agents in themselves, such as  $\text{HNO}_3$ ; sulfurous ( $\text{H}_2\text{SO}_3$ ); hot, concentrated  $\text{H}_2\text{SO}_4$ ; and acids carrying such oxidizing agents as  $\text{Fe}^{3+}$  salts, dichromate ions, or permanganate ( $\text{MnO}_4^-$ ) ions cannot be handled in equipment made of copper or its alloys.

The corrosive action of a dilute (up to 1% acid) nonoxidizing acid on copper is relatively low; corrosion rates are usually less than  $6 \text{ g/m}^2/\text{d}$  (equivalent penetration rate:  $250 \text{ } \mu\text{m}/\text{year}$ , or  $10 \text{ mils}/\text{year}$ ). This is true only of oxidizing acids when the concentration does not exceed 0.01%. At such low acid concentrations, aeration has little effect in either oxidizing or nonoxidizing acids.

Nonoxidizing acids with near-zero aeration have virtually no corrosive effect. Rates in  $1.2 \text{ N H}_2\text{SO}_4$ ,  $\text{HCl}$ , and  $\text{CH}_3\text{COOH}$  are less than  $0.1 \text{ g/m}^2/\text{day}$  ( $4 \text{ } \mu\text{m}/\text{year}$ , or  $0.15 \text{ mil}/\text{year}$ ) in the absence of air.

Except for  $\text{HCl}$ , nonoxidizing acids that contain as much air as is absorbed in quiet contact with the atmosphere are weakly corrosive. Rates generally range from  $0.5$  to  $6 \text{ g/m}^2$  per day (approximately  $20$  to  $250 \text{ } \mu\text{m}/\text{year}$ , or  $0.8$  to  $10 \text{ mils}/\text{year}$ ).

Air-saturated solutions of nonoxidizing acids are likely to be strongly corrosive, with corrosion rates of  $5$  to  $30 \text{ g/m}^2/\text{d}$  ( $0.2$  to  $1.25 \text{ mm}/\text{year}$ , or  $8$  to  $50 \text{ mils}/\text{year}$ ). This rate is higher for  $\text{HCl}$ . The actual corrosion in any aerated acid depends on acid concentration, temperature, and other factors that are difficult to classify. Except in very dilute solutions, oxidizing acids corrode copper rapidly--usually at rates above  $50 \text{ g/m}^2/\text{day}$  ( $2.1 \text{ mm}/\text{year}$ , or  $85 \text{ mils}/\text{year}$ ). The reaction is independent of aeration.

The corrosion rate of three common acids are compared in the following table (temperature and aeration are not specified):

Acid	Corrosion rate		
	$\text{g/m}^2/\text{d}$	$\text{mm}/\text{yr}$	$\text{mils}/\text{yr}$
<b>32% <math>\text{HNO}_3</math></b>	5700	240	9450
<b>Concentrated <math>\text{HCl}</math></b>	18	0.75	30
<b>17% <math>\text{H}_2\text{SO}_4</math></b>	2	0.1	4

Phosphoric,  $\text{CH}_3\text{COOH}$ , tartaric, formic, oxalic, malic, and similar acids normally react comparably to  $\text{H}_2\text{SO}_4$ .

## Alkalies

Copper and copper alloys resist alkaline solutions, except those containing ammonium hydroxide ( $\text{NH}_4\text{OH}$ ) or compounds that hydrolyze to  $\text{NH}_4\text{OH}$  or cyanides. Ammonium hydroxide reacts with copper to form soluble complex copper cations, but the cyanides react to form soluble complex copper anions. The rate of attack for copper-zinc alloys

exposed to alkalis other than those specified previously (e.g., sodium hydroxide) is  $\sim 50$  to  $500 \mu\text{m/year}$  (2 to 20 mils/year) at room temperature under stagnant conditions, but is about  $500$  to  $1750 \mu\text{m/year}$  (20 to 70 mils/year) in aerated boiling solutions.

Strong  $\text{NH}_4\text{OH}$  solutions attack copper and copper alloys rapidly, as compared with the rates of attack by metallic hydroxides because of the formation of a soluble complex copper-ammonium compound. However, in some applications, the corrosion of copper exposed to dilute solutions of  $\text{NH}_4\text{OH}$  is low. For example, copper specimens submerged in  $0.1 N$   $\text{NH}_4\text{OH}$  solution at room temperature for 1 week experienced weight loss of  $1.5 \text{ m/m}^2\text{day}$  ( $60 \mu\text{m/year}$ , or 2.5 mils/year).

Ammonium hydroxide solutions also attack copper-zinc alloys. Alloys containing more than 15% Zn are susceptible to SCC when exposed to  $\text{NH}_4\text{OH}$ . The stress may be due to applied service loads or to unrelieved residual stresses. In quiescent  $2 N$   $\text{NH}_4\text{OH}$  solutions at room temperature, copper-zinc alloys corrode at 1.8 to 6.6 mm/year (70 to 260 mils/year), copper-nickel alloys at 0.25 to 0.50 mm/year (10 to 20 mils/year), copper-tin alloys at 1.3 to 2.5 mm/year (50 to 100 mils/year), and copper silicon alloys at 0.75 to 5 mm/year (30 to 200 mils/year).

Copper and copper alloys are suitable for handling anhydrous  $\text{NH}_3$  if the  $\text{NH}_3$  remains anhydrous and is not contaminated with water and oxygen. In one test conducted for 1200 h, C11200 and C26000 each showed an average penetration of  $5 \mu\text{m/year}$  (0.2 mil/year) in contact with anhydrous  $\text{NH}_3$  at atmospheric temperature and pressure.

## **Salts**

Copper metals are widely used in equipment for handling saline solutions of various kinds, particularly those that are nearly neutral. Among these are the nitrates, sulfates, and chlorides of sodium and potassium. Chlorides are usually more corrosive than the other salts, especially in strongly agitated, aerated solutions.

The nonoxidizing acid salts, such as the alums and certain metal chlorides (magnesium and calcium chlorides) that hydrolyze in water to produce an acidic pH, exhibit essentially the same behavior as dilute solutions of the corresponding acids. Corrosion rates generally range from 2.5 to  $1500 \mu\text{m/year}$  (0.1 to 60 mils/year) at room temperature, depending on the degree of aeration and the acidity.

Neutral saline solutions can be successfully handled by copper alloys. Consequently, these alloys are used in heat exchanger and condenser equipment exposed to seawater.

Such alkaline salts as sodium silicate ( $\text{Na}_2\text{SiO}_3$ ), sodium phosphate ( $\text{Na}_2\text{CO}_3$ ) attack copper alloys at low but different rates at room temperature. On the other hand, alkali cyanide is aggressive and attacks copper alloys fairly rapidly because it forms a soluble complex copper anion.

**Oxidizing salts** corrode copper and copper alloys rapidly; therefore, copper metals should not be used with oxidizing saline solutions except those that are very dilute. Aqueous sodium dichromate ( $\text{Na}_2\text{Cr}_2\text{O}_7$ ) solutions can be safely handled by copper alloys, but the presence of a highly ionized acid, such as  $\text{H}_2\text{CrO}_4$  or  $\text{H}_2\text{SO}_4$ , may increase the corrosion rate several hundred times, because the dichromate acts as an oxidizing agent in acidic solutions. In one test, a copper-nickel corroded at 2.5 to  $250 \mu\text{m/year}$  (0.1 to 10 mils/year) and a copper-tin alloy (phosphor bronze) at  $5 \mu\text{m/year}$  (0.2 mil/year) when handling an aqueous  $\text{Na}_2\text{Cr}_2\text{O}_7$  solution. The rate increased 200 to 300 times for both metals when  $\text{H}_2\text{CrO}_4$  was added to the solution. In solutions containing  $\text{Fe}^{3+}$ , mercuric ( $\text{Hg}^{2+}$ ) or stannic ( $\text{Sn}^{4+}$ ) ions, a copper-nickel showed a corrosion rate of 27.4 mm/year (1080 mils/year), while copper-zinc and copper-tin alloys showed a still greater rate of 228 mm/year (8980 mils/year).

Salts of metals more noble than copper, such as the nitrates of mercury and silver, corrode copper alloys rapidly, simultaneously plating out the noble metal on the copper surface. Temperature and acidity influence the rate of attack. A film of mercury on high-zinc brass (more than 15% Zn) can cause intergranular cracking by liquid-metal embrittlement (LME) if the alloy is under tensile stress, either residual or applied.

## **Organic Compounds**

Copper and many copper alloys resist corrosive attack by most organic solvents and by organic compounds, such as amines, alkanolamines, esters, glycols, ethers, ketones, alcohols, aldehydes, naphtha, and gasoline. Although the corrosion rates of copper and copper alloys in pure alkanolamines and amines are low, they can be significantly increased

if these compounds are contaminated with water, acids, alkalies, salts, or combinations of these impurities, particularly at high temperatures.

**Gasoline**, naphtha, and other related hydrocarbons in pure form will not attack copper or any of the copper alloys. However, in the manufacture of hydrocarbon materials, process streams are likely to be contaminated with one or more of such substances as water, sulfides, acids, and various organic compounds. These contaminants attack copper and copper alloys. Corrosion rates for C44300 and C71500 exposed to gasoline are low and these two alloys are successfully used in equipment for refining gasoline.

**Creosote.** Copper and copper alloys are generally suitable for use with creosote, although creosote attacks some high-zinc brasses. Alloys C11000, C23000, C26000, C51000, and C65500 typically corrode at rates less than 500  $\mu\text{m}/\text{year}$  (2 mils/year) when exposed to creosote at 25 °C (75 °F).

**Linseed Oil.** Copper and copper alloys are fairly resistant to corrosion by linseed oil. All of the alloys show some attack, but none exhibits corrosion severe enough to make it unsuitable for this application. Alloys C11000, C51000, and C65500 showed corrosion rates less than 500  $\mu\text{m}/\text{year}$  (20 mils/year) in linseed oil at 25 °C (75 °F). Alloy C26000 had a rate of 500 to 1250  $\mu\text{m}/\text{year}$  (20 to 50 mils/year).

**Benzol and Benzene.** Alloys C11000, C23000, C26000, C51000, and C65500 tested in these materials at 25 °C (75 °F) had corrosion rates under 500  $\mu\text{m}/\text{year}$  (20 mils/year).

**Sugar.** Copper is successfully used for vacuum-pan heating coils, evaporators, and juice extractors in the manufacture of both cane and beet sugar. Inhibited admiralty metals, aluminum bronzes, and copper nickels are also used for tubes in juice heaters and evaporators. Bimetal tubes of copper and steel have been used by manufacturers of beet sugar to counteract SCC of copper tubes caused by  $\text{NH}_3$  from beets grown in fertilized soil.

**Beer.** Copper is extensively used in the brewing of beer. In one installation, the wall thickness of copper kettles thinned from an original thickness of 16 mm ( $\frac{5}{8}$  in.) to 10 mm ( $\frac{3}{8}$  in.) in a 30-year period. Brazing with BAg (copper-silver) filler metals eliminates the possibility that the alkaline compounds used for cleaning copper equipment will destroy joints by attacking tin-lead solders. Steam coils require more frequent replacement than any other component in brewery equipment. They have service lives of 15 to 20 years. The service lives of other copper items exposed to process streams in a brewery range from 30 to 40 years.

**Sulfur compounds** free to react with copper, hydrogen sulfide ( $\text{H}_2\text{S}$ ), sodium sulfide ( $\text{Na}_2\text{S}$ ), or potassium sulfide ( $\text{K}_2\text{S}$ ), form  $\text{CuS}$ . Reaction rates depend on alloy composition; the alloys of highest resistance are those of high zinc content (e.g., 60Cu-40Zn).

Inhibited admiralty metals are also excellent alloys for use in heat exchangers and condensers that handle sulfur-bearing petroleum products and use water as the coolant. Alloys C44300, C44400, and C44500, which are inhibited toward dezincification by the addition of arsenic, antimony, or phosphorus to the basic 70Cu-29Zn-1Sn composition, offer good resistance to corrosion from sulfur as well as excellent resistance to the water side of the heat exchanger.

## Protective Coatings

Copper metals resist corrosion in many environments because they react with one or more constituents of the environment upon initial exposure, thus forming an inert surface layer of protective reaction products. In certain applications, the corrosion resistance of copper metals can be increased by applying metallic or organic protective coatings. If the coating material is able to resist corrosion adequately, service life may depend on the impermeability, continuity, and adhesion to the basis metal of the coating. The electropotential relationship of the coating to the basis metal may be important, especially with metallic coatings and at uncoated edges. Tin, lead, and solder, used extensively as coatings, are ordinarily applied by hot dipping. Electroplating is also used.

**Tin** affects corrosion caused by sulfur; it is most effective as a coating for copper wire and cable insulated by rubber that contains sulfur. Lead-coated copper is primarily used for roofing applications, in which contact with flue gases or other products that contain dilute  $\text{H}_2\text{SO}_4$  is likely. Tin or lead coatings are sometimes applied to copper intended for ordinary atmospheric exposure, but this is done primarily for architectural effect; the atmospheric-corrosion resistance of bare copper is excellent in rural, urban, marine, and most industrial locations.

**Electroplated chromium** is used for decoration, for improvement of wear resistance, or for reflectivity. Because it is somewhat porous, it is not effective for corrosion protection. Where corrosion protection is important, electroplated nickel is most often used as a protective coating under electroplated chromium.

**Various organic coatings** are applied to copper alloys to preserve a bright metallic appearance.

## Manufacture of Cemented Carbides

All cemented carbide components are manufactured by powder metallurgy (P/M) processing. As described below, the important steps include powder processing, production of grade (alloy) powders, powder consolidation, sintering, and finishing.

**Powder Processing.** Tungsten carbide is manufactured through the reduction of tungsten oxide and subsequent carburization at 1400 to 1500 °C (2550 to 2730 °F). Particle sizes range from 0.5 to 3.0  $\mu\text{m}$ .

Cobalt is manufactured through reduction of cobalt oxides or derived from organic salts--particularly cobalt oxalate. The cobalt binder phase is altered significantly during milling with WC and subsequent liquid-phase sintering operations.

The TiC/TaC/NbC powders are produced from metal oxides of titanium, tantalum, and niobium. These oxides are mixed with metallic tungsten powder and carbon similar to the preparation of WC powder. The mixture is heated under a hydrogen atmosphere or vacuum to reduce the oxides and form solid-solution carbides. The Menstruum process is also effective for the production of mixed carbide.

**Production of Grade Powders.** Cemented carbide grade powders are produced by combining WC with cobalt or nickel binder and, depending on the application, varying amounts of TaC/TiC/NbC. The grade powder is milled in conventional ball mills, attrition mills, or vibratory mills. The milling process reduces the particle size of the raw materials and also provides uniformity of mixture. Milling operations are typically carried out in a protective solvent to minimize heating and subsequent oxidation of the powder, and to disperse the powder particles to achieve intimate mixing. During the grade powder manufacturing process, 2 to 3 wt% of a solid lubricant such as paraffin wax is added. This lubricant reduces the potential for oxidation and provides green strength to as-pressed components. The lubricant/solvent/powder slurry is then dried to remove the solvent. Spray drying is the most widely used method of powder drying. The slurry is atomized through a nozzle and sprayed into a stream of nitrogen gas. The solvent is vaporized, condensed outside the chamber, and reused. The dried powder is now in the form of free-flowing spherical aggregates on the order of 150 to 250  $\mu\text{m}$  in diameter.

**Powder consolidation** processes include a number of vastly different techniques. Many wear components are produced on automatic or semiautomatic presses at pressures of 50 to 150 MPa (7 to 22 ksi). In cold isostatic pressing, the grade powder is consolidated into a rough billet or ingot using equal pressure from all directions. This rough billet is then preformed or machined to a net shape. Extrusion of carbide grade powders is used to produce long components of small, constant cross section. There has also been limited injection molding of cemented carbides.

**Sintering operations** are carried out in batch-type or semicontinuous furnaces in either a vacuum, hydrogen, or other inert atmosphere. A 400 to 500 °C (750 to 930 °F) hold dewaxes the parts, and the vaporized lubricant is condensed outside the heating chamber and discarded. Final sintering takes place at 1300 to 1600 °C (2370 to 2910 °F); the precise temperature depends on the cobalt content--the grades with the higher cobalt contents have the lower sintering temperatures. The final sintering temperature is above the eutectic temperature of the carbide-binder system, and the binder partially melts. The excellent wettability of WC by cobalt results in rapid liquid-phase sintering, which promotes coalescence of the WC particles and produces a fully dense, virtually porosity-free microstructure. Linear shrinkage on the order of 15 to 25% takes place.

The advantages of hot isostatic pressing (HIP) have been exploited since the early 1970s. Components requiring high reliability and/or surface integrity are HIPed to eliminate residual porosity, pits, or flaws. Materials are heated to a temperature above the liquidus, and the vessel is pressurized with an inert gas to slightly less than 100 MPa (15 ksi). The combination of pressure and temperature forces the binder into any residual pits or porosity. Recent advances have combined liquid-phase sintering and HIP into a single sinter-HIP process. Sinter-HIP uses lower pressures and higher temperatures than conventional HIP with no sacrifice in component reliability. The resulting sinter-HIP microstructure is more uniform than that produced by conventional HIP, and sinter-HIP is more cost effective.

**Finishing operations** include grinding with diamond wheels, electrical discharge machining (EDM) using wire or shaped electrodes, and edge honing using a variety of abrasive techniques. Final lapping to mirrorlike finishes is accomplished using diamond-containing slurries or pastes.

## Cemented Carbides for Machining Applications

The performance of cemented carbides as a cutting tool lies between that of tool steel and cermets. Compared to tool steels, cemented carbides are harder and more wear resistant, but also exhibit lower fracture resistance and thermal conductivities than tool steels. Cermets, on the other hand, are more wear resistant than cemented carbides, but may not be as tough. The performance of either carbide or cermet cutting tools is strongly dependent on composition and microstructure, and the properties of cemented carbide tools depend not only on the type and amount of carbide but also on the carbide grain size and the amount of binder metal (see the discussion below on "Structure/Property Relationships").

**Tungsten Carbide-Cobalt Alloys.** The first commercially available cemented carbides consisted of WC particles bonded with cobalt. These are commonly referred to as straight grades. These alloys exhibit excellent resistance to simple abrasive wear and thus have many applications in metal cutting. Table 1 lists the representative properties of several straight WC-Co alloys.

Table 1 Properties of representative cobalt-bonded cemented carbides

Nominal composition	Grain size	Hardness, HRA	Density		Transverse strength		Compressive strength		Modulus of elasticity		Relative abrasion resistance <sup>(a)</sup>	Coefficient of thermal expansion, $\mu\text{m} \cdot \text{K}$		Thermal conductivity, W/m · K

(a) Based on a value of 100 for the most abrasion-resistant material

The commercially significant alloys contain cobalt in the range of 3 to 25 wt%. For machining purposes, alloys with 3 to 12% Co and carbide grain sizes from 0.5 to more than 5  $\mu\text{m}$  are commonly used.

The ideal microstructure of WC-Co alloys should exhibit only two phases: angular WC grains and cobalt binder phase. Representative microstructures of several straight WC-Co alloys are shown in Fig. 1. The carbon content must be controlled within narrow limits. Too high a carbon content results in the presence of free and finely divided graphite (C-type porosity), which in small amounts has no adverse effects in machining applications. Deficiency in carbon, however, results in the formation of a series of double carbides (for example,  $\text{Co}_3\text{W}_3\text{C}$  or  $\text{Co}_6\text{W}_6\text{C}$ ), commonly known as  $\eta$  phase, which causes severe embrittlement.

**Fig. 1** Microstructures of 90WC-10Co cemented carbide (straight grade). The light constituent is the cobalt binder. (a) Fine grain size. (b) Medium grain size. (c) Coarse grain size. All at 1500 $\times$

**Submicron Tungsten Carbide-Cobalt Alloys.** In recent years, WC-Co alloys with submicron carbide grain sizes have been developed for applications requiring more toughness or edge strength. Typical applications include indexable inserts and a wide variety of solid carbide drilling and milling tools. Grain refinement in these alloys is obtained by small additions (0.25 to 3.0 wt%) of TaC, NbC, VC, or CrC. Additions can be made before carburization of the tungsten or later in the powder blend.

**Alloys Containing Tungsten Carbide, Titanium Carbide, and Cobalt.** The WC-Co alloys, developed in the early 1920s, were successful in the machining of cast iron and nonferrous alloys at much higher speeds than were possible with high-speed steel tools, but were subject to chemical attack or diffusion wear when cutting steel. As a result, the tools failed rapidly at speeds not much higher than those used with high-speed steel. This led to the development of WC-TiC-Co alloys.

Tungsten carbide diffuses readily into the steel chip surface, but the solid solution of WC and TiC resists this type of chemical attack. Unfortunately, TiC and WC-TiC solid solutions are more brittle and less abrasion resistant than WC. The amount of TiC added to WC-Co alloys is therefore kept to a minimum, typically no greater than 15 wt%. The carbon content is less critical in WC-TiC-Co alloys than in WC-Co alloys, and the  $\eta$  phase does not appear in the microstructure unless carbon is grossly inadequate. In addition, free graphite rarely occurs in these alloys.

**Complex Grades.** The WC-TiC-Co alloys have given way to alloys of WC, cobalt, TiC, TaC, and NbC. The WC-Co alloys containing TiC, TaC, and NbC are called complex grades, multigrades, or steel-cutting grades. Adding TaC to WC-TiC-Co alloys partially overcomes the deleterious effect of TiC on the strength of WC-Co alloys. Tantalum carbide also resists cratering and improves thermal shock resistance. The latter property is particularly useful in applications involving interrupted cuts. Tantalum carbide is often added as (Ta,Nb)C because the chemical similarity between TaC and NbC makes their separation expensive. Fortunately, NbC has an effect similar to TaC in most cases. Unlike the WC-Co alloys, the microstructure of WC-TiC-(Ta,Nb)C-Co alloys shows three phases: angular WC grains, rounded WC-TiC-(Ta,Nb)C solid-solution grains, and cobalt binder (Fig. 2). The size and distribution of the phases vary widely, depending on the amounts and grain sizes of the raw materials employed and on the method of manufacture. Similarly, the properties of these complex alloys also vary widely, as indicated in Table 1 for representative steel-cutting grades.

**Fig. 2** Microstructure of 85WC-9(Ta,Ti,Nb)C-6Co steel-cutting grade of cemented carbide, medium grain size. The gray angular particles are WC, and the dark gray, rounded particles are solid-solution carbides. The white areas are cobalt binder. 1500×

**Classification of Cemented Carbides**

There is no universally accepted system for classifying cemented carbides. The systems most often employed by producers and users are discussed below.

**C-Grade System.** The U.S. carbide industry uses an application-oriented system of classification to assist in the selection of proper grades of cemented carbides. This C-grade system does not require the use of tradenames for identifying specific carbide grades (Table 2). Although this classification simplifies tool application, it does not reflect the material properties that significantly influence selection of the proper carbide grade. Additionally, the definitions of work materials involved in this classification scheme are imprecise. There is also no universal agreement on the meanings of the terms used to describe the various application categories. Despite these limitations, the C-grade classification has been successfully used by the manufacturing industry since 1942.

**Table 2 C-grade classification of cemented carbides**

C-grade	Application category
	Machining of cast iron, nonferrous, and nonmetallic materials
C-1	Roughing
C-2	General-purpose machining
C-3	Finishing
C-4	Precision finishing

Machining of carbon and alloy steels	
<b>C-5</b>	Roughing
<b>C-6</b>	General-purpose machining
<b>C-7</b>	Finishing
<b>C-8</b>	Precision finishing
Nonmachining applications	
<b>C-9</b>	Wear surface, no shock
<b>C-10</b>	Wear surface, light shock
<b>C-11</b>	Wear surface, heavy shock
<b>C-12</b>	Impact, light
<b>C-13</b>	Impact, medium
<b>C-14</b>	Impact, heavy

**ISO Classification.** In 1964, the International Organization of Standardization (ISO) issued ISO Recommendation R513 "Application of Carbides for Machining by Chip Removal." The basis for the ISO classification of carbides is summarized in Table 3.

**Table 3 ISO R513 classification of carbides according to use for machining**

Designation <sup>(a)</sup>	Groups of applications	
	Material to be machined	Use and working conditions
<b>P01</b>	Steel, steel castings	Finish turning and boring; high cutting speeds, small chip section, accuracy of dimensions and fine finish, vibration-free operation
<b>P10</b>	Steel, steel castings	Turning, copying, threading, and milling; high cutting speeds, small or medium chip sections
<b>P20</b>	Steel, steel castings, malleable cast iron with long chips	Turning, copying, milling, medium cutting speeds and chip sections; planing with small chip sections

<b>P30</b>	Steel, steel castings, malleable cast iron with long chips	Turning, milling, planing, medium or low cutting speeds, medium or large chip sections, and machining in unfavorable conditions <sup>(b)</sup>
<b>P40</b>	Steel, steel castings with sand inclusion and cavities	Turning, planing, slotting, low cutting speeds, large chip sections with the possibility of large cutting angles for machining in unfavorable conditions <sup>(b)</sup> and work on automatic machines
<b>P50</b>	Steel, steel castings of medium or low tensile strength, with sand inclusion and cavities	For operations demanding very tough carbide; turning, planing, slotting, low cutting speeds, large chip sections, with the possibility of large cutting angles for machining in unfavorable conditions <sup>(b)</sup> and work on automatic machines
<b>M10</b>	Steel, steel castings, manganese steel, gray cast iron, alloy cast iron	Turning, medium or high cutting speeds; small or medium chip sections
<b>M20</b>	Steel, steel castings, austenitic or manganese steel, gray cast iron	Turning, milling; medium cutting speeds and chip sections
<b>M30</b>	Steel, steel castings, austenitic steel, gray cast iron, high-temperature-resistant alloys	Turning, milling, planing; medium cutting speeds, medium or large chip sections
<b>M40</b>	Mild free-cutting steel, low-tensile steel, nonferrous metals, and light alloys	Turning, parting off, particularly on automatic machines
<b>K01</b>	Very hard gray cast iron, chilled castings of >85 scleroscope hardness, high-silicon aluminum alloys, hardened steel, highly abrasive plastics, hard cardboard, ceramics	Turning, finish turning, boring, milling, scraping
<b>K10</b>	Gray cast iron >220 HB, malleable cast iron with short chips, hardened steel, silicon aluminum alloys, copper alloys, plastics, glass, hard rubber, hard cardboard, porcelain, stone	Turning, milling, drilling, boring, broaching, scraping
<b>K20</b>	Gray cast iron up to 200 HB, nonferrous metals; copper, brass, aluminum	Turning, milling, planing, boring, broaching, demanding very tough carbide
<b>K30</b>	Low-hardness gray cast iron, low-tensile steel, compressed wood	Turning, milling, planing, slotting, for machining in unfavorable conditions <sup>(b)</sup> and with the possibility of large cutting angles
<b>K40</b>	Softwood or hardwood, nonferrous metals	Turning, milling, planing, slotting, for machining in unfavorable conditions <sup>(b)</sup> and with the possibility of large cutting angles

(a) In each letter category, low designation numbers are for high speeds and light feeds; higher numbers are for slower speeds and/or heavier feeds. Also, increasing designation numbers imply increasing toughness and decreasing wear resistance of the cemented carbide materials.

(b) Unfavorable conditions include shapes that are awkward to machine; material having a casting or forging skin; material having variable hardness; and machining that involves variable depth of cut, interrupted cut, or moderate to severe vibrations.

In the ISO system, all machining grades are divided into three color-coded groups:

- Highly alloyed WC grades (letter P, blue color) for machining steel
- Alloyed WC grades (letter M, yellow color, generally with less TiC than the corresponding P series) for multipurpose use, such as steels, nickel-base superalloys, and ductile cast irons
- Straight WC grades (letter K, red color) for cutting gray cast iron, nonferrous metals, and nonmetallic materials

Each grade within a group is assigned a number to represent its position from maximum hardness to maximum toughness. P-grades are rated from 01 to 50, M-grades from 10 to 40, and K-grades from 01 to 40. Typical applications are described for grades at more or less regular numerical intervals.

## Properties of Cemented Carbides

**Structure/Property Relationships.** Specific properties of individual grades of cemented carbides depend not only on the composition of the carbide but also on its grain size and on the amount and type of binder.

The compositions and properties of nine straight grades and two complex grades of cobalt-bonded carbide are given in Table 1. Because properties are influenced by both composition and structure, both characteristics must be specified to define a specific grade.

For straight WCs of comparable WC grain size, increasing cobalt content increases transverse strength and toughness but decreases hardness, compressive strength, elastic modulus, and abrasion resistance. If, for example, medium-grain carbides having 3, 7, and 25% Co are compared, 3% Co grade is found to have the greatest hardness and abrasion resistance--properties that make it well suited for wiredrawing dies and for cutting tools used in machining of cast iron and other abrasive or gummy materials. The 6% Co grade has moderate values for all properties and is a good general-purpose carbide material. The 25% Co grade has the greatest toughness and is used for applications involving heavy impact. Because of its relatively low hardness and abrasion resistance, it is not used for cutting tools. Similar parallels in properties and uses can be drawn both for the fine-grain grades and for the coarse-grain grades containing 6, 10, and 16% Co.

Another set of comparisons can be drawn for the grades containing 6% Co. All three grades--fine, medium, and coarse--are used for cutting tools, but the applications to which they are applied involve different machining conditions and different work materials. The fine-grain material is used for finish to medium-rough machining of ductile, gray, and chilled irons and of austenitic stainless steels, high-temperature alloys, and nonmetallic materials; the medium-grain material for light to heavy machining of these same wrought work materials; and the coarse-grain grade for heavy to extremely heavy rough machining of such materials. The medium-grain material is widely employed for general-purpose machining because its properties have been found to offer a good practical balance between hardness and toughness. The coarse-grain grade, which has the lowest hardness and abrasion resistance and the best toughness of the three grades, is used where a combination of moderate hardness and high toughness is needed. Similar comparisons can be made for the grades that contain 10 and 16% Co. In general, decreasing grain size improves abrasion resistance and makes it easier to retain the edge on a cutting tool; increasing grain size improves toughness and makes the cemented carbide more suitable for die applications.

For complex grades, comparisons similar to those drawn for the straight grades are not as readily made. Variations in carbide type, as well as in binder content, affect properties, which in turn influence suitability for specific types of service.

The two complex grades listed in Table 1 contain about the same amount of WC, but one contains about twice as much binder. The lower-cobalt grade is used for lighter-duty cutting. The complex grade high in TiC is relatively low in transverse strength and high in resistance to abrasion and cratering. It is used extensively for high-speed, light-duty finishing. The complex grade highest in cobalt content and in TaC is preferred for hot-work tools, in both cutting and shaping of metals.

**Hardness** is typically measured on the Rockwell A scale with values ranging from 83.0 HRA for high-cobalt coarse-grain grades to 93.0 HRA for low-cobalt fine-grain grades. Vickers diamond pyramid hardness (HV) is widely used in Europe; values range from 800 to 2000 kg/mm<sup>2</sup> using a 30 kg load. The precision and accuracy of hardness testing is

influenced significantly by the surface finish of the testpiece, parallelism between top and bottom surfaces, and the quality of hardness standards and diamond penetrators. For straight WC-Co grades with comparable WC grain size, hardness decreases with increasing binder content.

**Abrasion Resistance.** Superior abrasion resistance is the major reason for the selection of cemented carbides in a wide variety of industrial applications. Most producers of cemented carbides use a wet-sand abrasion test to measure abrasion resistance. In this test, a sample is held against a rotating wheel for a fixed number of revolutions while the sample and wheel are immersed in a water slurry containing aluminum oxide particles. Comparative rankings are reported, usually on the basis of a wear rating based on the reciprocal of volume loss. Although standard test procedures are available (e.g., ASTM test 611), carbide producers have not agreed on a single test method, and so the values of abrasion resistance cited in the literature vary widely. Because of this variance, it is almost impossible to make a valid comparison among test results reported by different producers. It is also fallacious to use abrasion resistance as a measure of the wear resistance of cemented carbide materials when they are used for cutting steel or other materials; abrasion resistance in a standard test does *not* correspond directly to wear resistance in machining operations.

Generally, the abrasion resistance of cemented carbides decreases as cobalt content or grain size is increased. Abrasion resistance is also lower for complex carbides than for straight WC grades having the same cobalt content. Values of comparative abrasion resistance are listed in Table 1.

**Toughness.** Cemented carbides are brittle materials; usually they show less than 0.2% elongation in a tensile test.

Values of Charpy impact strength for cemented carbides have little significance and may be misleading. The energy absorbed during impact testing of very hard materials consists mainly of energy absorbed in elastic bending of the specimen and energy absorbed by the testing machine. The portion of total absorbed energy that is a measure of the toughness of a material--namely, the energy of plastic work and the energy necessary to create new surfaces--is only a few percent of the total energy measured.

Fracture toughness ( $K_{Ic}$ ) values indicate the resistance of a material to fracture from intrinsic flaws. A variety of test methods and specimen geometries are used, so caution must be exercised when comparing reported values from different manufacturers. Fracture toughness increased with both increased cobalt content or WC grain size.

**Corrosion resistance** is not typically thought of as a requirement for carbides, and in terms of straight corrosion resistance, there are commercially available materials that are clearly superior. However, when a combination of corrosion resistance, wear resistance, stiffness, toughness, and thermal conductivity is required--such as for rotary mechanical seals in industrial pumps--cemented carbides are the material of choice.

The corrosion resistance of carbides is limited by the susceptibility of the cobalt binder to chemical attack, although there are some corrosive media that attack WC (e.g., nitric acid and hydrochloric acid). The corrosive media typically dissolve the cobalt binder from the matrix, leaving behind a weak, unsupported skeleton of WC grains, which are easily abraded away. The corrosion resistance of straight WC-Co alloys is, in general, inversely related to that of the binder content. The straight substitution of nickel binder for cobalt does provide limited improvement in both corrosion and oxidation resistance. Nickel, however, does not have the WC wettability exhibited by cobalt binders, and nickel-bonded grades have decreased hardness and toughness values relative to cobalt grades at identical binder levels. There are several grades available that utilize chromium additions to the cobalt binder to improve corrosion resistance. Chromium, however, promotes the formation of carbon-deficient  $\eta$  phase with a resultant decrease in toughness and strength. The development of nickel binder grades alloyed with chromium, molybdenum, and other elements has resulted in a significant improvement in corrosion resistance.

The WC-Co cemented carbides are reasonably resistant to oxidation in air up to about 650 to 700 °C (1200 to 1290 °F). The constituent affected the fastest is WC, which will oxidize to  $WO_3$ . In oxygen, the temperature limit is lower, and rapid deterioration occurs at about 500 °C (930 °F). Even in air, however, the practical temperature limit for WC-Co compositions for any length of time is 500 to 600 °C (930 to 1110 °F). The addition of TiC or TaC to the base WC-Co composition increases the oxidation resistance somewhat.

## Coated Cemented Carbides

**Physical or chemical vapor deposition (PVD or CVD)** are now used on the majority of metal-cutting inserts and on some wear parts. The coatings are on the order of 5  $\mu$ m thick and consist of TiC, TiN, Ti(C,N), HfN, AlO, aluminum

oxide, or a combination thereof (multilayer coatings). Their purpose is to minimize the wear process during steel machining; in particular, to minimize the dissolution of the workpiece material into the cutting tool, which leads to crater wear. Titanium nitride coatings are also purported to reduce the frictional forces at the tool/workpiece interface.

The methods of application for CVD and PVD coatings differ substantially. The CVD coatings are normally applied at temperatures of about 1000 °C (1830 °F) and as a result contain higher levels of residual stresses due to the difference in both thermal expansion coefficients and elastic moduli between the substrate and the coating. This results in a significant decrease (30%) in transverse-rupture strength of coated parts compared to uncoated parts. The residual tensile stresses in CVD coatings can also produce transverse cracks in the coating(s). While these cracks do not affect coating adhesion, they may initiate tool fracture in interrupted cutting operations in which the cutting edge is subjected to fatigue-type loading. One solution to the problem of coating-related tool fracture is to improve the fracture toughness of the substrate by increasing its peripheral cobalt content (cobalt enrichment). The cobalt-enriched surface zone, which is 10 to 40  $\mu\text{m}$  thick, provides superior edge strength while maintaining the diffusion wear resistance of the coating layers. An example of a multiple-layer coating applied to a cobalt-enriched complex grade substrate is shown in Fig. 3.

**Fig. 3** Multilayer CVD coating (TiC/Ti(C,N)/TiN) on a cobalt-enriched 86WC-8(Ti,Ta,Nb)-6Co substrate. Note increased cobalt content (white constituent) at the substrate surface.

The PVD process is applied at less than 500 °C (930 °F) and results in reduced stresses in the coating and minimizes any loss in strength. A disadvantage of the PVD process is that it is a line-of-sight deposition technique. This necessitates moving the tool fixtures during the PVD deposition to ensure uniformly thick coatings on both the rake and flank faces of tool inserts.

**Plasma-Assisted CVD Coatings.** A compromise between the CVD and PVD techniques is the plasma-assisted CVD coating process, which offers a combination of moderate deposition temperature ( $\sim 600$  °C, or 1110 °F) and good thickness uniformity without the need to rotate the tools during the coating process. Both conducting (TiN and TiC) and insulating ( $\text{Al}_2\text{O}_3$ ) coatings are applied using this technique.

**CVD/PVD Coatings.** A recent development in carbide cutting tool coatings combines an outer PVD TiN layer with inner CVD TiN/Ti(C,N) layers on a tough cobalt-enriched substrate for interrupted cutting applications such as milling. The inner CVD layers provide excellent adhesion and wear resistance, and the outer PVD layer offers a hard, fine-grain, crack-free, smooth surface endowed with compressive residual stress.

**Diamond Coatings.** The most recent addition to the development of hard coatings is the low-pressure synthesis of diamond films by carbonaceous gas decomposition in the presence of hydrogen ions. This process is an alternative to the high-pressure, high-temperature synthesis of bulk diamond, which is used to fabricate polycrystalline diamond (PCD). Diamond-coated carbides are used to machine aluminum-silicon alloys and nonmetallic composite materials.

## Cemented Carbides for Nonmachining Applications

Almost 50% of the total production of cemented carbides is now used for nonmetal cutting applications such as metalforming dies, punches, and rolls, transportation and construction, mining, oil and gas drilling, forestry tools, and

fluid-handling components. The majority of cemented carbides used for nonmachining applications are uncoated, straight WC-Co grades. Alloyed (complex) grades are used in only specialized applications. Examples of typical applications are shown in Table 4.

**Table 4 Nominal composition and properties of representative cemented carbides used for nonmachining applications**

Typical application	Binder content, wt%	Grain size	Hardness, HRA
Heavy blanking punches and dies, cold heading dies	20-30	Medium	85
Heading dies (severe impact), hot-forming dies, swaging dies	11-25	Medium to coarse	84
Back extrusion punches, hot-forming punches	11-15	Medium	88
Back extrusion punches, blanking punches, and dies for high shear strength steel	10-12	Fine to medium	89
Powder compacting dies, Sendzimir rolls, strip-flattening rolls, wire-flattening rolls	6	Fine	92
Extrusion dies (low impact), light blanking dies	10-12	Fine to medium	90
Extrusion dies (medium impact), blanking dies, slitters	12-16	Medium	88
Corrosion-resistant grades, valves and nozzles, rotary seals, bearings	6-12	Fine to medium	92
Corrosion-resistant grade with good impact resistance for valves and nozzles, rotary seals, and bearings	6-10 Ni	Medium	90
Deep draw dies (nongalling), tube sizing mandrels	10 Co with TiC and TaC	Medium	91

## Cermets

**Machining Grades.** Cermets used for machining applications include TiCs and Ti(C,N)s with nickel or nickel-molybdenum binders. The manufacture of TiC/Ti(C,N) cermets is carried out with P/M methods, including liquid-phase sintering, similar to those applied for conventional carbides. As with cemented carbides, the cermet microstructures show hard, wear-resistant particles embedded in a ductile binder phase. Although the hardness at room and elevated temperatures of these materials are comparable to those of cemented carbides, their density, strength, and toughness are somewhat lower than conventional cemented carbides. Properties vary with the proportion of binder in the overall composition. In general, the corrosion resistance of TiC- and Ti(C,N)-base cermets is superior to WC-base carbides. Cermets have clearly superior oxidation resistance when compared to cemented carbides and can be used at temperatures up to 900 °C (1650 °F).

The first cutting tool in the cermet family, a TiC-Ni alloy, was commercialized as early as the 1930s, but it could not compete with the inherently stronger WC-Co-base tools. Additions of molybdenum to TiC alloys in 1960 brought cermets closer in performance to WC-Co-base tools in finish machining of steels.

Titanium carbonitride cermets based on Ti(C,N)-Ni-Mo were introduced in 1970, followed by (TiMo)(C,N)-base compositions that provided a balance of wear resistance and toughness due to their finer microstructures. Continued development in this area has now resulted in complex cermets having a variety of additives, such as Mo<sub>2</sub>C, TaC, NbC, ZrC, HfC, WC, VC, Cr<sub>3</sub>C<sub>2</sub>, and aluminum. Various mixes of these additives impart different combinations of wear resistance, thermal shock resistance, and toughness, and they allow tools to be tailored for a wide range of machining applications. The newer cermets are used in semifinishing and finishing of carbon and alloy steels, stainless steels, ductile irons, free-machining aluminum and other nonferrous alloys, and some high-temperature alloys. The metal removal operations may include turning, boring, milling, threading, and grooving. Coatings (e.g., TiN) can be applied to cermet tools by the PVD process.

**Steel-bonded carbides** are P/M materials that are intermediate in wear resistance between tool steels and cemented carbides based on WC-Co. They consist of 25 to 45 vol% TiC homogeneously dispersed in a steel matrix. Matrices include tool steels, maraging steels, and martensitic stainless steels.

Steel-bonded TiCs respond to heat treatment and are machinable by conventional methods when the binder is in the annealed condition. Fully hardened steel-bonded carbides can be tempered at varying temperatures, thereby obtaining greater toughness than WC-Co. However, this gain in toughness is accompanied by some sacrifice in hardness. Steel-bonded carbides consisting of 45 vol% TiC have about one-half the density of the available grades of WC-Co. This is an important consideration when designing wear-resistant components for astronautical or aeronautical vehicles or for high-velocity rotating equipment.

Steel-bonded carbides are not recommended for cutting tools because the hardness drops off rapidly at the high temperatures developed during machining. They are, however, used for a variety of nonmachining wear-resistant applications such as warm and hot metalworking tools and dies.

# Magnetically Soft Materials

## Introduction

MAGNETIC MATERIALS are broadly classified into two groups with either hard or soft magnetic characteristics. Hard magnetic materials are characterized by retaining a large amount of residual magnetism after exposure to a strong magnetic field. These materials typically have coercive force,  $H_c$ , values of several hundred to several thousand oersteds (Oe), and are considered to be permanent magnets. The coercive force is a measure of the magnetizing force required to reduce the magnetic induction to zero after the material has been magnetized. In contrast, soft magnetic materials become magnetized by relatively low-strength magnetic fields, and when the applied field is removed, they return to a state of relatively low residual magnetism. Soft magnetic materials typically exhibit coercive force values of approximately  $400 \text{ A} \cdot \text{m}^{-1}$  (5 Oe) to as low as  $0.16 \text{ A} \cdot \text{m}^{-1}$  (0.002 Oe). Soft magnetic behavior is essential in any application involving changing electromagnetic induction such as solenoids, relays, motors, generators, transformers, magnetic shielding, and so on.

Important characteristics of magnetically soft materials include: (a) high permeability, (b) high saturation induction, (c) low hysteresis-energy loss, (d) low eddy-current loss in alternating flux applications, and (e) constant permeability at low field strengths and/or a minimum or definite change in permeability with temperature. Cost, availability, strength, corrosion resistance, and ease of processing are several other factors that influence the final selection of a soft magnetic material.

Magnetically soft materials manufactured in large quantities include high-purity iron, low-carbon irons, silicon (electrical) steels, nickel-iron alloys, iron-cobalt alloys, ferritic stainless steels, and ferrites (ceramics). Soft magnetic amorphous materials are being produced commercially; their characteristics are also covered in this article.

## Ferromagnetic Properties

The ferromagnetic and electrical properties of materials can be divided into two general categories: those that are structure sensitive and those that are structure insensitive. Structure insensitive refers to properties not markedly affected by small changes in gross composition, small amounts of certain impurities, heat treatment, or plastic deformation. Several generally accepted structure-insensitive properties are the saturation induction ( $B_s$ ), resistivity ( $\rho$ ), and Curie temperature ( $T_c$ ). These properties are largely dependent on the composition of the alloy selected and are not changed substantially in the process of manufacturing a component from the alloy.

Structure-sensitive properties are those drastically affected by impurities: residual strain, grain size, and so on. Permeability ( $\mu$ ), coercive force ( $H_c$ ), hysteresis losses ( $W_h$ ), residual induction ( $B_r$ ), and magnetic stability are all considered to be structure sensitive. A means of controlling structure-sensitive properties is through manufacturing processing of the alloy and/or by the proper use of a final annealing heat treatment.

**Effect of Impurities.** Elements such as carbon, oxygen, nitrogen, and sulfur are commonly found as impurities in all alloys. Even in very low concentrations these elements tend to locate at interstitial sites in the crystalline lattice; thus, the lattice can be severely strained. Very minor concentrations can interfere with the easy movement of magnetic domains and impair soft magnetic properties. Figure 1 shows the approximate relationship between carbon content and the hysteresis loss of iron. Hysteresis losses are similarly related to sulfur and oxygen content. Furthermore, if carbon and/or nitrogen remains in the alloy uncombined, or if these elements exceed their respective solubility limits near room temperature, they can migrate in time and precipitate in a form of fine particles that can pin the magnetic domain walls. This causes a hardening of the magnetic properties known as aging.

Fig. 2 Effect of alloying elements on electrical resistivity of iron

Addition of silicon in sufficient amounts eliminates the allotropic transformation in iron. Consequently, silicon-iron can be annealed at high temperature to promote grain growth, thus facilitating development of preferred grain orientation. However, room-temperature saturation induction is reduced by alloy additions other than cobalt (see Fig. 3).

Fig. 3 Effect of alloying elements on room-temperature saturation induction of iron

**Effects of Heat Treatment.** Magnetic materials such as iron-nickel alloys in the cold-rolled condition must be annealed to develop the desired grain structure and magnetic properties.

Annealing conditions required for silicon steels depend on processing carried out by the supplier and on cost-versus-performance factors. Semi-processed grades must be annealed near 840 °C (1550 °F), after stamping of laminations, for removal of carbon and development of magnetic properties. Fully processed grades of non-oriented or grain-oriented steels require annealing in the range 750 to 875 °C (1375 to 1600 °F) only for removal of fabrication stresses. For wide laminations used in a flat condition, as in large power transformers, low-stress strip requiring no annealing is available.

**Effects of Grain Size.** For most applications, grain size should be as large as possible for nonoriented materials (Fig. 4). In oriented grades of silicon steel, optimum magnetic properties are usually obtained with grain sizes of 2 to 10 mm depending on the degree of crystal orientation: increases in grain size above 10 mm are accompanied by significant increases in both domain-wall spacing and eddy-current losses.

Fig. 4 Relationship between grain size and hysteresis loss for high-purity iron at  $B = 1$  T (10 kG)

**Effects of Grain Orientation.** All ferromagnetic crystals are magnetically anisotropic--that is, they have different magnetic properties in different crystallographic directions. In nickel, the direction of easiest magnetization is the cube diagonal  $\langle 111 \rangle$ ; in iron it is the cube edge  $\langle 100 \rangle$ . Crystal orientation, therefore, is a basic factor in the determination and control of magnetic properties.

## High-Purity Irons

For many years, extremely high-purity (99.99%) iron has been produced for research purposes by annealing at 1300 to 1500 °C (2370 to 2730 °F) in hydrogen for several hours. It is necessary to cool slowly from the high temperature through the  $\gamma$  to  $\alpha$  transformation to produce excellent soft magnetic properties. A maximum dc permeability of greater than  $10^6$  for purified iron has been achieved.

The saturation induction of iron, based on a density of 7.878 g/cm<sup>3</sup> (0.2846 lb/in.<sup>3</sup>), is reported as 2.158 T (21.58 kG). The electrical resistivity is 9.8  $\mu\Omega \cdot \text{cm}$  (59  $\Omega \cdot \text{circ mil/ft}$ ) at 20 °C (68 °F), and the temperature coefficient of resistivity is 0.0065/°C (0.0036/°F).

Commercial irons with purities of 99.6 to 99.8% are available in a variety of shapes. These irons have a saturation induction of approximately 2.15 T (21.5 kG), a specific gravity of 7.86, and a resistivity of approximately 13  $\mu\Omega \cdot \text{cm}$  at 20 °C (68 °F). The as-supplied carbon content of low-carbon magnetic iron is below 0.025%, typically 0.010% or less.

## Low-Carbon Steels

For applications that require less than superior magnetic properties, low-carbon steels such as 1008, 1010, 12L14, and so on, are sometimes used. Such steels are not sold to magnetic quality specifications and may show considerable variation in quality, depending on melting methods and the physical condition of the as-supplied product. Parts made from these steels will generally show improved soft magnetic characteristics if annealed as normally recommended for higher-quality, soft magnetic, low-carbon iron. The degree of improvement is not guaranteed, however, and the parts may be subject to considerable magnetic aging over time. Due to their low cost, availability, and machinability, they have been used as pole pieces in electromagnets, magnetic clutches, and other noncritically designed flux carriers.

## Compressed Iron Powder

For applications in which complicated magnetic parts would otherwise require considerable machining, it can be helpful to press iron powder in a mold and sinter the part in vacuum or in a reducing atmosphere. Depending on the powder metallurgy (P/M) techniques, starting powder quality, and final part configuration, the density of finished P/M iron parts can range from 6.2 g/cm<sup>3</sup> (0.224 lb/in.<sup>3</sup>) to virtually full density of 7.8 g/cm<sup>3</sup> (0.282 lb/in.<sup>3</sup>). It has been shown that the magnetic properties, as well as electrical resistivity, are a function of the density of the component. Higher saturation induction, residual induction, and maximum permeability result from increased density, whereas coercive force and

resistivity are lowered. Soft magnetic P/M parts, including those containing 0.45 to 0.80% P, are covered in ASTM standards A 811 and A 839.

Nonoriented Silicon Steels

Except for saturation induction, the magnetic properties of iron containing a small amount of silicon are better than those of pure iron. Few commercial steels contain more than 3.5% silicon, because at levels above 4% the steel becomes brittle and difficult to process with cold rolling methods.

The commercial grades of silicon steel in common use (0.5 to 3.5% Si) are made mostly in electric or basic-oxygen furnaces. Nonoriented grades are melted with careful control of impurities; better grades have sulfur contents of approximately 0.01% or less. Continuous casting and vacuum degassing can be employed. After hot rolling, the hot bands are annealed, pickled, and cold rolled to final thickness as continuous coils.

Semiprocessed grades of strip are not sufficiently decarburized for general use, and so decarburization and annealing to develop potential magnetic quality must be done by the user. This procedure is practical for small laminations accessible to the annealing atmosphere. Fully processed grades are strand annealed in moist hydrogen at approximately 825 °C (1520 °F) to remove carbon. The final annealing operation is very important and is carried out at a higher temperature--up to 1100 °C (2000 °F) for continuous strip--to cause grain growth and development of magnetic properties. Use of a protective atmosphere is vital. The steel frequently is coated with organic or inorganic materials after annealing, to reduce eddy currents in lamination stacks.

The vast majority of finished nonoriented silicon steel is sold in either full-width coils (860 to 1220 mm, or 34 to 48 in.) or slit-width coils, but some is sold as sheared sheets.

ASTM and AISI specify standard grades of electrical steel. The AISI designations were adopted in 1946 to eliminate the wide variety in nomenclature formerly used. When originally adopted, the AISI designation number approximated ten times the maximum core loss in watts per pound, exhibited by 29 gage samples when tested at a flux density of 1.5 T (15 kG) and a magnetic circuit frequency of 60 Hz.

More specific information is given by the present ASTM designation. A typical ASTM designation is 47S200. The first two digits of the ASTM designation indicate the thickness in mm ( $\times 100$ ). Following these digits is a letter (C, D, F, S, G, H, or P) that indicates the material type and the respective magnetic test conditions. The last three digits provide an indication of the maximum allowable core loss in units of either (watts/kg)  $\times 100$ , or (watts/lb)  $\times 100$ . If the core-loss value is expressed in watts/kg, the grade designation takes the suffix M, indicating an ASTM metric standard. Several ASTM flat-rolled products specifications are written in English and metric versions, such as A 677-84 and its companion metric specification A 677M-83. Table 1 gives a general summary of the ASTM code letter designation. Refer to ASTM standard A 664 for a complete explanation of the identification practice and the conditions that apply to the test parameters. The typical relative peak permeability at 60 Hz and 1.5 T (15 kG) and typical 60 Hz root mean square (rms) excitation to produce 1.5 T (15 kG) induction are useful design parameters for the application of these materials. Best permeability at high induction is obtained in steels with lower silicon contents. Low core loss is obtained with higher silicon contents, larger grains, lower impurity levels, and thinner gages. Nonoriented silicon irons are preferred for motor laminations. Table 2 lists typical applications of electrical steel sheet and strip.

Table 1 ASTM letter code designations for electrical steel and lamination steel grades (ASTM standard A 664)

Letter code	Grade	Condition	Core loss test parameters with cyclic frequency, <i>f</i> , at 60 Hz				
			Induction, <i>B</i>		Test specimen	Specimen condition	
			T	kG			
C	Low-carbon lamination steel	Fully	1.5	15	50/50	grain	As sheared

		processed			Epstein			
<b>D</b>	Low-carbon lamination steel	Semiprocessed	1.5	15	50/50 Epstein	grain	Quality annealed <sup>(a)</sup>	development
<b>F</b>	Nonoriented electrical steel	Fully processed	1.5	15	50/50 Epstein	grain	As sheared	
<b>S</b>	Nonoriented electrical steel	Semiprocessed	1.5	15	50/50 Epstein	grain	Quality annealed <sup>(a)</sup>	development
<b>G</b>	Grain-oriented electrical steel	Fully processed	1.5	15	Parallel Epstein	grain	Stress-relief annealed <sup>(b)</sup>	
<b>H</b>	Grain-oriented electrical steel	Fully processed	1.7	17	Parallel Epstein	grain	Stress-relief annealed <sup>(b)</sup>	
<b>P</b>	Grain-oriented electrical steel, high permeability	Fully processed	1.7	17	Parallel Epstein	grain	Stress-relief annealed <sup>(b)</sup>	

Note: Refer to ASTM standards for detailed information regarding test methods, heat treatments, and so on.

(a) Quality development anneal--either 790 °C (1450 °F) or 845 °C (1550 °F) soak 1 h. Temperature depends on particular grade.

(b) Stress relief anneal--usually in the range from 790 °C (1450 °F) to 845 °C (1550 °F) for 1 h

**Table 2 Silicon contents, mass densities, and applications of electrical steel sheet and strip**

ASTM specification	AISI type	Nominal (Si + Al) content, %	Assumed density, g/cm <sup>3</sup>	Characteristics and applications
Lamination steel				
<b>A 726 or A 840</b>	...	0	7.85	High magnetic saturation; magnetic properties may not be guaranteed; intermittent-duty small motors
Nonoriented electrical steels				
<b>A 677 or A 677M (fully processed) and A 683 or A 683M (semiprocessed)</b>	M-47	1.05	7.80	Ductile, good stamping properties, good permeability at high inductions; small motors, ballasts, relays
	M-45	1.85	7.75	Good stamping properties, good permeability at moderate and high inductions, good core loss; small generators, high-efficiency, continuous-duty rotating machines, ac and dc
	M-43	2.35	7.70	

	M-36	2.65	7.70	Good permeability at low and moderate inductions, low core loss; high reactance cores, generators, stators of high-efficiency rotating machines
	M-27	2.80	7.70	
	M-22 <sup>(a)</sup>	3.20	7.65	Excellent permeability at low inductions, lowest core loss: small power transformers, high-efficiency rotating machines
	M-19 <sup>(a)</sup>	3.30	7.65	
	M-15 <sup>(a)</sup>	3.50	7.65	
Oriented electrical steels				
A 876 or A 876M	M-6	3.15	7.65	Grain-oriented steel has highly directional magnetic properties with lowest core loss and highest permeability when flux path is parallel to rolling direction; heavier thicknesses used in power transformers, thinner thicknesses generally used in distribution transformers. Energy savings improve with lower core loss.
	M-5	3.15	7.65	
	M-4	3.15	7.65	
	M-3	3.15	7.65	
High-permeability oriented steel				
...	...	2.9-3.15	7.65	Low core loss at high operating inductions

## Oriented Silicon Steels

Grain size is important in silicon steel with regard to core losses and low-flux density permeability. However, for high-flux density permeability, crystallographic orientation is a major controlling factor. Like iron, silicon steels are more easily magnetized in the direction of the cube edge, {100}.

When the silicon content in pure iron exceeds approximately  $2\frac{1}{2}\%$ , the allotropic transformation of iron from  $\alpha$  to  $\gamma$  is suppressed. The absence of this transformation allows the higher silicon-iron alloy to be fully ferritic up to the melting point. This behavior permits the manufacturer of these strip products to apply special cold-rolling and heat-treating techniques to promote secondary recrystallization in the final anneal. The processing results in a well-developed crystallographic texture with the cube edge parallel to the rolling direction {110}<001>, often referred to as the Goss or cube-on-edge orientation. Conventional-oriented (anisotropic) grades contain approximately 3.15% Si.

Around 1970, improved {110}<001> crystallographic texture was developed by modification of composition and processing. The improved high-permeability material usually contains approximately 2.9 to 3.2% Si. Conventional grain-oriented 3.15% Si steel has grains approximately 3 mm (0.12 in.) in diameter. The high-permeability silicon steel tends to have grains approximately 8 mm (0.31 in.) or larger in diameter. Ideally, grain diameter should be less than 3 mm (0.12

in.) to minimize excess eddy-current effects from domain-wall motion. Special coatings provide electrical insulation and induced tensile stresses in the steel substrate. In this case, the induced stresses lower core loss and minimize noise in transformers (Table 2).

High-grade silicon electrical steel does not age significantly as received from the mill, because its carbon content has been reduced to approximately 0.003% or less. With higher carbon contents, core loss can increase with time because of carbide precipitation. Also, silicon steel can age appreciably if not correctly heat treated in a manner that completely stabilizes its physical structure.

## Iron-Aluminum Alloys

Although aluminum and silicon have similar effects on electrical resistivity and some magnetic properties of iron, aluminum is seldom substituted for silicon because of the resulting difficulties in fabrication. Aluminum is used most commonly as small (<0.5%) additions to the better grades of nonoriented silicon steel to increase electrical resistivity and thereby reduce eddy currents without impairing cold workability. Alloys of 12% Al or 16% Al and iron have high resistivity and can provide high permeability. At low flux densities, the magnetic properties of these alloys can be made to approach those of some of the low nickel-content, nickel-iron alloys.

## Nickel-Iron Alloys

The effects of nickel content in nickel-iron alloys on saturation induction after annealing and on initial permeability are illustrated in Fig. 5 and 6, respectively. Various amounts of other elements, particularly molybdenum, often are added to these alloys to develop or accentuate specific characteristics.

**Fig. 5** Magnetic saturation of nickel-iron alloys at various field strengths. All specimens were annealed at 1000 °C (1830 °F) and cooled in the furnace.

**Fig. 6** Initial permeability at 2 mT (20 G) for annealed Ni-Fe alloys

In nickel-iron alloys, as in all magnetic materials, magnetic properties are controlled by saturation magnetization and magnetic anisotropy energies. Of the various types of magnetic anisotropy energy, the magnetocrystalline and magnetostrictive anisotropies are the most important in this system. Two broad classes of alloys have been developed in the nickel-iron system. The high-nickel alloys (approximately 79% Ni) have high initial permeability (Fig. 6) but low saturation induction (approximately 0.8 T, or 8 kG), whereas the low-nickel alloys (approximately 50% Ni) are lower in initial permeability but higher in saturation induction (1.5 T, or 16 kG).

The data plotted in Fig. 7 are from early laboratory studies and illustrate the effects of both composition and heat treatment on initial permeability ( $\mu_0$ ). Values of  $\mu_0$  above  $1.2 \times 10^4$  are now obtained commercially in 50% Ni alloys, and values above  $6 \times 10^4$  are obtained in 79% Ni alloys containing 4% Mo.

**Fig. 7** Relative initial permeability at 2 mT (20 G) for nickel-iron alloys given various heat treatments. Treatments were as follows: furnace cooled--1 h at 900 to 950 °C (1650 to 1740 °F), cooled at 100 °C/h (180 °F/h); baked--furnace cooled plus 20 h at 450 °C (840 °F); double treatment--furnace cooled plus 1 h at 600 °C (1110 °F) and cooled at 1500 °C/min (2700 °F/min).

To obtain high initial permeability, both magnetocrystalline anisotropy ( $K_1$ ) and magnetostrictive anisotropy ( $\lambda_s$ ) must be minimized. Cooling rate--or, in other words, the degree of atomic ordering achieved in the critical temperature range from 760 to 315 °C (1400 to 600 °F)--has a profound influence on the ability to minimize  $K_1$ . Consequently, cooling of this alloy from heat treating temperatures must be precisely controlled to obtain  $K_1 = 0$ . For commercially practical cooling rates of approximately 100 °C/min (180 °F/min), optimum composition for achieving  $K_1 = 0$  and  $\lambda_s = 0$  is approximately 4% Mo and 80% Ni.

Because  $K_1 = 0$  and  $\lambda_s = 0$  for commercial alloys such as Supermalloy, Moly Permalloy, and Hymu 80, all of which contain approximately 4% Mo and 80% Ni, grain orientation is not critical for these alloys. Purity, however, influences permeability and core loss. Interstitial impurities such as carbon and nitrogen must be minimized by special melting procedures and by careful final annealing of laminations and other core configurations. Oxygen and sulfur are also objectionable. Best magnetic properties in nickel-iron alloys are obtained by annealing in pure dry hydrogen (dew point less than -50 °C, or -58 °F) at 1000 to 1200 °C (1830 to 2200 °F) for several hours to reduce carbon, nitrogen, sulfur, and oxygen contents. Sulfur contents higher than several ppm and carbon in excess of 20 ppm are detrimental to final annealed magnetic properties.

Most applications of 50% Ni alloys are based on requirements for high saturation induction. Nickel content is not critical near the middle of the iron-nickel series (50% Ni) and can be varied from 45 to 60%, but for highest saturation induction it should be held close to 50% (Fig. 5). Although  $K_1 = 0$ , the value of  $\lambda_{100}$ , which is the magnetostrictive constant in the  $\langle 100 \rangle$  easy direction of magnetization, is close to zero for these alloys. Therefore, the initial permeability is still reasonable and in fact reaches a small maximum (Fig. 6). In some applications, such as converters, a high squareness ratio is desired--that is, a high ratio of remanence to saturation induction ( $B_r/B_s$ ). In 50% Ni alloys, where the magnetocrystalline anisotropy is not zero, excellent squareness can be achieved by careful development of a cube texture during the final high-temperature anneal. In applications of nickel-iron alloys it is thus important to control magnetic anisotropy energies, purity, and texture, depending on what combination of properties is desired.

## Iron-Cobalt Alloys

Pure iron has a saturation induction of 2.158 T (21.58 kG). Higher saturation values can be achieved only in alloys of iron and cobalt. The highest known value is approximately 2.46 T (24.6 kG), which occurs at a cobalt content of -35%. Use of alloys containing 25 to 50% Co is limited by low resistivity and high hysteresis loss, the high cost of cobalt and the brittleness of alloys containing more than 30% Co. However, with small additions of vanadium and special treatment in processing, 49Co-49Fe-2V alloys can be cold rolled commercially to any gage, and strip is ductile enough to be punched and sheared. The 27Co-0.6Cr-Fe alloy is more easily fabricated, and less subject to degradation by stresses, than the approximately 50% Co alloy. Furthermore, proper annealing of the 27% Co alloy produces magnetic properties suitable for both dc and ac applications. Alternating-current applications require low eddy-current and hysteresis losses. Eddy-current losses can be minimized by a proper combination of composition and thickness.

## Ferritic Stainless Steels

Ferritic stainless steels have been used as soft magnetic components in products such as solenoid housings, cores, and pole pieces. Although their magnetic properties are not generally as good as conventional soft magnetic alloys, they have been successfully used for magnetic components that must withstand corrosive environments. As such, they offer a cost-effective alternative to plated iron and silicon-iron components. In addition, the relatively high electrical resistivity of ferritic stainless steels has resulted in superior ac performance.

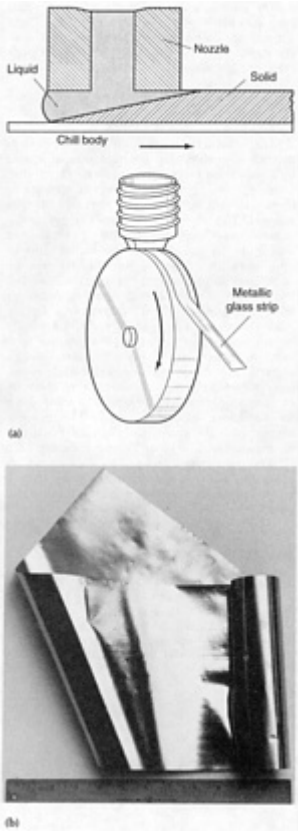

Special restricted analyses of AISI type 430F are produced for use in solenoid valve components. The ASTM A 838 specification provides typical properties for these alloys. Alloy type I is 430F containing approximately 0.4% Si and exhibiting an electrical resistivity of  $60 \mu\Omega \cdot \text{cm}$ . When fully mill annealed, it has a hardness of approximately 78 HRB. Its maximum dc permeability is approximately  $2 \times 10^3$ , with a coercivity of approximately  $160 \text{ A} \cdot \text{m}^{-1}$  (2 Oe). Alloy type 2 (430FR) is a higher-silicon version of 430F, with an electrical resistivity of  $76 \mu\Omega \cdot \text{cm}$  and a fully annealed hardness of 82 HRB. Despite its higher hardness, alloy type 2 typically exhibits a dc permeability of  $2.6 \times 10^3$  and a coercivity of  $130 \text{ A} \cdot \text{m}^{-1}$  (1.6 Oe).

## Amorphous Metals

Suitable alloys prepared in amorphous, noncrystalline form (metallic glasses) have the attractive combinations of high permeability and high volume resistivity. In the preferred planar-flow casting method of production, the metal is rapidly quenched from the melt onto cooled rotating drums to form long ribbons approximately 30 to 50  $\mu\text{m}$  thick and up to 1 m (40 in.) wide (Fig. 8). Alloys produced for soft magnetic applications include iron-, iron/nickel-, and cobalt base alloys containing varying amounts of metalloids (boron, silicon, carbon, and phosphorus) and other alloying elements such as chromium, molybdenum, nickel, iron, and aluminum. Examples of commonly employed compositions include:

Fe-base	$\text{Fe}_{80}\text{B}_{20}$
	$\text{Fe}_{80}\text{P}_{13}\text{C}_7$
	$\text{Fe}_{80}\text{P}_{16}\text{B}_1\text{C}_3$
	$\text{Fe}_{67}\text{Co}_{18}\text{B}_{14}\text{Si}_1$
	$\text{Fe}_{81}\text{B}_{13.5}\text{Si}_{2.5}\text{C}_2$
	$\text{Fe}_{76.5}\text{Cr}_2\text{B}_{16}\text{Si}_5\text{C}_{0.5}$

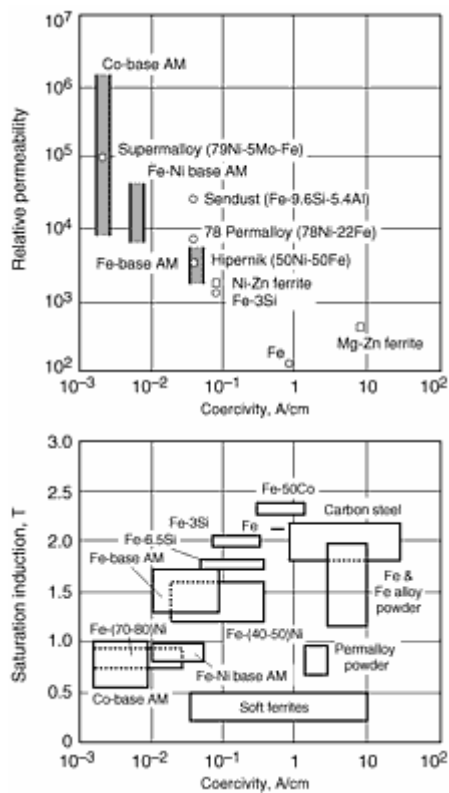

$\text{Fe}_{75}\text{Ni}_{14}\text{Mo}_3\text{B}_{16}\text{Si}_2$	
<b>FeNi-base</b>	$(\text{FeNi})_{80}\text{B}_{20}$
	$(\text{FeNi})_{80}\text{P}_{10}\text{B}_{10}$
	$\text{Fe}_{40}\text{Ni}_{38}\text{P}_{14}\text{B}_6$
	$\text{Fe}_{38.5}\text{Ni}_{38.5}\text{P}_{14}\text{B}_6\text{Al}_{1.5}\text{Si}_{1.5}$
<b>Co-base</b>	$\text{Co}_{72}\text{Fe}_3\text{P}_{16}\text{B}_6\text{Al}_3$

**Fig. 8** Preparation of metallic glass (amorphous metal) strip. (a) Schematic of the planar-flow casting method. The arrow indicates the direction of the material flow, which is identical to the direction of the chill wheel rotation. (b) Sheet of metallic glass prepared by the planar-flow casting process, which is used to wind power-distribution transformer cores

These materials are characterized by low hysteresis loss and low coercive force. However, Curie temperature is limited to approximately 475 °C (900 °F), and magnetic saturation is limited to approximately 1.7 T (16 kG). Figure 9 compares the magnetic properties of amorphous metals and conventional crystalline soft magnetic materials.

**Fig. 9** Saturation induction and relative permeability versus coercivity for commercial available amorphous metals (AM) and crystalline soft ferromagnets. Permeabilities for amorphous metal depend on heat treatments and are indicated by shaded bars.

The innovation of the planar flow casting method for producing uniform sheets of metallic glass has resulted in the commercialization of metallic glasses as a core material for power-distribution transformers. Distribution transformers are used by the utility companies in the final voltage step down in the network that supplies power to residences, stores, offices, and small industries.

These transformers are put into service for a period of 25 to 40 years, and during that time the primary coil is continuously energized. The significance of this duty pattern lies in the fact that the core material in the transformer is cycled at a frequency of 50 or 60 Hz continuously during the lifetime of the transformer. During each cycle, energy is lost to the magnetic core material. In addition, the alternating field produces eddy currents and accompanying losses within the transformer. Core losses are essentially determined by the coercive force, whereas the eddy current losses are proportional to the electrical conductivity of the material and inversely proportional to the thickness of the individual sheets of magnetic material from which the core is wound.

The low electrical conductivity of metallic glasses compared with conventional crystalline core materials (grain-oriented silicon steels) makes amorphous metals extremely attractive for reducing eddy current losses. The low coercive forces compared with competing crystalline materials reduce core loss (core losses of amorphous metal distribution transformers are approximately  $\frac{1}{3}$  to  $\frac{1}{6}$  those of silicon steels). Taken together with the fact that the continuous planar flow casting process leads to low fabrication costs, these features have led to the introduction of metallic glasses into the commercial transformer core market. The use of amorphous metals in this application can reduce energy losses, thereby reducing costs.

## Ferrites

Ferrites for high-frequency applications are ceramics with characteristic spinel-magnetic structures ( $M\cdot Fe_2O_4$ , where M is a metal) and usually comprise solid solutions of iron oxide and one or more oxides of other metals such as manganese, zinc, magnesium, copper, nickel, and cobalt. They are unique among magnetic materials in their outstanding magnetic properties at high frequencies, which result from very high resistivities ranging from approximately  $10^8 \Omega \cdot \text{cm}$  to as high

as  $10^{14} \Omega \cdot \text{cm}$ . Hence, at frequencies where eddy-current losses for metals become excessive, ferrites make ideal soft magnetic materials. Because ferrites have inherently high corrosion resistance, parts made of these materials normally do not require protective finishing.

Disadvantages of ferrites include low magnetic saturation, low Curie temperature, and relatively poor mechanical properties compared with those of metals. Ferrites are produced from powdered raw materials by mixing, calcining, ball milling, pressing to shape, and firing to the desired magnetic properties. The final product is hard, brittle, and unmachinable, and thus close dimensional tolerances must be obtained by grinding.

Many different ferrites are available for magnetic use. They can be classified into three general types: square-loop ferrites for computer memories, linear ferrites for transformers and for inductors in filters, and microwave ferrites for microwave devices. In recent years, due to increasing use of semiconductors for computer memories, square-loop ferrites have decreased in importance.

Microstructure and composition have much stronger influences on the magnetic properties of ferrites than on those of metals. Hence, properties of finished ferrite parts can vary drastically with purity and structure of raw materials, with the nature of binders used, and with the ceramic-processing technique employed. In general, lithium ferrites, Mn-Mg-Zn ferrites, and Mn-Mg-Di ferrites are used for computer memories. (Di is the symbol for didymium, a mixture of the rare earth elements praseodymium and neodymium.) Lithium ferrite is higher in Curie temperature and saturation magnetization, but lower in switching speed, than Mn-Mg-Zn and Mn-Mg-Di ferrites. Linear ferrites comprise manganese-zinc and nickel-zinc ferrites. Manganese-zinc ferrite is higher in saturation magnetization, but lower in resistivity, than nickel-zinc ferrite. Manganese-zinc ferrite is preferred for frequencies up to approximately 1 MHz. For microwave applications, Ni-Zn, Mg-Mn-Al, and Mg-Mn-Cu ferrites are used, as well as garnets of the type  $M_{3+x}Fe_{5-x}O_{12}$  (where  $M = Y + Al$ , or  $M = Y + Gd + Al$ ).

## Constant Permeability with Changing Temperature

In all magnetic materials, magnetic properties change with temperature. Proper selection and preparation of materials, and proper circuit design, can minimize these changes.

Change in flux density with temperature for iron tested at four different values of magnetizing force is plotted in Fig. 10. Operation of a device at a flux density of 1.5 T (15 kG) would be only slightly affected by variations in operating temperature near ambient. There is a similar minimized temperature effect for all materials, except that the flux density for optimum operation depends on the materials, given the proper flux density and temperature range. Great changes occur at temperatures approaching the Curie temperature (Fig. 10).

**Fig. 10** Variation of induction with temperature for iron, at four different values of magnetizing force

For many reasons, it is not always possible to operate a material at the best flux density for temperature stability. One way of obtaining better temperature stability is to use magnetic materials in insulated powder form, such as pressed Permalloy powder cores, which have good temperature stability due to the presence of many built-in air gaps. Another method involves use of nickel-iron alloys, such as Isoperm or Conpernik, that have been drastically cold rolled and then underannealed to produce a partly strained alloy less sensitive to temperature changes.

In a third method, two alloy powders with opposite temperature coefficients are combined for use in the desired temperature range. Special Permalloy powder cores are combined with small amounts of Ni-Fe-Mo powder having a low Curie temperature and a negative temperature coefficient near room temperature. The 30% Ni irons are of the low-Curie-temperature type.

## Alloys for Magnetic Temperature Compensation

Many measuring instruments and other devices depend on maintaining constant flux, produced by a permanent magnet, across an air gap. Unfortunately, as a permanent magnet is warmed, it loses strength and the air gap flux density changes. To compensate for such changes, a certain amount of the magnetic flux can be shunted around the air gap of the instrument by using an alloy with high negative magnetic temperature coefficient in the temperature range of interest. The amount of shunted flux, therefore, decreases with increasing ambient temperature, forcing more flux through the gap than would normally occur. Nearly complete compensation for temperature changes can be made by correct design of parts. Watt-hour meters and automobile speedometers are examples in which a temperature compensator shunt has been used to compensate for the change in pole strength of the permanent magnet (and the change in electrical resistivity of the aluminum drag disk) over their designed working-temperature range. Nickel-iron alloys containing between approximately 28% and 36% Ni are frequently used commercially for this purpose.

# Permanent Magnet Materials

---

## Introduction

PERMANENT MAGNET is the term used to describe solid materials that have sufficiently high resistance to demagnetizing fields and sufficiently high magnetic flux output to provide useful and stable magnetic fields. Permanent magnets are normally used in a single magnetic state. This implies insensitivity to temperature effects, mechanical shock, and demagnetizing fields. This article does not consider magnetic memory or recording materials in which the magnetic state is altered during use. It does include, however, hysteresis alloys used in motors.

Permanent magnet materials include a variety of alloys, intermetallics, and ceramics. Commonly included are certain steels, Alnico (a cast or sintered iron-base alloy containing 7 to 10% Al, 15 to 19% Ni, 13 to 35% Co, 3 to 4% Cu, with an optional 1 to 5% Ti), Cunife (60Cu-20Ni-20Fe), iron-cobalt containing vanadium or chromium, platinum-cobalt, hard ferrites ( $\text{SrO-Fe}_2\text{O}_3$  or  $\text{BaO-6Fe}_2\text{O}_3$ ), cobalt-rare earth alloys ( $\text{SmCo}_5$  or  $\text{Sm}_2\text{CO}_{17}$ ), and neodymium-iron-boron alloys made by powder metallurgy processing. Each type of magnet material possesses unique magnetic and mechanical properties, corrosion resistance, temperature sensitivity, fabrication limitations, and cost. These factors provide designers with a wide range of options in designing magnetic parts.

Permanent magnet materials are based on the cooperation of atomic and molecular moments within a magnet body to produce a high magnetic induction. This induced magnetization is retained because of a strong resistance to demagnetization. These materials are classified ferromagnetic or ferrimagnetic and do not include diamagnetic or paramagnetic materials. The natural ferromagnetic elements are iron, nickel, and cobalt. Other elements, such as manganese or chromium, can be made ferromagnetic by alloying to induce proper atomic spacing. Ferromagnetic metals combine with other metals or with oxides to form ferrimagnetic substances; ceramic magnets are of this type. Although scientific literature lists many magnetic substances, relatively few have gained commercial acceptance because of the commercial requirement for low cost and high efficiency.

Permanent magnet materials are developed for their chief magnetic characteristics: high induction, high resistance to demagnetization, and maximum energy content. Magnetic induction is limited by composition; the highest saturation

induction is found in binary iron-cobalt alloys. Resistance to demagnetization is conditioned less by composition than by shape or crystal anisotropies and the mechanisms that subdivide materials into microscopic regions. Precipitations, strains and other material imperfections, and fine particle technology are all used to obtain a characteristic resistance to demagnetization.

Maximum energy content is most important because permanent magnets are used primarily to produce a magnetic flux field (which is a form of potential energy). Maximum energy content and certain other characteristics of materials used for magnets, are best described by its hysteresis loop. Hysteresis is measured by successively applying magnetizing and demagnetizing fields to a sample and observing the related magnetic induction.

## Fundamentals of Magnetism

For understanding a permanent magnet, Faraday's concept of representing a magnetic flux field by lines of force is very useful. The lines of force radiate outward from a north pole and return at a south pole. The lines of force can be revealed by a powder pattern made by sprinkling iron powder on a paper placed above a bar magnet. The number of lines per unit area is the magnetic induction and is designated  $B$ . Induction in the magnet consists of lines of force due to the magnetic field and lines of magnetization due to the ferromagnetism of the magnet:

$$B = H + B_i \quad (\text{Eq 1})$$

where  $H$  is the magnetic field strength and  $B_i$  is the intrinsic induction.

**Magnetic Hysteresis.** A hysteresis loop is a common method of characterizing a permanent magnet. The intrinsic induction is measured as the magnetizing field is changed (see Fig. 1). Starting with a virgin state of the material at the origin 0, induction increases along curve I to the point marked +S as the field is increased from zero to maximum. The point +S is the point at which induction no longer increases with higher magnetizing field, and is known as the saturation induction. When the magnetizing field is reduced to zero in permanent magnets, most of the induction is retained. In Fig. 1, when the field is reduced through zero and reversed to -S, the induction decreases from +S to  $B_r$  to -S. At zero field, there is a remanent magnetization in the sample, defined as  $B_r$ ; the value of  $B_r$  approaches the saturation induction in well prepared permanent magnet materials. This point on the hysteresis loop is called residual induction.

**Fig. 1** Major hysteresis loop for a permanent magnet material.  $B_i$  (sat) is the saturation induction

If the field is increased again in the positive direction, the induction passes through  $-B_r$  to +S as shown, and not through the origin. Thus, there is a hysteresis effect, and this plot is called the hysteresis loop. The two halves of the loop are generally symmetrical and form a major loop, which represents the maximum energy content, or the amount of magnetic energy that can be stored in the material. Innumerable minor loops can be measured within the major loop, measurements being made to show the effects of lesser fields on magnets under operating conditions.

**Demagnetization.** The particular value of the demagnetizing field needed to reduce  $B_i$ , (or  $J$ ) to zero is called the intrinsic coercive force  $H_{ci}$ . Figure 1 includes the normal demagnetization curve derived from the intrinsic curve. The field required to reduce induction  $B$  to zero is the normal coercive force  $H_c$ . The important practical features of the curve for application to permanent magnet materials are the numerical values of  $B_r$ ,  $H_c$ ,  $H_{ci}$ , and the area within the hysteresis loop.

Because a permanent magnet most often is used to provide a flux field in a space outside itself, the material rests within its own field, which is a self-demagnetizing field. Therefore, for practical applications, a magnet designer is interested primarily in the second quadrant of the hysteresis loop, called the demagnetization curve (see Fig. 2). This curve represents the resistance to demagnetization and, in an affirmative sense, the ability of a material to establish a magnetic field in an air gap or adjoining magnetic material.

Fig. 2 Normal demagnetization curve for a permanent magnet material

**Magnetic Energy.** The maximum magnetic energy available for use outside the magnet body is proportional to the largest rectangle that fits inside the normal demagnetization curve. It is indicated by the product  $(B_d H_d)_{\max}$ , and is usually cited as the figure of merit for determining the quality of permanent magnet materials.

A characteristic useful in selecting permanent magnet materials subjected to varying demagnetizing conditions is the permeability (that is, the ratio of the induction to the corresponding magnetizing force) at the operating point:

$$\mu = B_d / H_d \quad (\text{Eq 2})$$

For example, a straight-line demagnetization curve where  $B_r = H_c$  would have the ideal permeability of 1.0; a magnet of such a material would recover spontaneously all flux when a partial demagnetizing field is removed. The corresponding intrinsic curve would be flat out to the knee, and the material would retain maximum energy. Rare-earth alloys and high coercivity hard ferrite magnets come closest to ideal permanent magnet behavior.

Figure 3 is the product curve of  $B$  and  $H$  at each point along the demagnetization curve, plotted against  $B$ . On the demagnetization curve, each value of  $B$  or  $H$  involves the other as a coordinate variable. The maximum value of their product-- $(B_d H_d)_{\max}$ --represents the maximum magnetic energy that a unit volume of the material can produce in an air gap. Often, the most efficient design for a magnet is that which employs the magnet at the flux density corresponding to the  $(B_d H_d)_{\max}$  value.

**Fig. 3** Typical energy-product curve for a permanent magnet material

The amount of total external magnetic flux available from a magnet operating in an open-circuit condition (that is, some flux both in air or nonmagnetic substance) depends on its shape. Figure 4 shows this relation for one specific shape. The permeability  $\mu$  is the ratio of the total external permeance  $B_d$  to that of the permeance of the space occupied by the magnet,  $H_d$ , and is equal to the slope of the demagnetization curve.

**Fig. 4** Relation between magnetic properties and dimensions of straight bar magnets of circular cross section

Figure 5 gives an enlarged plot of the first and second quadrants of the intrinsic induction curve. The intrinsic demagnetization curve is of interest to both the materials scientist and the applications engineer. Material scientists are concerned about the effect of composition and processing on the various intrinsic parameters of the material:  $B_{is}$ ,  $B_r$ , and  $H_{ci}$ . Applications engineers are concerned about the flux density in an air gap due to both  $B_i$  and  $H$ . Accordingly, they are interested in the normal induction curve and in the values of  $B_r$ ,  $H_c$ , and  $(BH)_{max}$ . Design engineers use the intrinsic induction curve to predict performance while the magnet is under the influence of temperature, armature reaction, or other demagnetizing forces.

Fig. 5 Intrinsic magnetization curve  $B_i$  in the first and second quadrants compared with the curve for  $B$

Lines of constant energy product ( $B_d H_d$ ) usually are plotted in the second quadrant area of a hysteresis loop, As illustrated in Fig. 6, they appear as a series of hyperbolic curves superimposed on the rectangular  $B$ - $H$  grid of the demagnetization curves. The maximum values of external energy are therefore readily available in relation to the demagnetization curve. In this form, the grid constitutes an efficient guide for the design engineer. In practice, a magnet with a fixed air gap would have one fixed  $B_d/H_d$  operating point on the demagnetization curve corresponding to the material being used. For variable air gaps, such as are produced by relative movement between the armature and field poles of electrical machinery, the external energy available at the air gap changes continuously, resulting in a so-called minor loop with minimum and maximum values. In practice, the minor loop is plotted on the demagnetization curve to determine location of the loop on the curve, and to evaluate the extent of flux variation within the minor loop cycle. Efficient design of equipment using permanent magnets, such as magnetos, small generators, and motors, requires that the minor loop operate near the  $(B_d H_d)_{\max}$  point.

Fig. 6 Magnetization curves for anisotropic cast Alnico permanent magnet materials

Magnetically soft materials differ from permanent magnet materials not only in their higher permeabilities, but also, and more significantly, in their much lower resistance to demagnetization. The best magnetically soft materials have  $H_c$  values of virtually zero. The hysteresis loop of such a material retraces itself through or near the origin point with each cycle.

Conversely, permanent magnet materials have wide hysteresis loops, characterized by high values of  $H_{ci}$ , which range from approximately 8 to  $>1.6 \times 10^3$  kA  $\cdot$  m<sup>-1</sup> (100 Oe to >20 kOe).

## Permanent Magnet Materials

**Compositions and Properties.** Table 1 lists selected permanent magnet materials commercially available in the United States and their nominal compositions. Magnetic properties are given in Table 2. Physical and mechanical properties are summarized in Table 3. The production of permanent magnet materials is controlled to achieve magnetic characteristics, and other properties are allowed to vary according to the manufacturing process used. The selection of materials and the design of permanent magnets for particular applications is a well-defined engineering art; design assistance is available from most producers.

**Selection and Application.** Over the years, the number and range of applications utilizing permanent magnets has increased dramatically. Some of the more predominant applications include aircraft magnetos, alternators, magnetos for lawn mowers, garden tractors, and outboard motors; small and large direct current (dc) motors (including automotive motors); acoustic transducers; magnetic couplings; magnetic resonance imaging; magnetic focusing systems; ammeters and voltmeters; and watt-hour meters. Table 4 lists the materials recommended for various applications.

**Table 4 Applications of permanent magnet materials**

Application	Recommended material	Primary reason for selection	Alternative material	Condition or reason favoring selection of alternative material
<b>Aircraft magnetos, military or civilian</b>	SmCo	Maximum energy per unit volume	Cast Alnico 5	Availability or cost restraint
<b>Alternators</b>	SmCo	Compactness and reliability	Ferrite Alnico	Where space is available for a larger volume of material of lower magnetic energy and cost
<b>Magnetos for lawn mowers, garden tractors, and outboard engines</b>	Ferrite	Adequate magnetic energy at lower cost than Alnico	Alnico NdFeB	Higher energy material is required
<b>Small direct current motors</b>	Bonded ferrite	Shape favors fabrication; adequate magnetic energy at lower cost	Bonded NdFeB Sintered ferrite	Higher magnetic energy is required
<b>Large direct current motors</b>	SmCo	Maximum energy per unit volume	NdFeB	Where lower cost is required, operating temperature is low
<b>Automotive direct current motors</b>	Ferrite	Adequate magnetic energy at lower cost than alternate materials	Bonded NdFeB	Higher magnetic energy and less weight
<b>Automotive cranking motors</b>	Ferrite	Adequate magnetic energy at lower cost than alternate materials	Bonded NdFeB	Higher magnetic energy and less weight
<b>Voice coil motors (computers)</b>	NdFeB	High energy	SmCo	Availability
<b>Acoustic transducers</b>	Ferrite	Low cost	NdFeB	Higher magnetic energy allows smaller size and weight
<b>Magnetic couplings (small gap)</b>	Ferrite	Adequate magnetic energy at lower cost	Bonded NdFeB	Higher torque is required
<b>Magnetic couplings (large gap)</b>	NdFeB	High energy	SmCo	High operating temperature
<b>Transport systems</b>	NdFeB	High Energy	SmCo	Availability
<b>Separators</b>	Ferrite	Adequate magnetic energy at lower cost	NdFeB	High magnetic energy required
<b>Magnetic resonance imaging</b>	NdFeB	High energy	Ferrite	Where space is available for a larger volume of material of lower energy
<b>Magnetic focusing systems</b>	NdFeB	High energy	SmCo	High operating temperatures or low-temperature coefficient is required
<b>Synchronous hysteresis motors</b>	Isotropic FeCrCo	Shape favors fabrication from wrought material	Cobalt steel	Availability
<b>Holding devices</b>	Ferrite	Adequate magnetic energy at low cost	Alnico	Where holding force versus temperature must not vary over wide ranges
<b>Ammeters and voltmeters</b>	Alnico	Low temperature coefficient	Not available	...
<b>Watt-hour meters</b>	Alnico 5 or 6	Low temperature coefficient	Not available	...

### Optimum Alloy Usage

## ***Stabilization and Stability***

There is an important group of permanent magnet applications where the accuracy or performance of the device is drastically affected by very small changes (1% or less) in the strength of the magnet. These applications include braking magnets for watt-hour meters, magnetron magnets, special torque motor magnets, and most dc panel and switchboard instrument magnets. Operation of these devices requires extreme accuracy over a moderate range of conditions or moderate accuracy over an extreme range of conditions.

If the nature and magnitude of the conditions are known, it often is possible to predict the flux change. It also may be possible, by exposing the magnet to certain influences in advance, to render the magnet insensitive to subsequent changes in service. For many years, permanent magnets in instruments have exhibited long-term stability of the order of one part per thousand (0.1%). More recently, investigations in conjunction with inertial guidance systems for space vehicles have shown that long-term stability of the order of one to 10 ppm (0.0001 to 0.001%) can be achieved. This incredible stability of a magnetic field achieved with modern permanent magnets contrasts sharply with the instability of very early (steel) permanent magnets, in which both structural and magnetic changes caused a significant loss of magnetization with time.

## ***Irreversible Changes***

Losses in magnetization with time can be classified as reversible or irreversible. Irreversible changes are defined as changes where the affected properties remain altered after the influence responsible for the change has been removed. For example, if a magnet loses field strength under the influence of elevated temperature and if the flux does not return to its original value when the magnet is cooled to room temperature, the change is considered irreversible.

**Temperature Effects.** The properties of a magnet vary with temperature in a manner that usually can be predicted. The variation of  $B_{is}$  with temperature can be calculated from theory, provided detailed knowledge of the crystallographic and magnetic structure of the magnetic phase is available. In many other instances, such information is not yet available, but direct measurements of  $B_{is}$  versus  $T$  have been made. Both irreversible and reversible magnetization losses have been documented.

Changes in  $H_{ci}$  with temperature can be predicted from the changes with temperature of anisotropy and magnetization. This assumes knowledge of the physical origin of all anisotropies contributing to  $H_{ci}$ . For a case where shape anisotropy is dominant, calculated and experimental results also are in good agreement, especially when the small crystal anisotropy contributions are considered. In the case of Alnico, crystal anisotropy is more in evidence. In addition, there is greater uncertainty as to the effect of the so-called nonmagnetic phase, especially at lower temperatures where the nonmagnetic phase can contribute appreciable magnetization. In the case of steels, the temperature dependence based on the inclusion mechanism is difficult to predict. Demagnetization curves can change in both shape and peak with changes in temperature.

**Changes in Metallurgical State.** Irreversible changes begin to occur at different temperatures for different alloys. These changes usually depend on both time and temperature, and thus short exposures above the recommended temperatures may be tolerated. These changes can take the form of growth of the precipitate phase, such as in Alnico and Cunife; precipitation of another phase, such as  $\gamma$  precipitation in Alnico; an increase in the amount of an ordered phase, such as in platinum-cobalt; an increase in grain size, as in  $\text{SrO} \cdot 6\text{Fe}_2\text{O}_3$ ; oxidation, as occurs with metals, or reduction, as occurs with oxides, radiation damage, cracking, or changes in dimensions.

Irreversible metallurgical changes often can be counteracted, and original properties restored, by a suitably chosen thermal treatment. For example, if Alnico 5 has become degraded by exposure to 700 °C (1290 °F), it can be solution treated at 1300 °C (2370 °F), cooled in a magnetic field, and aged at 600 °C (1110 °F) to reattain the optimum metallurgical structure.

A nuclear environment is known to cause changes in metallurgical structure and thus changes in magnetic properties. Permanent magnet materials tested were not affected by neutron (n) irradiation at levels below approximately  $3 \times 10^{17}$  n/cm<sup>2</sup> ( $2 \times 10^{18}$  n/in.<sup>2</sup>). Results of later work at levels up to  $10^{20}$  n/cm<sup>2</sup> ( $6 \times 10^{20}$  n/in.<sup>2</sup>) showed some degradation. The Alnico materials are not affected by radiation up to  $5 \times 10^{20}$  n/cm<sup>2</sup> ( $3 \times 10^{21}$  n/in.<sup>2</sup>) at neutron energies greater than 0.4 eV, and up to  $2 \times 10^{19}$  n/cm<sup>2</sup> ( $1 \times 10^{20}$  n/in.<sup>2</sup>) for neutron energies greater than 2.9 MeV. Radiation effects were found to be independent of temperature, but high temperatures tended to counteract radiation effects. More recently developed permanent magnet materials such as  $\text{Sm}_2\text{Co}_5$  and  $\text{NdFeB}$  are more sensitive to radiation.

**Changes in magnetic state** can be caused by temperature effects, such as ambient temperature changes or statistical local temperature fluctuations within the material; mechanical effects, such as mechanical shock or acoustical noise; or magnetic field effects, such as external fields, circuit reluctance changes, or magnetic surface contacts. In all of these situations, the loss of magnetization can be restored by remagnetizing.

Mechanical shock and vibration add energy to a permanent magnet and decrease the magnetization in the same manner as discussed for the case of thermal energy. The only difference is that energy imparted thermally to the magnet is precisely  $kT$ , where  $k$  is the Boltzmann constant and  $T$  is the temperature, whereas the energy imparted mechanically usually is not known. Thus, repetitive shocks or continual vibration should decrease the magnetization by the same logarithmic relations as for thermal effects, but where time is replaced, for example, by number of impacts.

Little work has been done regarding stabilization to minimize mechanical effects because it is seldom found necessary. It is generally conceded that modern permanent magnet materials are not affected by mechanical shock.

### ***Reversible Changes***

A loss of magnetization caused by a disturbing influence, such as temperature or an external magnetic field, is considered reversible if the original properties of the magnet return when the disturbing influence is removed.

**Time Effects at Constant Temperature.** In ferromagnetic materials, the intensity of magnetization does not instantly attain its equilibrium value when the applied field is suddenly changed. This time dependence can be due to eddy current effects or to reversible or irreversible magnetic viscosity. In general, eddy current effects are important only for a very short time--normally, less than a second after a change in the applied field. Such effects are not considered here. Reversible magnetic viscosity has been shown to be due to ionic diffusion in the crystal lattice and thus has a time-temperature dependence characteristic of diffusion processes. The time constant is:

$$\tau = \tau_{\infty} \exp (E/RT) \quad (\text{Eq 3})$$

where  $\tau_{\infty}$  is the time constant at infinite temperature,  $R$  is the reluctance (the reciprocal of permeance), and  $E$  is the activation energy, normally 0.1 to 1 eV. The time constant appears to be important only in magnetically soft materials, and only at high frequencies.

Irreversible magnetic viscosity is important to the stability of permanent magnets. Irreversible magnetic viscosity is due to the influence of thermal fluctuations on magnetization or the domain process responsible for magnetization. The effect of thermal agitation has been considered in terms of the energy required to activate irreversible domain processes. The time-temperature dependence of magnetization was shown to be given by:

$$M(t) = S \ln t \quad (\text{Eq 4})$$

where  $S = \lambda N M_s kT$ . Here,  $N$  is the number of blocks, or regions of magnetization  $M_s$  per unit volume, and  $\lambda$  is the constant probability density of energy  $E$  of all these blocks. Because these factors are all relatively independent of temperature (except near the Curie temperature),  $S$  is nearly directly proportional to  $T$ . The results of experiments are in agreement with this equation. Aging at room temperature results in losses in magnetization for many materials.

### ***Design Considerations***

Stability can have a significant influence on choice of magnet material, as well as on component shape and magnetic circuit arrangement. For example, the rather drastic change in coercive force of oriented hard ferrite with temperature requires special considerations in design. Here, the lowest permeance coefficient ( $B/H$ ) that can be used is established by stability considerations rather than by magnetic circuit analysis.

For the more widely used permanent magnet materials, reversible changes in magnetization are encountered by cooling below room temperature. Because the reversible remanence changes are closely approximated by a straight line, a reversible temperature coefficient is listed in magnetic property tabulations. The values of the temperature coefficient

vary with the material. When the values of the coefficient are very small, they can be of a different sign for different magnet shapes. Consequently, it is often possible to carefully design magnet shape to yield very small variations in remanence with temperature. Similar changes may result on heating above room temperature. It is important to distinguish between irreversible losses and reversible changes. It is common practice prior to use to cycle a magnet between the temperature extremes to be encountered in service. Nearly all of the irreversible loss is encountered in one temperature cycle, but in some instances four or five cycles may be necessary.

In applications that are extremely sensitive to magnetization changes, it is very common to use a temperature compensating circuit to counteract reversible changes over the operating temperature range. Temperature-sensitive iron-nickel alloys are used as magnetic shunts for this purpose. A shunt is mounted beside the permanent magnet and simply diverts flux from the air gap as the temperature decreases. Temperature compensation by shunting requires overdesign of the magnet to allow for the loss in flux through the shunt at low operating temperatures.

**Exposure at Very High Temperatures.** There is considerable interest in using permanent magnets at temperatures approaching the Curie temperature of the permanent magnet material. The anisotropic Alnico 5 and Alnico 6 have been considered for use at 500 to 700 °C (930 to 1290 °F). At these temperatures, metallurgical effects as well as irreversible and reversible temperature effects are present. Alnico 5 exposed to 700 °C (1290 °F) for 20 h resulted in the reduction of  $(BH)_{\max}$  and  $H_c$  to approximately one half of their initial values. It is possible to program such changes into equipment and devices to allow permanent magnets to function for a limited time at extreme temperatures.

**Stress Effects.** Some magnets subjected to tension or compression show large changes in properties. This is especially true of Vicalloy and Cunife. The changes are reversible, often even after considerable deformation has occurred. The changes are due to the contribution that stress makes to the total anisotropy of the system.

**Magnetization Prior to Use.** Magnets are magnetized in applied fields supplied by dc or pulsed-current electromagnets. Where practical, saturating magnetizing fields are recommended to gain full use of magnetic potential energy. Most magnets are demagnetized by heating to the Curie temperature or by applying an ac or dc field to reduce the measured induction to zero. Materials such as Alnico and samarium cobalt cannot be demagnetized by exposure to their Curie temperature because the metallurgical changes alter the permanent magnet properties.

# Superconducting Materials

## Introduction

SUPERCONDUCTORS are materials that exhibit a complete disappearance of electrical resistivity on lowering the temperature below a critical temperature ( $T_c$ ). For all superconductors presently known, the critical temperatures are well below room temperature, and they are attained by cooling with liquified gas (helium or nitrogen), either at or below atmospheric pressure. A superconducting material must also exhibit perfect diamagnetism, that is, the complete exclusion of an applied magnetic field from the bulk of the superconductor. Superconductivity permits electric power generators and transmission lines to have capacities many times greater than recently possible. It also allows the development of levitated transit systems capable of high speeds and provides an economically feasible way of producing the large magnetic fields required for the confinement of ionized gases in controlled thermonuclear fusion.

---

## Basic Principles

The critical temperature varies from superconductor to superconductor, but lies between approximately 1 and 20 K for metals and alloys. More recently developed ceramic superconductors have critical temperatures exceeding 100 K. At temperatures below  $T_c$ , the superconducting state will cease upon application of a sufficiently large magnetic field, termed the critical field,  $H_c$ , which depends on temperature and decreases with increasing temperature. The same is true for current density; that is, a critical applied current density,  $J_c$ , exists below which a material is superconductive. Figure 1 shows how these three factors are interrelated. Materials lying within the  $T_c H_c J_c$  envelope boundary in Fig. 1 will be superconductive; outside the boundary, conduction is normal.

**Fig. 1** Critical temperature, current density, and magnetic field boundary separating superconducting and normal conducting states. These data, which are for a niobium-titanium superconducting alloy, are based on measurements at 4.2 K.

On the basis of magnetic response, superconducting materials can be divided into two classifications designated as type I and type II. Type I materials, while in the superconducting state, are completely diamagnetic; that is, all of an applied magnetic field will be excluded from the body of the material. This phenomenon, known as the Meissner effect, is shown schematically in Fig. 2. As  $H$  is increased, the material remains diamagnetic until the critical magnetic field  $H_c$  is reached. At this point, conduction becomes normal, and complete magnetic flux penetration occurs. Several metallic elements including aluminum, lead, tin, and mercury belong to the type I group.

**Fig. 2** Schematic of the Meissner effect. (a) While in the superconducting state, a body of material (shaded circle) excludes a magnetic field (arrows) from its interior. (b) The magnetic field penetrates the same body of material once it becomes normally conductive.

Type II superconductors are completely diamagnetic at low applied fields, and field exclusion is total. However, the transition from the superconducting state to the normal state is gradual and occurs between lower critical and upper

critical fields, designated  $H_{c1}$  and  $H_{c2}$ , respectively. The magnetic flux lines begin to penetrate into the body of material at  $H_{c1}$ , and with increasing applied magnetic field, this penetration continues; at  $H_{c2}$ , field penetration is complete. For fields between  $H_{c1}$  and  $H_{c2}$ , the materials exists in what is termed a "mixed state"--superconductivity persists in the mixed state up to  $H_{c2}$ , above which the material is a normal conductor. Type II superconductors are preferred over type I for most practical applications by virtue of their higher critical temperatures and critical magnetic fields. Table 1 compares the properties of various type I and type II superconducting materials.

**Table 1 Approximate superconducting properties of selected superconducting materials**

Material	Type	Critical temperature, $T_c$ at 0 T	Parameters at 4.2 K

## Superconductor Categories

Superconductivity is observed in several hundred materials. These include more than half of the metallic elements and a wide range of alloys and compounds (type II superconductors). To date, however, the materials that have received the most attention are niobium-titanium superconductors (the most widely used superconductor), A15 compounds (in which class the important ordered intermetallic Nb<sub>3</sub>Sn lies), ternary molybdenum chalcogenides (Chevrel phases), and high  $T_c$  ceramic superconductors. Figure 3 compares the critical temperatures for metallic and ceramic superconducting materials. The advantage of the higher  $T_c$  ceramics is that they can be cooled with liquid nitrogen, which is much cheaper and more abundant than helium (the cooling medium for metallic superconductors). The brittle nature of ceramic superconductors, however, limits the ability of these materials to be fabricated into useful forms such as wires. The goal of superconductor research is to develop fabricable conductors that can be cooled with conventional refrigeration equipment or function at room temperature.

**Fig. 3** The critical temperature for various superconducting materials as a function of their date of development. The open circles are metallic superconductors, while the closed circles are ceramic.

**Niobium-titanium superconductors** are actually composite wires that consist of niobium-titanium filaments ( $<10 \mu\text{m}$  in diameter) embedded in a ductile matrix (stabilizer) that must provide high electrical conductivity and thermal conductivity, high heat capacity, and good mechanical strength at cryogenic temperature. High-purity, oxygen-free copper (C10100) satisfies all of these requirements and is the most frequently stabilizing matrix material. Commercially pure aluminum (alloy 1100, 99.0% Al) and copper-nickel alloy (typically in concentrations of 90 to 10 or 70 to 30) matrices have also been utilized. The filament alloy most widely used is Nb-46.5Ti. Binary niobium-titanium superconductors in the range of 45 to 50% Ti exhibit  $T_c$  values of 9.0 to 9.3 K. Composite conductors containing as few as one to as many as 25,000 filaments have been processed by advanced extrusion and wire-drawing techniques. Important applications for niobium-titanium superconductors include magnets for use in magnetic resonance imaging (MRI) devices used in hospitals, high-energy physics pulsed accelerator magnet applications (particle accelerators), and devices for magnetically confining high-energy plasma for thermonuclear fusion.

**A15 superconductors** (A15 refers to a cubic crystal type in the Strukturbericht system) are brittle intermetallic compounds with the chemical formula  $A_3B$ , where A is a transition metal and B can be either a transition metal or nontransition element. Of the 76 known A15 compounds, 46 are known to be superconducting. Important examples include Nb<sub>3</sub>Ge ( $T_c = 23 \text{ K}$ ), Nb<sub>3</sub>Ga ( $T_c = 20.3 \text{ K}$ ), Nb<sub>3</sub>Al ( $T_c = 18.9 \text{ K}$ ), Nb<sub>3</sub>Sn ( $T_c = 18.3 \text{ K}$ ), V<sub>3</sub>Si ( $T_c = 17.1 \text{ K}$ ), and V<sub>3</sub>Ga ( $T_c = 15.4 \text{ K}$ ). Because of ease of fabrication, Nb<sub>3</sub>Sn is the most commercially important A15 compound. Like niobium-titanium superconductors, Nb<sub>3</sub>Sn is also assembled into multifilamentary wires embedded by various techniques into a copper stabilizing matrix (Fig. 4). Diffusion barriers (niobium, tantalum, or vanadium) are also used to prevent reaction between the matrix and filaments during elevated-temperature processing. Applications for Nb<sub>3</sub>Sn-based superconductors include large commercial solenoid magnets, alternating current (ac) motors, and generators for power generation, power transmission cables, and high-energy physics and fusion technology applications.

**Fig. 4** Cross section of a multifilamentary  $\text{Nb}_3\text{Sn}$  superconductor wire (20 mm, or 0.78 in. diam). The 18 filaments in the wire each have individual bimetal diffusion barriers composed of concentric rings of niobium around vanadium. The matrix surrounding the filaments is copper. 75×

The **ternary molybdenum chalcogenides** represent a vast class of materials with a general formula of  $M_x\text{Mo}_6X_8$ , where  $M$  is a cation and  $X$  is a chalcogen (sulfur, selenium, or tellurium). Most of the research on these materials has centered around  $\text{PbMo}_6\text{S}_8$  (PMS) and  $\text{SnMo}_6\text{S}_8$  (SMS), the former having a  $T_c$  of 14 to 15 K. The PMS or SMS wire is embedded in a copper or molybdenum matrix. A niobium diffusion layer is used in the case of copper matrices.

**High-temperature superconductors** ( $T_c$  values exceeding 90 K) are ceramic oxides in wire, tape, or thin-film form. The systems that have been extensively studied include Y-Ba-Cu-O (most notably  $\text{YBa}_2\text{Cu}_3\text{O}_7$  with a  $T_c = 92$  K), Bi-Sr-Ca-Cu-O ( $T_c = 110$  K), and Tl-Ba-Ca-Cu-O ( $T_c > 120$  K). Oxide-base superconductors in wire or tape form are produced by packing the powder in a silver tube, which is then swaged or drawn into a wire, or if desired, rolled into a tape.

# Electrical Resistance Alloys

## Introduction

ELECTRICAL RESISTANCE ALLOYS include both the types used in instruments and control equipment to measure and regulate electrical characteristics and those used in furnaces and appliances to generate heat. In the former applications, properties near ambient temperature are of primary interest: in the latter, elevated-temperature characteristics are of prime importance. In common commercial terminology, electrical resistance alloys used for control or regulation of electrical properties are called resistance alloys, and those used for generation of heat are referred to as heating alloys. Electrical resistance materials of a third class, used in applications where heat generated in a metal resistor is converted to mechanical energy, are termed thermostat metals.

## Resistance Alloys

The primary requirements for resistance alloys are uniform resistivity, stable resistance (no time-dependent aging effects), reproducible temperature coefficient of resistance, and low thermoelectric potential versus copper. Properties of secondary importance are coefficient of expansion, mechanical strength, ductility, corrosion resistance, and ability to be joined to other metals by soldering, brazing or welding. Availability and cost are also factors.

Table 1 lists nominal compositions and physical properties of metals and alloys used to make resistors for instruments and controls.

- (a) At 20 °C (68 °F).
- (b) To convert to  $\Omega$ -circular-mil/ft, multiply by 0.6015.
- (c) Temperature coefficient of resistance is  $(R - R_0)/R_0 (t - t_0)$ , where  $R$  is resistance at  $t$  °C and  $R_0$  is resistance at the reference temperature  $t_0$  °C.
- (d) At 25 to 105 °C.
- (e) Shunt manganin

Resistance alloys must be ductile enough so that they can be drawn into wire as fine as 0.01 mm (0.0004 in.) in diameter or rolled into narrow ribbon from 0.4 to 50 mm ( $\frac{1}{64}$  to 2 in.) wide and from 0.025 to 3.8 mm (0.001 to 0.15 in.) thick.

Alloys must be strong enough to withstand fabrication operations, and it must be easy to procure an alloy that has consistently reproducible properties. For instance, successive batches of wire must have closely similar electrical characteristics: if properties vary from lot to lot, resistors made of wire from different batches may cause a given model of instrument to exhibit widely varying performance under identically reproduced conditions or may cause large errors in a given instrument when a resistor from one batch is used as a replacement part for a resistor from another batch.

Coefficients of expansion of both the resistor and the insulator on which it is wound must be considered because stresses can be established that will cause changes in both resistance and temperature coefficient of resistance. It is equally important that consideration be given to the choice between single-layer and multiple-layer wound resistors because of the difference in rate of heat dissipation between the two styles.

In design of primary electrical standards of very high accuracy, cost of resistance material is not a consideration. For ordinary production components, however, cost may be the deciding factor in material selection.

## Resistors

Resistors for electrical and electronic devices can be divided into two arbitrary classifications on the basis of permissible error: those employed in precision instruments in which over-all error is considerably less than 1% and those employed where less precision is needed. The choice of alloy for a specific resistor application depends on the variation in properties that can be tolerated.

In many electronic devices, resistors with error in resistance value of 5 to 10% are entirely satisfactory. Most resistors for this classification are made of carbon. Carbon resistors are not discussed in this article. This section is concerned chiefly with metallic resistors such as wirewound precision resistors and potentiometers, resistance thermometers, and ballast resistors.

Some applications of resistance materials require devices with large thermal coefficients of resistance, either positive or negative. A device of this type is called a thermistor. Thermistors are made almost exclusively of ceramic semiconductor materials.

**Precision resistors** (those with less than 1% error) require careful material selection. The ideal material for a precision resistor should have a thermal coefficient of resistance equal to zero for the temperature range over which the resistor will operate. In addition, to ensure freedom from thermoelectric effects, it should have a small or negligible thermoelectric potential versus copper, which is the material normally used for the connecting conductor. Temperature differentials may exist among various junctions between a resistance wire and a connecting wire, resulting in a network of thermocouples that can cause parasitic electromotive forces in the circuits; this effect is especially critical in precise direct current (dc) circuits. In an apparatus where extreme precision is required, it is advisable to make the connecting wires of the same material as the resistors or to design the apparatus so that all dissimilar metal junctions are at the same operating temperature.

Selection of a material for, and specific dimensions of, a precision resistor must include consideration of equipment size and heat-dissipation characteristics. Temperature excursions from the ambient or from a specified operating temperature may be undesirable, because they can cause net changes in resistance that will affect the stability or accuracy of the instrument. The magnitude of the change in resistance can be calculated using the temperature coefficient of resistance. For example, a resistor made of a low resistivity material could be several times larger than one made of a higher-resistivity material and yet achieve the same total resistance. The large resistor would have a much greater surface area, could dissipate much more heat, and thus, despite its low resistivity, attain a lower steady-state temperature than would be possible for a small, high-resistivity resistor operating under the same conditions. Alloys used for precision resistors generally have resistivities ranging from 500 to 1350  $\text{n}\Omega \cdot \text{m}$  (300 to 800  $\Omega \cdot \text{circular-mil/ft}$ ).

**Resistance thermometers** are commonly made of copper, nickel, or platinum; these devices are precision resistors whose resistance change with temperature is stable and reproducible over specified ranges of temperature. For resistance thermometers, the larger the temperature coefficient of the material, the greater the accuracy and ease of measurement. Temperature coefficients of relatively pure metals are greatly affected by small amounts of impurities. In fact, one of the most sensitive tests of the purity of a metal is measurement of its temperature coefficient of resistivity, which decreases sharply with increasing impurity or alloy content.

**Ballast resistors** are used extensively in industrial circuits to maintain constant currents over long periods of time. In such an application, a ballast resistor must be able to dissipate energy in such a way as to control current over a wide range of voltages. Wires with the proper temperature coefficient of resistance can be made to change resistance rapidly with changes in current, due to self heating, in such a manner that the current in the circuit will remain nearly constant even when there are fluctuations in voltage across the circuit. Because ballast resistors operate at elevated temperatures, mechanical properties are important also. Typical materials used in ballast resistors are pure iron, pure nickel, and nickel-iron alloys such as 71Ni-29Fe (see Table 1).

**Reference resistors** and virtually all other applications of resistance alloys demand temperature coefficients of resistance lower than  $\pm 20 \text{ ppm}/^\circ\text{C}$  ( $\pm 20 \mu\Omega/\Omega \cdot ^\circ\text{C}$ ). This requirement stems from the fact that, for these applications, resistance errors resulting from the small changes in ambient temperature that are continually occurring cannot be tolerated. In the most demanding of these applications, resistors often are mounted in thermally insulated containers and are carefully maintained at a temperature slightly above the maximum anticipated ambient temperature.

The most important requirement of a resistor used as a reference standard is that its value be predictable within narrow limits over long periods of time. Many reference resistors exhibit a nearly linear change in resistance with time. Hence, resistance between dates of calibration can be determined by interpolation; resistance at future points in time can be determined by extrapolation, but undue reliance should not be placed on extrapolated values, Figure 1 shows the change in resistance with time for a 10  $\text{k}\Omega$  resistor made of a Ni-Cr-Al-Cu alloy.

**Fig. 1** Change in resistance of a 10 k $\Omega$  resistor with time

**Stability**, or the ability to maintain a specific value of resistance within narrow limits over a long period of time, is an important requirement of materials for precision resistors and reference resistors. Principal sources of instability are (a) relief of residual stresses during service; (b) time-dependent or time-temperature-dependent metallurgical changes, such as precipitation of a second phase; and (c) corrosion or oxidation; and (d) humidity.

Residual stresses often are relieved at room temperature over long periods of time through a process known as stress relaxation. Stress relaxation alters the resistance of a coil at a rate of change that increases with the original level of residual stress. For this reason, only carefully preannealed wires are used for precision resistors. Stresses induced during winding, weaving, or other operations in fabrication of resistors from preannealed wire must be kept to a minimum. Thorough annealing of finished resistors is not always possible because the wires can be enameled or coated with a textile insulation of only moderate resistance to heat. Either type of coating limits the temperature that can be used for stress relieving finished resistors to approximately 140 °C (285 °F).

Figure 2 shows the effect of residual stress on the stability of a manganin alloy subjected to different amounts of cold work. The top curve illustrates that a low-temperature, stress-relieving treatment substantially eliminates the stresses that would, in time, have been eliminated due to natural relaxation at room temperature.

**Fig. 2** Change in resistance of manganin resistors upon aging at room temperature

Resistors represented by the top curve were stress relieved at 140 °C (285 °F) for 48 h to stabilize their resistance within approximately 20 ppm of the nominal value. Resistors not stress relieved, as represented by the other curves, continue to change in resistance almost indefinitely. For most modern, hermetically sealed precision resistors annealed at 140 °C (285 °F), the change in resistance does not exceed 10 ppm/year, and for many it does not exceed 5 ppm/year. However, resistors made of manganin that are used as reference standards require greater stability, and stress relief at 140 °C (285 °F) is not adequate. One-ohm resistors of the best grade (the double-wall type) are treated as follows. A coil of wire is wound on a steel mandrel and annealed at approximately 500 °C (930 °F) in a protective atmosphere for 6 h or more. The coil is removed and slipped over an insulated tube of the same diameter as the mandrel, and then is hermetically sealed

using a second tube slightly greater in diameter. In most resistors of this type, the change in resistance does not exceed 1 ppm/year.

The second factor affecting stability of precision resistors is the metallurgical stability of the alloy being used as the resistance element; any metallurgical change will be detrimental. All resistance alloys are single-phase, solid-solution alloys; thus, the changes in resistance that occur are relatively small but not insignificant. Changes in resistance are caused by internal changes such as long-range, order-disorder reactions in 71Ni-29Fe alloys, short-range order or clustering in quaternary nickel-chromium alloys, and even minor ordering in manganin alloys. Accordingly, resistance of these alloys is affected by heat treatment and by rates of cooling from heat treating temperatures. Power resistors that can operate at temperatures as high as 300 °C (570 °F) can in effect be heat treated during service. The net effect during service can be an increase in resistance for nickel-chromium alloys, a decrease for manganin, and either an increase or a decrease for nickel-iron alloys.

The third factor affecting stability of resistors is corrosion and/or oxidation. Corrosion of the resistance element will decrease its effective cross section, resulting in a corresponding increase in resistance. If the corrosive attack is selective, changes will occur in temperature coefficient of resistance and thermal electromotive force (emf) as well as in resistivity. These corrosive effects can be minimized by protecting the wire with an enamel or plastic coating. One relatively common source of corrosive attack, but one that is often overlooked, is flux residue at soldered or brazed joints. Another less obvious cause of instability is the presence of tin-containing solder. Intergranular stress corrosion, believed to originate during thermal stress-relieving treatments, can cause open circuits.

The fourth factor affecting the stability of enameled wire-wound resistors is humidity. The change in resistance is dependent on enamel thickness, wire diameter, and change in the amount of moisture to which the resistor is exposed. Increasing the moisture for a given resistor will cause a positive change in resistance, whereas decreasing the moisture causes a negative shift. This factor can be eliminated where it is physically possible to hermetically seal the resistor.

Combinations of these four factors--residual stresses, metallurgical instability, corrosion or oxidation, and humidity--account for the complex changes in resistance that often occur in resistors.

**Solderability or Joining.** The ease with which alloys can be soldered, brazed, or welded is an important consideration in selection of materials for precision resistors. Improperly brazed or soldered joints frequently cause resistance instability in the circuit. Metals to be soldered must be cleaned prior to tinning so that solder can completely wet the surfaces and maintain electrical continuity. For copper-nickel alloys this is relatively simple because protective oxide coatings are not formed on these alloys. Nickel-chromium alloys must be tinned immediately after cleaning and before an inherent protective oxide forms.

**Pressure Coefficients of Resistance.** The resistance value of a resistor may change if the hydrostatic pressure on the resistance element is changed; for manganin this change is approximately  $23 \text{ p}\Omega/\Omega \cdot \text{Pa}$  ( $0.16 \text{ p}\Omega/\Omega \cdot \text{psi}$ ). Sealed resistors can also be affected by changes in external pressure. In a double-wall, one-ohm resistor, for example, a change in pressure on the inner tube will cause a change in tube diameter, thus altering the length of wire wound on the tube. The magnitude of the resistance change depends in part on the thickness of the wall, and for commercial resistors is typically less than the hydrostatic pressure coefficient (PCR) of manganin. Unsealed resistors wound on mica cards containing air bubbles may have pressure coefficients several times greater than that predicted from the hydrostatic pressure coefficient of the alloy. This effect is important only if there is a large change in pressure, which would be most likely if there were a large change in elevation above sea level.

## Thermostat Metals

A thermostat metal is a composite material (usually in the form of sheet or strip) that consists of two or more materials bonded together, of which one can be a nonmetal. Because the materials bonded together to form the composite differ in thermal expansion, the curvature of the composite is altered by changes in temperature: this is the fundamental characteristic of any thermostat metal. A thermostat metal is, therefore, a complete, self-contained transducing system capable of transforming heat directly into mechanical energy for control, indicating, or monitoring purposes.

In applications such as circuit breakers, thermal relays, motor overload protectors, and flashers, the change in temperature necessary for operation of the element is produced by the passage of current through the element itself--in other words,

the charge is produced by  $I^2R$  heating. In certain other applications, any increase in the temperature of the thermostat element caused by  $I^2R$  heating is objectionable, and a thermostat metal with low electrical resistivity is required.

For circuit breakers and similar devices, there are thermostat metals that differ in electrical resistivity but that are similar in other properties. This allows a manufacturer to design a complete series of circuit breakers of different ratings in which the thermostat elements are all of the same size but have different electrical resistances. Resistivity is varied by incorporating a layer of a low-resistivity metal between outer layers of two other metals that have high resistivities and that differ widely in expansion coefficient.

In one series of commercial thermostat metals with resistivities ranging from 165 to 780  $n\Omega \cdot m$  (100 to 470  $\Omega \cdot \text{circular-mil/ft}$ ) at 24 °C (75 °F), high-purity nickel is used for the intermediate layer. In a series with resistivities from 33 to 165  $n\Omega \cdot m$  (20 to 100  $\Omega \cdot \text{circular-mil/ft}$ ), high-conductivity copper alloys are employed for the intermediate layer.

The use of a Mn-Cu-Ni alloy having a resistivity of 1745  $n\Omega \cdot m$  (1050  $\Omega \cdot \text{circular-mil/ft}$ ) for one of the outer layers has extended the practical upper resistivity limit of thermostat metals to 1620  $n\Omega \cdot m$  (975  $\Omega \cdot \text{circular-mil/ft}$ ) at 24 °C.

Tolerances on resistivity at a standard temperature vary from  $\pm 3$  to  $\pm 10\%$ , depending on the type of thermostat metal and its resistivity.

Approximately 30 different alloys are used to make over 50 different thermostat metals. Most of these 30 alloys are nickel-iron, nickel-chromium-iron, chromium-iron, high-copper, and high-manganese alloys.

Thermostat metals are available as strip or sheet in thicknesses ranging from 0.13 to 3.2 mm (0.005 to 0.125 in.) and widths from 0.5 to 300 mm (0.020 to 12 in.). They are easily formed into the required shapes. Thermostat metals usually are selected on the basis of the temperature range in which they are required to operate. They are available for various operating ranges between -185 and +540 °C (-300 and +1000 °F). Table 2 gives properties and typical bimetal combinations for several temperature ranges.

**Table 2 Properties of thermostat metals frequently selected for some common service temperatures**

Temperature range of maximum sensitivity		Composition		Resistivity at 24 °C (75 °F)		Flexivity <sup>(a)</sup>	
°C	°F	High-expanding side	Low-expanding side	$n\Omega \cdot m$	$\Omega \cdot \text{circular-mil/ft}$	$\mu\text{m/m} \cdot ^\circ\text{C}$	$\mu\text{in./in.} \cdot ^\circ\text{F}$

(a) At 40-50 °C (100-300 °F). See ASTM B 106 for standard test method for determining flexivity of thermostat metals.

## Heating Alloys

Resistance heating alloys are used in many varied applications--from small household appliances to large industrial process heating systems and furnaces. In appliances or industrial process heating, the heating elements are usually either open helical coils of resistance wire mounted with ceramic bushings in a suitable metal frame or enclosed metal-sheathed elements consisting of a smaller-diameter helical coil of resistance wire electrically insulated from the metal sheath by compacted refractory insulation. In industrial furnaces, elements often must operate continuously at temperatures as high as 1300 °C (2350 °F) for furnaces used in metal-treating industries, 1700 °C (3100 °F) for kilns used for firing ceramics and occasionally 2000 °C (3600 °F) or higher for special applications.

The primary requirements of materials used for heating elements are high melting point, high electrical resistivity, reproducible temperature coefficient of resistance, good oxidation resistance, absence of volatile components, and resistance to contamination. Other desirable properties are good elevated-temperature creep strength, high emissivity, low thermal expansion, and low modulus (both of which help minimize thermal fatigue), good resistance to thermal shock, and good strength and ductility at fabrication temperatures.

Table 3 gives physical and mechanical properties, and Table 4 presents recommended maximum operating temperatures for resistance heating materials for furnace applications. Of the four groups of materials listed in these tables, the first group (Ni-Cr and Ni-Cr-Fe alloys) serves by far the greatest number of applications.

**Table 3 Typical properties of resistance heating materials**

W	1650 °C (3000 °F)	2480 °C (4500 °F)	1700 °C (3100 °F)

- (a) Recommended atmospheres for these metals are a vacuum of 10<sup>-4</sup> to 10<sup>-5</sup> mm Hg, pure hydrogen, and partly combusted city gas dried to a dew point of 4 °C (40 °F). For the recommended temperatures in these atmospheres, see the entries for Mo, Ta, and W at the end of this table.
- (b) Decomposes before melting at 1740 °C (3165 °F) for MoSi<sub>2</sub>, and 1825 °C (3315 °F) for MoSi<sub>2</sub> + 10% ceramic additives.
- (c) Graphite volatilizes without melting at 3650 to 3700 °C (6610 to 6690 °F).
- (d) At approximately 400 °C (750 °F) (threshold oxidation temperature), graphite undergoes a weight loss of 1% in 24 h in air. Graphite elements can be operated at surface temperatures up to 2205 °C (4000 °F) in inert atmospheres.

The ductile wrought alloys in the first group have properties that enable them to be used at both low and high temperatures in a wide variety of environments. The Fe-Cr-Al compositions (second group) are also ductile alloys. They play an important role in heaters for the higher temperature ranges, which are constructed to provide more effective mechanical support for the element. The pure metals that comprise the third group have much higher melting points. All of them except platinum are readily oxidized and are restricted to use in nonoxidizing environments. They are valuable for a limited range of application, primarily for service above 1370 °C (2500 °F). The cost of platinum prohibits its use except in small, special furnaces.

The fourth group, nonmetallic heating-element materials, are used at still higher temperatures. Silicon carbide can be used in oxidizing atmospheres at temperatures up to 1650 °C (3000 °F); three varieties of molybdenum disilicide are effective up to maximum temperatures of 1700, 1800, and 1900 °C (3100, 3270, and 3450 °F) in air. Molybdenum disilicide heating elements are gaining increased acceptance for use in industrial and laboratory furnaces. Among the desirable properties of molybdenum disilicide elements are excellent oxidation resistance, long life, constant electrical resistance, self-healing ability, and resistance to thermal shock. Nonmetallic heating elements described are considerably more fragile as compared to metal heating alloys.

## Design of Resistance Heaters

Regardless of which heating alloy is selected, design of the heating element is important. One of the most important rules is to allow for unhindered expansion and contraction so as to avoid concentration of stresses as the temperature changes.

For service at lower temperatures, particularly from 400 to 600 °C (750 to 1100 °F), formed heating elements are used in ovens. In this construction, a heater support is made of two high-alloy rods spaced approximately 300 mm (12 in.) apart in a frame made of angle sections. The rods, whose length is determined by rated electrical input, contain spool insulators around which is wound a ribbon element made of a heating alloy. In a similar alternative construction, the ribbon element is replaced by a continuous helical coil of five gage or smaller wire.

Ribbon sizes for oven heaters range from 0.09 to 0.20 mm (0.0035 to 0.008 in.) thick and from 9.5 to 16 mm ( $\frac{3}{8}$  to  $\frac{5}{8}$  in.) wide. Oven heaters are rated to give maximum output at a watt density of approximately 8 kW/m<sup>2</sup> (5 W/in.<sup>2</sup>). (Watt density is obtained by dividing total power input to the elements by total surface area of the heater.) For 120 or 240 V oven heaters operating under normal conditions, expected life of nickel-chromium elements in air is three to five years (depending on temperature, atmosphere, and cyclic conditions).

For furnace temperatures up to 1175 °C (2150 °F), sinuous loop elements generally are formed from ribbon having a width-to-thickness ratio of approximately 12 to 1 and dimensions varying from 0.76 to 3.2 mm (0.030 to 0.125 in.) in thickness and from 13 to 38 mm ( $\frac{1}{2}$  to  $1\frac{1}{2}$  in.) in width. Round rods of resistance material also can be formed into elements. Rod-type elements have been used by several furnace manufacturers.

## Atmospheres

Based on element temperature, Table 5 rates serviceabilities of various heating-element materials as good, fair, or not recommended for the temperatures and atmospheres indicated. Types and compositions of standard furnace atmospheres are given in Table 6. Element temperatures are always higher than furnace control temperatures; the difference depends on watt-density loading on the element surface. Thus, when furnaces are operated near maximum element temperature in the more active atmospheres, watt-density loading should be lower and element cross-sectional area should be higher.

**Table 5 Comparative life of heating-element materials in various furnace atmospheres**

See Table 6 for atmosphere compositions.

309	Endothermic + hydrocarbon + ammonia	No standard composition					...	...

- (a) This atmosphere, refrigerated to obtain a dew point of 4 °C (40 °F), is widely used.

With the exception of molybdenum, tantalum, tungsten, and graphite, commonly used resistor materials have satisfactory life in air and in most other oxidizing atmospheres.

**Atmosphere Contamination.** Sulfur, if present, will appear as hydrogen sulfide in reducing atmospheres and as sulfur dioxide in oxidizing atmospheres. Sulfur contamination usually comes from one or more of the following sources: high-sulfur fuel gas used to generate the protective atmosphere, residues of sulfur-base cutting oil on the metal being processed; high-sulfur refractories, clays, or cements used for sealing carburizing boxes, and the metal being processed in the furnace. Sulfur is destructive to nickel-chromium and nickel-chromium-iron heating elements. Pitting and blistering of the alloy occur in oxidizing atmospheres, and a nickel-sulfur eutectic that melts at 645 °C (1190 °F) can form in any type of atmosphere. The higher the nickel content, the greater the attack. Therefore, if sulfur is present and cannot be eliminated, Fe-Cr-Al elements are preferred over those made of nickel-base alloys.

Lead and zinc contamination of a furnace atmosphere may come from the work being processed. This is a common occurrence in sintering furnaces for processing powder metallurgy parts. In the presence of a reducing atmosphere, lead will vaporize from leaded bronze powders (such as those used to make sintered bronze bushings) and attack the heating elements, forming lead chromate. Metallic lead vapors are even more harmful than sulfur to nickel-chromium alloys, and will cause severe damage to a heating element in a matter of hours if unfavorable conditions of concentration and temperature exist. Higher-nickel alloys are affected more than lower-nickel alloys. Elements made of 35Ni-20Cr-43.5Fe-1.5Si give satisfactory life for sintering lead-bearing bronze powders at 845 °C (1550 °F) in reducing atmospheres: 80Ni-20Cr elements give poor life in this application.

Zinc contamination results from zinc stearate used as a lubricant and binder when P/M compacts are pressed. The zinc stearate volatilizes when the compacts are heated and can carburize the heating element. (Brazing of nickel silvers, which contain at least 18% Zn, also results in a high concentration of zinc vapors in the furnace atmosphere.) Zinc vapors, which alloy with nickel-chromium heating elements and result in poor life, can be eliminated at the higher sintering

temperatures by using a separate burn-off furnace at 650 °C (1200 °F), with heating elements protected by full muffle, by sheathing, or by a high-temperature ceramic protective coating. If these precautions are not feasible, silicon carbide elements (which are not affected by sulfur, lead, or zinc contamination) should be used at both low and high temperatures when contamination is anticipated.

# Electrical Contact Materials

## Introduction

ELECTRICAL CONTACTS are metal devices that make and break electrical circuits. If an ideal electrical contact material could be found, it would have high electrical conductivity to minimize the heat generated during passage of current; high thermal conductivity to dissipate both the resistive and arc heat developed; high reaction resistance to all environments in which it was to be used to avoid formation of insulating oxides, sulfides, and other compounds; and immunity to arcing damage on the making and breaking of electrical contact. The force required to close a contact made of this material would be low, as would the electrical resistance between mating members. The melting point of the material would be high enough to limit arc erosion, metal transfer, and welding or sticking, but it would also be low enough to increase resistance to reignition in switching. (When the melting point is high, contacts continue to heat gas in the contact gap after the current drops to zero, thus facilitating reignition.) The vapor pressure would be low to minimize arc erosion and metal transfer. Hardness would be high to provide good wear resistance, and yet ductility would be high enough to ensure ease of fabrication. Purity of the material would be maintainable at a level that ensures consistent performance. Neither the material nor any process step necessary to fabricate it would present an environmental hazard. Finally, the material would be available at low cost in any desired form.

Because no metal has all the desired properties, a wide variety of contact materials is required to accomplish the objectives of different contact applications. The economic choice of materials is usually a compromise between the various processing variables and the application requirements. Load conditions, service requirements, and ambient conditions present during the life of the unit must be considered in the selection of contact materials.

## Failure Modes of Make-Break Contacts

In an electric make-break switching device, there are two different types of contacts: arcing contacts and sliding contacts. The arcing contact points, which usually consist of a pair of thin shaped slabs, perform the actual duty of making, carrying, and breaking the current. Arcing contacts differ from sliding contacts in that the moving member of the switching device travels perpendicular to the contact surfaces. As a result, arcs generated during opening and closing actions always strike and consequently damage the conducting surfaces.

**Arcing**, except in a circuit with an extremely low potential or low current, is a major factor--if not the main factor--causing failure of contact points.

When a pair of contacts opens in a live circuit, an arc is often generated between the contact pair, which remains until they are separated by a certain gap. Relatively less severe arcing occurs when the contacts close. Arcing also occurs when the moving contact bounces away from the stationary contact during closing. The arc causes contact erosion by blowing away the molten metal droplets, vaporizing the material, and transforming the metal to ion jets. Sometimes the material vaporizes from one contact and then condenses onto the other contact, thereby altering the surface configuration of both contacts. This is known as material transfer.

**Welding.** When a pair of contacts close, the arcs generated during closing and bouncing of a moving contact melt a small portion of both contacts. On reclosure, solidification of the molten material welds the contact pair in the same manner as fusion welding.

Another type of welding occurs after the contacts are made. To make a pair of contacts more conductive, a mechanical load is always applied on the contact pairs. Theoretically, the load could make two rigid contact surfaces touch at no more than three points. However, the touching points at both surfaces yield either elastically or plastically, resulting in larger areas of contact. These constricted regions carry the current through the contacts and form regions of high current density. Heat is generated in these areas and, if the temperature becomes high enough, the two contact points eventually are welded together. Occasionally, the strength of the weld exceeds the opening force of the switching device, resulting in catastrophic failure of the entire electrical system because the contacts fail to open on command.

**Bridge Formation.** When a pair of contacts opens, the contact area gradually decreases because of the gradual lessening of contact pressure. The continuous opening action causes the contact areas to reach a stage at which the current density of the constricted areas is so great that it melts the material in these regions. Continuous separation of the contact points now pulls the molten metal, forming a current-carrying bridge. The temperature of the molten bridge continues to rise as the contact points pull apart. It may become high enough to evaporate the material and finally break the circuit. This "bridge" phenomenon during the opening of a pair of contacts slightly damages the surfaces of the contacts and evaporates some of the bridge material. This generally results in pitting of one contact surface and buildup of material on the other; an uneven continuous transfer can eventually erode one of the contacts. Furthermore, the surface asperities from the continuous bridge formation can interlock the contact pair and interfere with their mechanical separation.

**Oxidation** of the contact surfaces, which can be accelerated by the heat from arcing, is a serious problem because most metallic oxide films are nonconductive or semiconductive. The oxide film may easily increase contact resistance. In high-current circuits, this can cause excessive contact heating. In low-voltage and low-current circuits, the oxide films can grow so thick that they completely insulate the contact surfaces before the contact bodies erode. This happens more frequently when a pair of contacts operates in a hostile environment such as a polluted industrial atmosphere. Condensed organic polymers also play a role in precious metal contacts at light loads. These polymers come from monomers, which evaporate from resins and are polymerized on the active catalytic metal surfaces of contacts.

## Property Requirements for Make-Break Arcing Contacts

The four failure modes discussed in the section "Failure Modes of Make-Break Contacts" determine the requirements of materials for arcing contacts. In selecting a material, it is often necessary to reach a compromise that provides adequate properties without jeopardizing essential qualities of the component as a whole, such as reliability, life, and cost. The most important requirements are listed in the following paragraphs.

**Electrical Conductivity.** Because the conduction of electricity between the pair of contacts depends on only a few constricted spots, the higher the electrical conductivity, the less the amount of heat that will be generated by high current density in these spots.

**Thermal Properties.** High melting and boiling points decrease evaporation loss caused by high arcing heat. High thermal conductivity disperses the heat rapidly and quenches the arc.

**Chemical Properties.** Contact materials should be corrosion resistant so that insulating films (either oxides or other compounds) do not form easily when the contacts operate in a hostile environment.

**Mechanical Properties.** The major loads applied to a contact pair are the closing force and the impact between movable and stationary contact points during closing. An induced relative movement between two contact surfaces always exists when closing. In some devices, such as certain types of relays, a wiping motion is purposely designed into the device to destroy any oxide films that form. However, friction between wiping surfaces produces wear of the contacts upon repeated opening and closing. Generally, hard materials are more resistant to wear. However, hard materials often have high contact resistances and low thermal conductivities, both of which contribute to a greater tendency to contact welding. Hard materials also have high tensile strengths, which may or may not be advantageous in electrical contact applications.

**Fabrication Properties.** Contact materials should have the capability of being welded, brazed, or otherwise joined to backing materials. In addition, they should have sufficient malleability to enable them to be shaped, or they should be capable of being formed by powder metallurgy (P/M) techniques.

## Sliding Contacts

The applications of sliding contacts are usually quite different from those of arcing contacts. Friction, contact temperature, mechanical considerations, and wear also are different.

The fundamental difference between arcing contacts and sliding contacts is that sliding contacts require films on the contact faces to facilitate sliding without seizure or galling; shear must occur within this film with only minor disturbance of both materials. A lubricant of some kind is always necessary. This can be provided by graphite if there is moisture present--such as in an environment having a dew point of  $-20^{\circ}\text{C}$  ( $-4^{\circ}\text{F}$ ) or higher. Alternatively, lubrication can be provided by very thin oil films, although excessive oil vapor causes over filming. It can also be provided by molybdenum disulfide, and other chalcogenides of molybdenum, tungsten, and niobium. Oxygen, sulfur, and other contaminants cause increased filming.

In applications in air, a drop in voltage can result from an equilibrium between oxidation and filming (which tend to increase the drop) and fretting or film breakdown and cleaning action (which tend to decrease the drop). In the absence of lubricants, fretting and oxidation are most important. In inert or reducing gases, oxidation is largely eliminated, and the voltage drop decreases until counteracted by mechanical factors. Noble metals that are properly lubricated also minimize voltage drops in air.

**Brush contacts** generally contain an appreciable amount of metal if they are intended for use in low-voltage ( $<24\text{ V}$ ) applications. Large quantities of brush contacts are used in automotive and related industries as starter brushes and auxiliary motor brushes; copper-graphite is the principal material. Silver-graphite brushes are used primarily in instruments and in outer space applications. Some silver-graphite brushes are used in seam welders and similar equipment.

Oxidation of sliding contacts is similar to that of arcing contacts, except that the surface disturbed by friction oxidizes more rapidly. In most applications in air, the metal surface generates a film that is a complex mixture of graphite, oxide, sulfide, and water, which tends to decrease the conducting area.

The surfaces generated on metal-graphite brushes as they wear are effective cleaning agents in that they abrade films and keep larger areas available for conduction. Even so, it is sometimes advisable to have additional abrasive material in the brushes to prevent over filming in critical atmospheres.

Because the major factor in friction is the shear strength of any film that is present, the composition of this film, as affected by atmospheric contaminants, is important.

**Brush Materials.** Considering the range of commercially available metal powders, graphites, other lubricants, and processing variables, there are unlimited possibilities for development of suitable brush materials. However, only a limited number of commercial grades have been developed, and most of these are copper-graphite (4 to 70% graphite) and silver-graphite (3 to 50% graphite) alloys (the latter alloys can also contain molybdenum disulfide).

More brush contacts are made from copper and copper alloys than from any other class of material. In applications where copper metals undergo substantial oxidation, silver metals can be used. Tungsten or, more rarely, molybdenum is used where a high melting point is required. Platinum, palladium, and gold are used where reliable closure with low force is required. Brushes clad or electroplated with precious metals and brushes made of sintered alloys are important for general applications in power-switching relays.

**Interdependence Factors.** When contacts are attached to a carrier, which is usually a copper alloy, the properties of the carrier material and the properties of the interface between contact and carrier (that is, the area of bond and the conductivity across the interface) are critical to ultimate performance. The contact carrier serves as a heat sink as well as a structural member and electrical conductor. The overall efficiency of the system depends on the contact, the contact carrier, and the method of attachment, all of which affect the size of the contact required for a specific application. To conserve precious metal, the contact materials, carrier material, and method of attachment must be optimized. Some high-strength, high-conductivity copper alloys are used for carriers because of their structural properties and resistance to softening at brazing temperatures.

The attachment method that provides minimum interface alloying, minimum softening of the carrier, and maximum bond area generally produces the best combination of properties for the contact system as a whole. Common attachment methods include brazing, resistance welding, percussion welding, and resistance induction torch welding. Welding methods provide the most localized heat input and therefore minimize softening of the carrier, which can occur during

brazing methods. A more weldable backing such as steel, nickel, or monel is often clad to the precious metal to provide optimum welding compatibility with the carrier. Projections can also be coined or rolled into the contact backing to assist in welding.

Percussion welding does not require a special backing for attachment. However, percussion welding has fallen out of favor due to relatively high cost in comparison with brazing, welding, and mechanical attachment (riveting).

## Commercial Contact Materials

Commercial materials for electrical contacts are divided into two categories based on their manufacturing methods: (a) wrought materials, which include both pure metals and alloys and (b) composite materials, which include powder metallurgy products and internally oxidized silver alloys.

### Copper Metals

High electrical and thermal conductivities, low cost, and ease of fabrication account for the wide use of copper in electrical contacts. The main disadvantage of copper contacts is low resistance to oxidation and corrosion. In many applications, the voltage drop resulting from the film developed by normal oxidation and corrosion is acceptable. In some circuit breaker applications, the contacts are immersed in oil to prevent oxidation. In other applications, such as in drum controllers, sufficient wiping occurs to maintain fairly clean surfaces, thus providing a circuit of low resistance. In some applications, such as knife switches, plugs, and bolted connectors, contact surfaces are protected with grease or coatings of silver, nickel, or tin. In power circuits, where oxidation of copper is troublesome, contacts frequently are coated with silver. Vacuum-sealed circuit breakers use oxygen-free copper contacts (wrought or powder metal) for optimum electrical properties.

In air, copper does not provide high resistance to arcing, welding, or sticking. Where these characteristics are important, copper-tungsten or copper-graphite mixtures are used. However, when used in a helium atmosphere, a Cu-CdO contact performs similarly to an Ag-CdO contact. Copper alloys are used for high currents in vacuum interrupters.

Pure copper is relatively soft, anneals at low temperatures, and lacks the spring properties sometimes desired. Some copper alloys, harder than pure copper and having much better spring properties, are listed in Table 1. The annealing temperature of copper can be increased by additions of 0.25% Zn, 0.5% Cr, 0.03 to 0.06% Ag (10 to 20 oz per ton), or small amounts of finely dispersed metal oxides, such as Al<sub>2</sub>O<sub>3</sub>, with little loss of conductivity. Conversely, improved spring properties are obtained only at the expense of electrical conductivity. Precipitation-hardened alloys, dispersion-hardened alloys, and powder metal mixtures can provide a wide range of mechanical and electrical properties.

Table 1 Properties of copper metals used for electrical contacts

**Applications.** Copper-base metals are commonly used in plugs, jacks, sockets, connectors, and sliding contacts. Because of tarnish films, the contact force and amount of slide must be kept high to avoid excessive contact resistance and high levels of electrical noise. Yellow brass (C27000) is preferred for plugs and terminals because of its machinability. Phosphor bronze (C50500 or C51000) is preferred for thin socket and connector springs and for wiper-switch blades because of its strength and wear resistance. Nickel silver is sometimes preferred over yellow brass for relay and jack springs because of its high modulus of elasticity and strength, and also for its resistance to tarnishing and better appearance. Sometimes, copper alloy parts are nickel plated to improve surface hardness, reduce corrosion, and improve appearance. However, nickel carries a thin but hard oxide film that has high contact resistance; very high contact force and long slide are necessary to rupture the film. To maintain low levels of resistance and noise, copper metals should be plated or overlaid with a precious metal.

## Silver Metals

Silver, in pure or alloyed form, is the most widely used material for a considerable range of make-and-break contacts (1 to 600 A). Mechanical properties and hardness of pure silver are improved by alloying, but its thermal and electrical conductivities are adversely affected. Figure 1 shows the effect of different alloying elements on the hardness and electrical resistivity of silver. Properties of the principal silver metals used for electrical contacts are given in Table 2. Silver is widely used in contacts that remain closed for long periods of time and, in the form of electroplate, is widely used as a coating for connection plugs and sockets. It is also used on contacts subject to occasional sliding, such as in rotary switches, and to a limited extent for low-resistance sliding contacts, such as slip rings.

**Table 2 Properties of silver metals used for electrical contacts**

Fig. 1 Hardness and electrical resistivity versus alloy content for silver alloy contacts

**Electrical and Thermal Conductivity.** Because silver has the highest electrical and thermal conductivities of all metals at room temperature, it can carry high currents without excessive heating, even when dimensions of the contacts are only moderate. Although good thermal conductivity is desired once the contact is in service, such conductivity increases the difficulty of assembly welding unless a higher resistance layer is added by cladding.

In component assemblies, migration of silver through and around electrical insulation can cause failure of the insulation. When in contact with certain materials, such as phenol fiber, and when under electric potential, silver migrates ionically through or across the insulating material, producing thread-like connections that lower the resistance across the insulation. This reduces insulating qualities, and the reduction is even greater if moisture is present in the atmosphere. Insulators must be designed with care to avoid this hazard.

**Oxidation Resistance.** Silver is used instead of copper chiefly because of its resistance to oxidation in air. In general, silver oxide is not a problem on silver contacts, whether or not the contacts make and break the circuit. However, silver oxide can be produced by exposure to ozone, as well as by other methods. This oxide has high resistivity, is decomposed slowly on heating at approximately 175 °C (350 °F), is decomposed rapidly at approximately 350 °C (650 °F), and is removed by arcing. This "self-cleaning" characteristic is most unusual among metals and is a chief reason for the attraction of silver as a contact material.

Silver is vulnerable to attack by sulfur or sulfide gases in the presence of moisture. The resulting sulfide film can produce significant contact resistance, particularly where contact force, voltage, or current is low. Direct current brings silver ions from the matrix into the sulfide where they form connecting bridges. Therefore, particularly at high direct current, the film becomes somewhat conducting. The resistance of a silver sulfide film decreases as temperature increases-- $\text{Ag}_2\text{S}$  decomposes slowly at 360 °C (680 °F) and more rapidly at higher temperatures. In addition, the film can increase erosion and entrap dust.

**Limitations of Silver Contacts.** Silver will provide a fairly long contact life for make-break contacts and will handle up to 600 A. In pure silver contacts, difficulties sometimes arise from transfer of metal from one electrode to the other, which leads to the formation of buildups on one contact surface and holes in the other. When used in direct current (dc) circuits, silver contacts are subject to ultimate failure by mechanical sticking as a direct result of metal transfer. The direction of transfer is generally from the positive contact to the negative, but under the influence of arcing, the direction can be reversed. With high currents or inductive loads, it may be desirable to shunt the load with a resistance-capacitance protection network to reduce erosion.

When arcing produces a glow discharge in air, the rate of erosion of silver is unusually high because of a chemical interaction with air to form  $\text{AgNO}_2$ .

For low resistance and low noise levels, the design of the contact device must provide sufficient force and slide to break through any silver sulfide film and maintain film-free, metal-to-metal contact at the interface. Connectors should have high slide force and several newtons normal force. Rotary switches that have up to 490 mN (0.11 lbf) normal force and considerable slide should have a protective coating of grease to reduce sulfiding and to remove abrasive particles. In low-

noise transmission circuits, silver should not be used on relay and other butting contacts that have less than 195 mN (0.044 lbf) force; other precious-metal coatings, such as gold or palladium, should be used instead of silver.

A silver sulfide film has a characteristic voltage drop of several tenths of a volt. Where this drop is tolerable, silver contacts will provide reliable contact closure. Failure to close, however, can be greater than with other precious metal contacts because of impacted dirt, with a sulfide film acting as a dirt catcher.

For many applications, silver is too soft to give acceptable mechanical wear. Alloying additions of copper, cadmium, platinum, palladium, gold, and other elements are effective in increasing the hardness and modifying the contact behavior of silver. These additions do, however, lower both the electrical conductivity and the oxidation resistance relative to pure silver.

## Gold Metals

Pure gold has unsurpassed resistance to oxidation and sulfidation, but a low melting point and susceptibility to erosion limit its use in electrical contacts to situations where the current is not more than 0.5 A. Although oxide and sulfide films do not form on gold, a carbonaceous deposit is sometimes formed when a gold contact is operated in the presence of organic vapors. The resistance of this film can be several ohms.

When gold is used in contact with palladium or rhodium, very low contact resistances have been reported.

The low hardness of gold can be increased by alloying with copper, silver, palladium, and platinum, but usage is necessarily restricted to low-current applications because of the low melting point.

Properties of gold and its alloys are listed in Table 3. If low tarnish rates and low contact resistance are to be preserved, the gold content should not be less than approximately 70%.

## Precious Metals of the Platinum Group

Platinum and palladium are the two most important metals of the platinum group. These metals have a high resistance to tarnishing, and therefore provide reliable contact closure for relays and other devices having contact forces of less than 490 mN (0.110 lbf). Their high melting points, low vapor pressure, and resistance to arcing make them suitable for contacts that close and open the load, particularly in the range up to 1 A. The low electrical and thermal conductivities of these metals, as well as their cost, generally exclude them from use at currents above approximately 5 A.

Palladium has an arcing limit only slightly less than that of platinum and gives comparable performance in relays for telephones and similar services handling 1 A or less. Palladium is a satisfactory substitute for platinum in these applications. Table 4 lists properties of platinum, palladium, and platinum and palladium alloys.

(a) For material in annealed condition

**Corrosion Resistance.** Platinum has it high resistance to corrosion, including resistance to oxidation, sulfidation, and salt water. It will not form a stable oxide at any temperature.

Palladium is resistant to oxidation at ordinary temperatures. If heated above 350 °C (660 °F), it will oxidize slowly to form an oxide that is stable at room temperature. However, the oxide is decomposed promptly on heating to 800 °C (1470 °F) or by arcing. The oxide is not considered to be a significant factor in the reliability of closure of telephone-type relays.

The presence of organic vapors in the contact area can seriously influence the life and reliability of electrical contacts, particularly the low-force precious metal contacts universally employed in high-reliability, low-noise circuits. The damaging organic vapors can arise from coil forms, wire coatings, insulation, soldering flux, potting and sealing compounds, and other organics in associated electrical equipment, as well as from external sources.

### **Precious Metal Overlays**

Silver, gold, rhodium, and, to a lesser extent, platinum and palladium are employed in clad and electroplated contacts. Electrodeposition and cladding compete for many of the same applications. Clad overlays are favored because of their lower porosity, but electrodeposits are slightly less expensive for those applications requiring a very thin layer of precious metal. Electrodeposits frequently have higher hardness than the annealed wrought material; rhodium, which has a deposit hardness in excess of 600 HV in the annealed condition, is an outstanding example. High hardness accounts for the superior wear resistance of electroplated rhodium where rubbing or wiping occurs. Even at a thickness of 0.13 to 0.50  $\mu\text{m}$  (5 to 20  $\mu\text{in.}$ ) over silver or base-metal contacts, rhodium improves wear resistance and minimizes tarnishing.

Electroplated gold is employed on silver contacts to minimize tarnishing. Nickel underlayers (barrier coats) are used to prevent migration of silver through the gold plate. Recent studies indicate that migration of silver along nickel grain boundaries is rapid at high temperatures. Hence, a nickel barrier coat is questionable for high-temperature applications. Other work in this area has disclosed that palladium can be substituted for gold as a protective coating for extension of

shelf life. Electroplated gold also is used on palladium contacts to minimize polymer formation in dry circuits. However, gold electrodeposits on both silver and palladium contacts soon wear off if the contacts wipe, rub, or arc.

Electroplated silver is sometimes applied to copper-base materials to make less expensive components. Electroplated silver is slightly harder than annealed wrought silver. Palladium and platinum electroplated on silver have improved tarnish resistance. Platinum, palladium, and gold electroplates are used on silver to prevent the development of conducting filaments in insulating supports.

Clad overlays are used extensively in applications requiring precious-metal thicknesses from 0.025 to 1.3 mm (0.001 to 0.050 in.). These thicknesses cannot be obtained by electroplating. These applications include electromechanical devices operating in current ranges where arcing and subsequent erosion are likely to occur. In these devices, sufficient precious metal must be available to survive the erosion that will occur over the required device cycle life.

### ***Tungsten and Molybdenum***

Most tungsten and molybdenum contacts are made in the form of composites with silver or copper as the other principal component (see the subsection "Composite Materials" ). Tungsten, which was one of the earliest metals other than copper and silver adopted for electrical contact applications, has the highest boiling point (5930 °C, or 10,700 °F) and melting point (3110 °C, or 5625 °F) of all metals; it also has very high hardness at both room and elevated temperatures. Therefore, as a contact material, it offers excellent resistance to mechanical wear and electrical erosion. Its main disadvantages are low corrosion resistance and low electrical conductivity (31% IACS). After a short period of operation, an oxidized film will build up on tungsten contacts, resulting in very high contact resistance. Considerable force is required to break through the film, but high pressure and considerable impact cause little damage to the underlying metal because of its high hardness. Tungsten contacts are used in switching devices with closing forces of more than 20 N (4.5 lbf) and in circuits with high voltages and currents not more than 5 A, such as automotive ignitions, vibrators, horns, voltage regulators, magnetos, and electric razors. In low-voltage direct current (dc) devices, tungsten is always used as the negative contact, and is paired with a positive contact made of precious metal.

Tungsten rods or strips that are consolidated by swaging or rolling from sintered powder compacts have very poor ductility. They cannot be cold worked, in contrast to other contact materials. Tungsten disks are usually cut from rods or punched from strips and then brazed directly to functional parts such as breaker arms, brackets, or springs.

Properties such as grain size, grain configuration, and the degree of fibrous structure, which affect contact behavior, are controlled by using special swaging methods and annealing cycles. Tungsten disks usually are supplied with a ground finish, but they can also be electrochemically polished to obtain high-luster surfaces.

The high boiling and melting points of molybdenum--5560 °C (10,040 °F) and 2610 °C (4730 °F), respectively--are second only to those of tungsten and rhenium. Molybdenum is not used as widely as tungsten because it oxidizes more readily and erodes faster on arcing than tungsten. Nevertheless, because the density of molybdenum (10.2 g/cm<sup>3</sup> or 0.369 lb/in.<sup>3</sup>) is about half that of tungsten (19.3 g/cm<sup>3</sup>, or 0.697 lb/in.<sup>3</sup>), use of molybdenum is advantageous where mass is important. The cost of molybdenum by volume is also lower.

In addition to use in make-break contacts, molybdenum is widely used for mercury switches because it is not attacked, but only wetted by mercury.

Like tungsten, molybdenum strips and sheets are made by swaging or rolling sintered powder compacts. Disks made from rods or sheets are brazed to blanks or other structural components.

### ***Aluminum***

Aluminum is generally a poor contact material because it oxidizes readily, but it is used in some contact applications because of its good electrical and mechanical properties, availability, and cost. Aluminum 1350 is used for some contact applications.

Where aluminum is used in contacting joints, it should be plated or clad with copper, silver, or tin. Aluminum should never be used for power applications where arcing is present. For instance, if aluminum contacts were substituted for silver in a motor starter, an explosion due to noninterruption of current on motor-starter de-energization would probably occur on load interruption.

## Composite Materials

There are three major groups of composite materials made by P/M or internal oxidation (IO) methods, or combinations of P/M and IO: refractory metal or carbide-base, silver-base, and copper-base. Table 5 lists the various types of contact materials and their respective manufacturing methods. Contacts based on refractory metals or their carbides include Mo-Ag, WC-Ag, W-Ag, WC-Cu, and W-C-Ag systems. Silver-base composites can be divided into two types: type 1 uses a pure element (nickel, tungsten, or molybdenum) or graphite as the dispersed phase; and type 2 composites use semirefractory oxides (CdO, SnO<sub>2</sub>, or ZnO) as the dispersed phase. In both types, hardness increases and conductivities decrease as the volume fraction of dispersed phase increases. The silver-cadmium oxide group of electrical contact materials is the most widely used of all the silver semirefractory contact materials. Copper-base contacts contain tungsten as the dispersed phase.

## Composite Manufacturing Methods

**Infiltration** is used exclusively for making refractory metal and carbide-base composite contact materials. Metal powder or carbide powder is first blended to the desired composition with or without a small amount of binder to impart green strength, then is pressed and sintered into a skeleton of the required shape. Silver or copper is then infiltrated into the pores of the skeleton. This method produces the most densified composites, generally 97% or more of theoretical density. Complete densification is not possible because of the presence of some closed pores in the sintered skeleton. After infiltration, the contact is sometimes chemically or electrochemically etched so that only pure silver appears on the surface. The contact thus treated has better corrosion resistance and performs better in the early stages of use.

**Press-Sinter.** For small refractory-metal contacts (not exceeding approximately 25 mm, or 1 in., in diameter), a high-density material can be obtained by pressing a blended powder of exact final composition into shape and then sintering it at the melting temperature of the low-melting-point component (liquid-phase sintering). In some cases, an activating agent such as nickel, cobalt, or iron is added to improve the sintering effect on the refractory metal particles. For this process, powders of much finer particle size are required so that more bonding surface exists. However, the skeleton formed by this process is weaker than that formed by the infiltration process. Formation of the skeleton usually shrinks the apparent volume of the refractory portion of the composition, thus bleeding out the molten component onto the surface of the finished contact.

**The press-sinter-repress process** is used for all categories of contact materials, especially those in the silver-base category. Blended powders of the correct composition are compacted to the required shape and then sintered. Afterward, the material is further densified by a second pressing (repressing). Sometimes the properties can be modified by a second sintering or annealing. The versatility of this process makes it applicable for contacts of any configuration and of any material. However, it is difficult to obtain material with as high a density as is obtained with other processes. Material thus produced also may have weak bonding between particles.

**Press-Sinter-Extrude Process.** Blended powder of final composition is pressed into an ingot and sintered. The ingot is then extruded into wires, slabs, or other desired shapes. The extruded material can be subsequently worked by rolling, swaging, or drawing. Material made by this method is usually fully dense.

The press-sinter-extrude process is used mostly for silver-base composites. Other processes used for manufacturing silver-base composite contacts are direct extrusion or direct rolling of loose powder. Although they appear to be uncommon, they are economically feasible if the equipment is properly designed and built.

**Internal Oxidation.** Silver-base composites with dispersed metal oxides can be produced by internal oxidation. In this process, a silver alloy (such as a silver-cadmium alloy) is first cast into ingots, which are rolled into strips or fabricated further into the finished product form. The silver-alloy material is then heated in air or oxygen, so that the oxygen diffuses

into the alloy and forms metal oxide particles (such as CdO in the case of a silver-cadmium alloy) dispersed in the silver matrix.

Internal oxidation is used in the production of a substantial portion of Ag-CdO composites. The initial silver-cadmium alloy can be internally oxidized either in strip or finished product form. The silver-cadmium alloy is heated between 800 and 900 °C (1470 and 1650 °F) in a furnace with air, oxygen-enriched air, or pressurized oxygen. Under this condition, the oxygen species diffuse into the silver-cadmium alloy and oxidize the cadmium species. Upon the completion of the oxidation, the cross section of the material will display a microstructure of cadmium oxide particles embedded in a silver matrix. Contact parts are punched from the strip and then coined into required shapes.

**The preoxidized-press-sinter-extrude process** is used exclusively for making silver-cadmium oxide (Ag-CdO) material. Alloys are reduced to small particles in the shape of flakes, slugs, or shredded foil. These particles are oxidized and then consolidated with the press-sinter-extrude process. Material made by this method is more uniform than the same material made by conventional internal oxidation. Mechanical properties are superior to those of the same material made by the press-sinter-repress method.

**Coprecipitation.** Conventional blending or mechanical mixing of silver and cadmium oxide powders begins by dissolving the proper amounts of silver and cadmium metals in nitric acid. Compounds of silver and cadmium coprecipitate from the solution when the pH value of the solution is changed by adding either hydroxide or carbonate solutions. During subsequent calcination at approximately 500 °C (930 °F), the compound mixture decomposes to form a mixture of silver and cadmium oxide. Alkali-metal content can be controlled in the ppm range by adequate washing. Controlled amounts of sodium, potassium, and lithium may enhance electrical life. Excessive amounts of these elements can lead to rapid erosion, restrike, and generally poor electrical life. Depending on device design, the range can be from 10 to 300 ppm. Contacts are consolidated from this mixture by conventional P/M methods. The microstructure of contacts made by this method displays a finer particle size and a more uniformly dispersed CdO phase than material made by conventional blending.

## Commercial Contact Materials

Commercial materials for electrical contacts are divided into two categories based on their manufacturing methods: (a) wrought materials, which include both pure metals and alloys and (b) composite materials, which include powder metallurgy products and internally oxidized silver alloys.

### *Copper Metals*

High electrical and thermal conductivities, low cost, and ease of fabrication account for the wide use of copper in electrical contacts. The main disadvantage of copper contacts is low resistance to oxidation and corrosion. In many applications, the voltage drop resulting from the film developed by normal oxidation and corrosion is acceptable. In some circuit breaker applications, the contacts are immersed in oil to prevent oxidation. In other applications, such as in drum controllers, sufficient wiping occurs to maintain fairly clean surfaces, thus providing a circuit of low resistance. In some applications, such as knife switches, plugs, and bolted connectors, contact surfaces are protected with grease or coatings of silver, nickel, or tin. In power circuits, where oxidation of copper is troublesome, contacts frequently are coated with silver. Vacuum-sealed circuit breakers use oxygen-free copper contacts (wrought or powder metal) for optimum electrical properties.

In air, copper does not provide high resistance to arcing, welding, or sticking. Where these characteristics are important, copper-tungsten or copper-graphite mixtures are used. However, when used in a helium atmosphere, a Cu-CdO contact performs similarly to an Ag-CdO contact. Copper alloys are used for high currents in vacuum interrupters.

Pure copper is relatively soft, anneals at low temperatures, and lacks the spring properties sometimes desired. Some copper alloys, harder than pure copper and having much better spring properties, are listed in Table 1. The annealing temperature of copper can be increased by additions of 0.25% Zn, 0.5% Cr, 0.03 to 0.06% Ag (10 to 20 oz per ton), or small amounts of finely dispersed metal oxides, such as Al<sub>2</sub>O<sub>3</sub>, with little loss of conductivity. Conversely, improved

spring properties are obtained only at the expense of electrical conductivity. Precipitation-hardened alloys, dispersion-hardened alloys, and powder metal mixtures can provide a wide range of mechanical and electrical properties.

**Applications.** Copper-base metals are commonly used in plugs, jacks, sockets, connectors, and sliding contacts. Because of tarnish films, the contact force and amount of slide must be kept high to avoid excessive contact resistance and high levels of electrical noise. Yellow brass (C27000) is preferred for plugs and terminals because of its machinability. Phosphor bronze (C50500 or C51000) is preferred for thin socket and connector springs and for wiper-switch blades because of its strength and wear resistance. Nickel silver is sometimes preferred over yellow brass for relay and jack springs because of its high modulus of elasticity and strength, and also for its resistance to tarnishing and better appearance. Sometimes, copper alloy parts are nickel plated to improve surface hardness, reduce corrosion, and improve appearance. However, nickel carries a thin but hard oxide film that has high contact resistance; very high contact force and long slide are necessary to rupture the film. To maintain low levels of resistance and noise, copper metals should be plated or overlaid with a precious metal.

## Silver Metals

Silver, in pure or alloyed form, is the most widely used material for a considerable range of make-and-break contacts (1 to 600 A). Mechanical properties and hardness of pure silver are improved by alloying, but its thermal and electrical conductivities are adversely affected. Figure 1 shows the effect of different alloying elements on the hardness and electrical resistivity of silver. Properties of the principal silver metals used for electrical contacts are given in Table 2. Silver is widely used in contacts that remain closed for long periods of time and, in the form of electroplate, is widely used as a coating for connection plugs and sockets. It is also used on contacts subject to occasional sliding, such as in rotary switches, and to a limited extent for low-resistance sliding contacts, such as slip rings.

Fig. 1 Hardness and electrical resistivity versus alloy content for silver alloy contacts

**Electrical and Thermal Conductivity.** Because silver has the highest electrical and thermal conductivities of all metals at room temperature, it can carry high currents without excessive heating, even when dimensions of the contacts are only moderate. Although good thermal conductivity is desired once the contact is in service, such conductivity increases the difficulty of assembly welding unless a higher resistance layer is added by cladding.

In component assemblies, migration of silver through and around electrical insulation can cause failure of the insulation. When in contact with certain materials, such as phenol fiber, and when under electric potential, silver migrates ionically through or across the insulating material, producing thread-like connections that lower the resistance across the insulation. This reduces insulating qualities, and the reduction is even greater if moisture is present in the atmosphere. Insulators must be designed with care to avoid this hazard.

**Oxidation Resistance.** Silver is used instead of copper chiefly because of its resistance to oxidation in air. In general, silver oxide is not a problem on silver contacts, whether or not the contacts make and break the circuit. However, silver oxide can be produced by exposure to ozone, as well as by other methods. This oxide has high resistivity, is decomposed slowly on heating at approximately 175 °C (350 °F), is decomposed rapidly at approximately 350 °C (650 °F), and is removed by arcing. This "self-cleaning" characteristic is most unusual among metals and is a chief reason for the attraction of silver as a contact material.

Silver is vulnerable to attack by sulfur or sulfide gases in the presence of moisture. The resulting sulfide film can produce significant contact resistance, particularly where contact force, voltage, or current is low. Direct current brings silver ions from the matrix into the sulfide where they form connecting bridges. Therefore, particularly at high direct current, the film becomes somewhat conducting. The resistance of a silver sulfide film decreases as temperature increases--Ag<sub>2</sub>S decomposes slowly at 360 °C (680 °F) and more rapidly at higher temperatures. In addition, the film can increase erosion and entrap dust.

**Limitations of Silver Contacts.** Silver will provide a fairly long contact life for make-break contacts and will handle up to 600 A. In pure silver contacts, difficulties sometimes arise from transfer of metal from one electrode to the other, which leads to the formation of buildups on one contact surface and holes in the other. When used in direct current (dc) circuits, silver contacts are subject to ultimate failure by mechanical sticking as a direct result of metal transfer. The direction of transfer is generally from the positive contact to the negative, but under the influence of arcing, the direction can be reversed. With high currents or inductive loads, it may be desirable to shunt the load with a resistance-capacitance protection network to reduce erosion.

When arcing produces a glow discharge in air, the rate of erosion of silver is unusually high because of a chemical interaction with air to form AgNO<sub>2</sub>.

For low resistance and low noise levels, the design of the contact device must provide sufficient force and slide to break through any silver sulfide film and maintain film-free, metal-to-metal contact at the interface. Connectors should have high slide force and several newtons normal force. Rotary switches that have up to 490 mN (0.11 lbf) normal force and considerable slide should have a protective coating of grease to reduce sulfiding and to remove abrasive particles. In low-noise transmission circuits, silver should not be used on relay and other butting contacts that have less than 195 mN (0.044 lbf) force; other precious-metal coatings, such as gold or palladium, should be used instead of silver.

A silver sulfide film has a characteristic voltage drop of several tenths of a volt. Where this drop is tolerable, silver contacts will provide reliable contact closure. Failure to close, however, can be greater than with other precious metal contacts because of impacted dirt, with a sulfide film acting as a dirt catcher.

For many applications, silver is too soft to give acceptable mechanical wear. Alloying additions of copper, cadmium, platinum, palladium, gold, and other elements are effective in increasing the hardness and modifying the contact behavior of silver. These additions do, however, lower both the electrical conductivity and the oxidation resistance relative to pure silver.

**Gold Metals**

Pure gold has unsurpassed resistance to oxidation and sulfidation, but a low melting point and susceptibility to erosion limit its use in electrical contacts to situations where the current is not more than 0.5 A. Although oxide and sulfide films do not form on gold, a carbonaceous deposit is sometimes formed when a gold contact is operated in the presence of organic vapors. The resistance of this film can be several ohms.

When gold is used in contact with palladium or rhodium, very low contact resistances have been reported.

The low hardness of gold can be increased by alloying with copper, silver, palladium, and platinum, but usage is necessarily restricted to low-current applications because of the low melting point.

Properties of gold and its alloys are listed in Table 3. If low tarnish rates and low contact resistance are to be preserved, the gold content should not be less than approximately 70%.

### Precious Metals of the Platinum Group

Platinum and palladium are the two most important metals of the platinum group. These metals have a high resistance to tarnishing, and therefore provide reliable contact closure for relays and other devices having contact forces of less than 490 mN (0.110 lbf). Their high melting points, low vapor pressure, and resistance to arcing make them suitable for contacts that close and open the load, particularly in the range up to 1 A. The low electrical and thermal conductivities of these metals, as well as their cost, generally exclude them from use at currents above approximately 5 A.

Palladium has an arcing limit only slightly less than that of platinum and gives comparable performance in relays for telephones and similar services handling 1 A or less. Palladium is a satisfactory substitute for platinum in these applications. Table 4 lists properties of platinum, palladium, and platinum and palladium alloys.

**Table 4 Properties of platinum and palladium metals used for electrical contacts**

(a) For material in annealed condition

**Corrosion Resistance.** Platinum has it high resistance to corrosion, including resistance to oxidation, sulfidation, and salt water. It will not form a stable oxide at any temperature.

Palladium is resistant to oxidation at ordinary temperatures. If heated above 350 °C (660 °F), it will oxidize slowly to form an oxide that is stable at room temperature. However, the oxide is decomposed promptly on heating to 800 °C (1470 °F) or by arcing. The oxide is not considered to be a significant factor in the reliability of closure of telephone-type relays.

The presence of organic vapors in the contact area can seriously influence the life and reliability of electrical contacts, particularly the low-force precious metal contacts universally employed in high-reliability, low-noise circuits. The

damaging organic vapors can arise from coil forms, wire coatings, insulation, soldering flux, potting and sealing compounds, and other organics in associated electrical equipment, as well as from external sources.

### ***Precious Metal Overlays***

Silver, gold, rhodium, and, to a lesser extent, platinum and palladium are employed in clad and electroplated contacts. Electrodeposition and cladding compete for many of the same applications. Clad overlays are favored because of their lower porosity, but electrodeposits are slightly less expensive for those applications requiring a very thin layer of precious metal. Electrodeposits frequently have higher hardness than the annealed wrought material; rhodium, which has a deposit hardness in excess of 600 HV in the annealed condition, is an outstanding example. High hardness accounts for the superior wear resistance of electroplated rhodium where rubbing or wiping occurs. Even at a thickness of 0.13 to 0.50  $\mu\text{m}$  (5 to 20  $\mu\text{in.}$ ) over silver or base-metal contacts, rhodium improves wear resistance and minimizes tarnishing.

Electroplated gold is employed on silver contacts to minimize tarnishing. Nickel underlayers (barrier coats) are used to prevent migration of silver through the gold plate. Recent studies indicate that migration of silver along nickel grain boundaries is rapid at high temperatures. Hence, a nickel barrier coat is questionable for high-temperature applications. Other work in this area has disclosed that palladium can be substituted for gold as a protective coating for extension of shelf life. Electroplated gold also is used on palladium contacts to minimize polymer formation in dry circuits. However, gold electrodeposits on both silver and palladium contacts soon wear off if the contacts wipe, rub, or arc.

Electroplated silver is sometimes applied to copper-base materials to make less expensive components. Electroplated silver is slightly harder than annealed wrought silver. Palladium and platinum electroplated on silver have improved tarnish resistance. Platinum, palladium, and gold electroplates are used on silver to prevent the development of conducting filaments in insulating supports.

Clad overlays are used extensively in applications requiring precious-metal thicknesses from 0.025 to 1.3 mm (0.001 to 0.050 in.). These thicknesses cannot be obtained by electroplating. These applications include electromechanical devices operating in current ranges where arcing and subsequent erosion are likely to occur. In these devices, sufficient precious metal must be available to survive the erosion that will occur over the required device cycle life.

### ***Tungsten and Molybdenum***

Most tungsten and molybdenum contacts are made in the form of composites with silver or copper as the other principal component (see the subsection "Composite Materials"). Tungsten, which was one of the earliest metals other than copper and silver adopted for electrical contact applications, has the highest boiling point (5930 °C, or 10,700 °F) and melting point (3110 °C, or 5625 °F) of all metals; it also has very high hardness at both room and elevated temperatures. Therefore, as a contact material, it offers excellent resistance to mechanical wear and electrical erosion. Its main disadvantages are low corrosion resistance and low electrical conductivity (31% IACS). After a short period of operation, an oxidized film will build up on tungsten contacts, resulting in very high contact resistance. Considerable force is required to break through the film, but high pressure and considerable impact cause little damage to the underlying metal because of its high hardness. Tungsten contacts are used in switching devices with closing forces of more than 20 N (4.5 lbf) and in circuits with high voltages and currents not more than 5 A, such as automotive ignitions, vibrators, horns, voltage regulators, magnetos, and electric razors. In low-voltage direct current (dc) devices, tungsten is always used as the negative contact, and is paired with a positive contact made of precious metal.

Tungsten rods or strips that are consolidated by swaging or rolling from sintered powder compacts have very poor ductility. They cannot be cold worked, in contrast to other contact materials. Tungsten disks are usually cut from rods or punched from strips and then brazed directly to functional parts such as breaker arms, brackets, or springs.

Properties such as grain size, grain configuration, and the degree of fibrous structure, which affect contact behavior, are controlled by using special swaging methods and annealing cycles. Tungsten disks usually are supplied with a ground finish, but they can also be electrochemically polished to obtain high-luster surfaces.

The high boiling and melting points of molybdenum--5560 °C (10,040 °F) and 2610 °C (4730 °F), respectively--are second only to those of tungsten and rhenium. Molybdenum is not used as widely as tungsten because it oxidizes more readily and erodes faster on arcing than tungsten. Nevertheless, because the density of molybdenum (10.2 g/cm<sup>3</sup> or 0.369 lb/in.<sup>3</sup>) is about half that of tungsten (19.3 g/cm<sup>3</sup>, or 0.697 lb/in.<sup>3</sup>), use of molybdenum is advantageous where mass is important. The cost of molybdenum by volume is also lower.

In addition to use in make-break contacts, molybdenum is widely used for mercury switches because it is not attacked, but only wetted by mercury.

Like tungsten, molybdenum strips and sheets are made by swaging or rolling sintered powder compacts. Disks made from rods or sheets are brazed to blanks or other structural components.

## Aluminum

Aluminum is generally a poor contact material because it oxidizes readily, but it is used in some contact applications because of its good electrical and mechanical properties, availability, and cost. Aluminum 1350 is used for some contact applications.

Where aluminum is used in contacting joints, it should be plated or clad with copper, silver, or tin. Aluminum should never be used for power applications where arcing is present. For instance, if aluminum contacts were substituted for silver in a motor starter, an explosion due to noninterruption of current on motor-starter de-energization would probably occur on load interruption.

## Composite Materials

There are three major groups of composite materials made by P/M or internal oxidation (IO) methods, or combinations of P/M and IO: refractory metal or carbide-base, silver-base, and copper-base. Table 5 lists the various types of contact materials and their respective manufacturing methods. Contacts based on refractory metals or their carbides include Mo-Ag, WC-Ag, W-Ag, WC-Cu, and W-C-Ag systems. Silver-base composites can be divided into two types: type 1 uses a pure element (nickel, tungsten, or molybdenum) or graphite as the dispersed phase; and type 2 composites use semirefractory oxides (CdO, SnO<sub>2</sub>, or ZnO) as the dispersed phase. In both types, hardness increases and conductivities decrease as the volume fraction of dispersed phase increases. The silver-cadmium oxide group of electrical contact materials is the most widely used of all the silver semirefractory contact materials. Copper-base contacts contain tungsten as the dispersed phase.

**Table 5 Properties of selected composite electrical contact materials**

## Composite Manufacturing Methods

**Infiltration** is used exclusively for making refractory metal and carbide-base composite contact materials. Metal powder or carbide powder is first blended to the desired composition with or without a small amount of binder to impart green strength, then is pressed and sintered into a skeleton of the required shape. Silver or copper is then infiltrated into the pores of the skeleton. This method produces the most densified composites, generally 97% or more of theoretical density. Complete densification is not possible because of the presence of some closed pores in the sintered skeleton. After infiltration, the contact is sometimes chemically or electrochemically etched so that only pure silver appears on the surface. The contact thus treated has better corrosion resistance and performs better in the early stages of use.

**Press-Sinter.** For small refractory-metal contacts (not exceeding approximately 25 mm, or 1 in., in diameter), a high-density material can be obtained by pressing a blended powder of exact final composition into shape and then sintering it at the melting temperature of the low-melting-point component (liquid-phase sintering). In some cases, an activating agent such as nickel, cobalt, or iron is added to improve the sintering effect on the refractory metal particles. For this process, powders of much finer particle size are required so that more bonding surface exists. However, the skeleton formed by this process is weaker than that formed by the infiltration process. Formation of the skeleton usually shrinks the apparent volume of the refractory portion of the composition, thus bleeding out the molten component onto the surface of the finished contact.

**The press-sinter-repress process** is used for all categories of contact materials, especially those in the silver-base category. Blended powders of the correct composition are compacted to the required shape and then sintered. Afterward,

the material is further densified by a second pressing (repressing). Sometimes the properties can be modified by a second sintering or annealing. The versatility of this process makes it applicable for contacts of any configuration and of any material. However, it is difficult to obtain material with as high a density as is obtained with other processes. Material thus produced also may have weak bonding between particles.

**Press-Sinter-Extrude Process.** Blended powder of final composition is pressed into an ingot and sintered. The ingot is then extruded into wires, slabs, or other desired shapes. The extruded material can be subsequently worked by rolling, swaging, or drawing. Material made by this method is usually fully dense.

The press-sinter-extrude process is used mostly for silver-base composites. Other processes used for manufacturing silver-base composite contacts are direct extrusion or direct rolling of loose powder. Although they appear to be uncommon, they are economically feasible if the equipment is properly designed and built.

**Internal Oxidation.** Silver-base composites with dispersed metal oxides can be produced by internal oxidation. In this process, a silver alloy (such as a silver-cadmium alloy) is first cast into ingots, which are rolled into strips or fabricated further into the finished product form. The silver-alloy material is then heated in air or oxygen, so that the oxygen diffuses into the alloy and forms metal oxide particles (such as CdO in the case of a silver-cadmium alloy) dispersed in the silver matrix.

Internal oxidation is used in the production of a substantial portion of Ag-CdO composites. The initial silver-cadmium alloy can be internally oxidized either in strip or finished product form. The silver-cadmium alloy is heated between 800 and 900 °C (1470 and 1650 °F) in a furnace with air, oxygen-enriched air, or pressurized oxygen. Under this condition, the oxygen species diffuse into the silver-cadmium alloy and oxidize the cadmium species. Upon the completion of the oxidation, the cross section of the material will display a microstructure of cadmium oxide particles embedded in a silver matrix. Contact parts are punched from the strip and then coined into required shapes.

**The preoxidized-press-sinter-extrude process** is used exclusively for making silver-cadmium oxide (Ag-CdO) material. Alloys are reduced to small particles in the shape of flakes, slugs, or shredded foil. These particles are oxidized and then consolidated with the press-sinter-extrude process. Material made by this method is more uniform than the same material made by conventional internal oxidation. Mechanical properties are superior to those of the same material made by the press-sinter-repress method.

**Coprecipitation.** Conventional blending or mechanical mixing of silver and cadmium oxide powders begins by dissolving the proper amounts of silver and cadmium metals in nitric acid. Compounds of silver and cadmium coprecipitate from the solution when the pH value of the solution is changed by adding either hydroxide or carbonate solutions. During subsequent calcination at approximately 500 °C (930 °F), the compound mixture decomposes to form a mixture of silver and cadmium oxide. Alkali-metal content can be controlled in the ppm range by adequate washing. Controlled amounts of sodium, potassium, and lithium may enhance electrical life. Excessive amounts of these elements can lead to rapid erosion, restrike, and generally poor electrical life. Depending on device design, the range can be from 10 to 300 ppm. Contacts are consolidated from this mixture by conventional P/M methods. The microstructure of contacts made by this method displays a finer particle size and a more uniformly dispersed CdO phase than material made by conventional blending.

# Thermocouple Materials

## Introduction

THE THERMOCOUPLE THERMOMETER is by far the most widely used device for measurement of temperature used in the metals industry. It is estimated that well over 90% of the temperature sensing devices used in this industry are

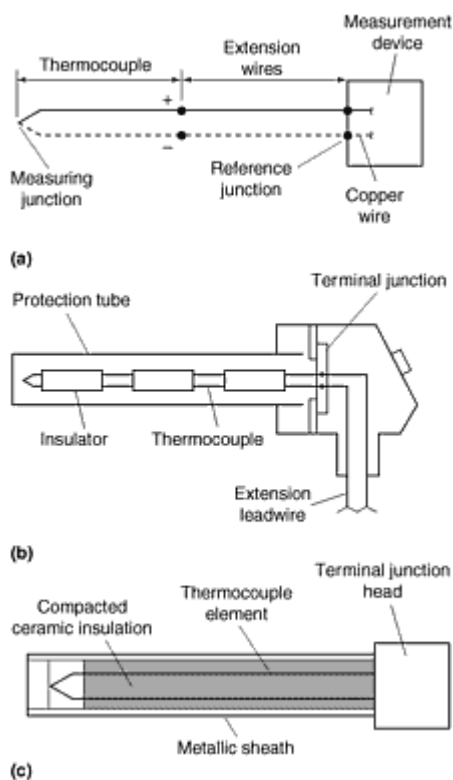

thermocouple thermometers. Favorable characteristics of these devices include good accuracy, suitability over a wide temperature range, fast thermal response, ruggedness, high reliability, low cost, and great versatility of application.

Essentially, a thermocouple thermometer is a system consisting of a temperature-sensing element called a thermocouple, which produces an electromotive force (emf) that varies with temperature, a device for measuring emf, which may include a printed scale for converting emf to equivalent temperature units and an electrical conductor (extension wires) for connecting the thermocouple to the emf measurement device. The principles on which thermocouples depend, as well as their design considerations are described in detail in the article "Thermocouple Materials," in Volume 2 of *ASM Handbook*.

## Thermocouple Principles

A thermocouple is a device in which the temperature difference between the ends of a pair of dissimilar metal wires is deduced from a measurement of the difference in the thermo-electric potentials developed along the wires. The presence of a temperature gradient in a metal or alloy leads to an electric potential gradient being set up along the temperature gradient. This thermoelectric potential gradient is proportional to the temperature gradient and varies from metal to metal. It is the fact that the thermoelectric emf is different in different metals and alloys for the same temperature gradient that allows the effect to be used for the measurement of temperature.

**The basic circuit** of a thermocouple is shown in Fig. 1(a). Thermocouples consist of two dissimilar wires joined (brazed or welded) at one end, forming a measuring, or hot, junction. The other end, which is connected to the copper wire of the measuring circuitry, is called the reference, or cold, junction. The electrical signal output in millivolts is proportional to the difference in temperature between the measuring (hot) junction and the reference (cold) junction. The different types of thermocouples, classified by their metallurgical compositions, have differing output signal calibrations.

**Fig. 1** Schematics showing (a) the basic thermocouple circuit (the positive and negative symbols represent the positive and negative thermoelements with reference to Platinum 67), (b) conventional thermocouple assembly, and (c) compacted ceramic thermocouple assembly

The thermocouple wire combination is called a thermocouple element. A complete thermocouple assembly includes the element and a system for electrically insulating the wires and protecting them from the operating environment (see the subsection "Insulation and Protection" ). In addition, the assembly provides mounting fittings and a terminal junction in a

head assembly. Extension lead wires, which match the thermoelectric characteristics of the thermocouple elements, are used to connect these terminal junctions to the instrumentation. Figure 1(b) shows a complete thermocouple assembly in a protection tube. The operating life and accuracy of a thermocouple depend on operating temperature, time at operating temperature, and number of high-to-low temperature cycles.

## Types of Thermocouples

Commercially available thermocouples are grouped according to material characteristics (base metal or noble metal) and standardization. At present, five base-metal thermocouples and three noble-metal thermocouples have been standardized and given letter designations by ANSI (American National Standards Institute), ASTM (American Society for Testing and Materials), and ISA (Instrument Society of America). Among the remaining thermocouples in use, some have not been assigned letter designations because of limited usage, and some are being considered for standardization.

### Standard Thermocouples

Table 1 presents base compositions, melting points, and electrical resistivities of the individual thermoelements of the seven standard thermocouples. Maximum operating temperatures and limiting factors in environmental conditions are listed also.

**Table 1 Properties of standard thermocouples**

Type	Thermoelements	Base composition	Melting point, °C	Resistivity $\mu\Omega \cdot m$	Recommended service	Maximum temperature	
						°C	°F

	RN	Pt	1769	104			
<b>S</b>	SP	90Pt-10Rh	1850	189	Oxidizing or inert	1480	2700
	SN	Pt	1769	104			
<b>B</b>	BP	70Pt-30Rh	1927	190	Oxidizing, vacuum or inert	1700	3100

**The type J** thermocouple is widely used, primarily because of its versatility and low cost. In this couple, the positive thermoelement is iron (containing small amounts of carbon, cobalt, manganese, and silicon), and the negative thermoelement is constantan, a 44Ni-55Cu alloy. Type J couples can be used in both oxidizing and reducing atmospheres at temperatures up to approximately 760 °C (1400 °F). They find extensive use in heat-treating applications in which they are exposed directly to the furnace atmosphere.

**Type K** thermocouples, like type J couples, are also widely used in industrial applications. The positive thermoelement is a 90Ni-9Cr alloy; the negative thermoelement is a 94% Ni alloy containing silicon, manganese, aluminum, iron, and cobalt as alloying constituents. Type K thermocouples can be used at temperatures up to 1250 °C (2280 °F) in oxidizing atmospheres.

Type K couples should not be used in elevated-temperature service in reducing atmospheres or in environments containing sulfur, hydrogen or carbon monoxide. At elevated temperatures in oxidizing atmospheres, uniform oxidation occurs, and the oxide formed on the surface of the positive (90Ni-10Cr) thermoelement is a spinel, NiO-Cr<sub>2</sub>O<sub>3</sub>. However, in reducing atmospheres, preferential oxidation of chromium occurs forming only Cr<sub>2</sub>O<sub>3</sub>. The presence of this greenish oxide (commonly known as "green rot") depletes the chromium content, causing a very large negative shift of the thermal emf and rapid deterioration of the thermoelement.

**Type N.** The Nicrosil/Nisil thermocouple (type N in Table 1) was developed for oxidation resistance and emf stability superior to those of type K thermocouples at elevated temperatures. The positive thermoelement is Nicrosil (nominal composition 14 Cr, 1.3 Si, 0.1 Mg, bal Ni), and the negative thermoelement is Nisil (nominal composition 4.4 Si, 0.1 Mg, bal Ni). These couples have been shown to have longer life and better emf stability than type K thermocouples at elevated temperatures in air, both in the laboratory and in several industrial applications.

**Type T** thermocouples are used extensively for cryogenic measurements. The positive thermoelement is oxygen-free high conductivity (OFHC) copper (C10100). The constantan (44Ni-55Cu) used for the negative thermoelement of the type T couple has the same base composition as that of the constantan used in the type J couple, but is slightly different in minor alloying constituents. Type T couples can be used in either oxidizing or reducing atmospheres. They should not be used above 370 °C (700 °F) because of the poor oxidation resistance of copper.

**Type E.** The positive thermoelement of the type E thermoelement is 90Ni-9Cr, the same as that of the type K thermocouple; the negative element is 44Ni-55Cu, the same as that of the type T couple. The recommended maximum operating temperature for type E thermocouples is 870 °C (1600 °F). Like type K thermocouples, the type E couples should be used only in oxidizing atmospheres because their use in reducing atmospheres results in preferential oxidation of chromium (green rot).

**The type S** thermocouple served as the interpolating instrument for defining the International Practical Temperature Scale of 1968 (amended in 1975) from the freezing point of antimony (630.74 °C, or 1167.33 °F) to the freezing point of gold (1064.43 °C, or 1947.97 °F). It is characterized by a high degree of chemical inertness and stability at high temperatures in oxidizing atmospheres. The materials used in the legs of this thermocouple, Pt-10Rh and platinum, both are ductile and can be drawn into fine wire (as small as 0.025 mm, or 0.001 in., in diameter for special applications).

The type S couple is widely used in industrial laboratories as a standard for calibration of base-metal thermocouples and other temperature-sensing instruments. It is commonly used for controlling processing of steel, glass, and many refractory materials. It should be used in air or in oxidizing or inert atmospheres. It should not be used unprotected in reducing atmospheres in the presence of easily reduced oxides, atmospheres containing metallic vapors such as lead or zinc, or atmospheres containing nonmetallic vapors such as arsenic, phosphorus, or sulfur. It should not be inserted directly into metallic protection tubes and is not recommended for service in vacuum at high temperatures except for short periods of time. Because the negative leg of this couple is fabricated from high-purity platinum (approximately 99.99% for commercial couples and 99.995%+ for special grades), special care should be taken to protect the couple from contamination by the insulators used as well as by the operating environment.

**The type R** thermocouple (Pt-13Rh/Pt) has characteristics and end-use applications similar to those of the type S couple.

**Type B** thermocouples (Pt-30Rh/Pt-6Rh) can be used in still air or inert atmospheres for extended periods at temperatures up to 1700 °C (3100 °F) and intermittently up to 1760 °C (3200 °F) (Pt-6Rh leg melts at approximately 1826 °C, or 3319 °F). Because both of its legs are platinum-rhodium alloys, the type B couple is less sensitive than type R or type S to pickup of trace impurities from insulators or from the operating environment. Under corresponding conditions of temperature and environment, type B thermocouples exhibit less grain growth and less drift in calibration than type R or type S thermocouples.

The type B couple also is suitable for short-term use in vacuum at temperatures up to approximately 1700 °C (3100 °F). It should not be used in reducing atmospheres, or in those containing metallic or nonmetallic vapors, unless suitably protected with ceramic protection tubes. It should never be inserted directly into a metallic primary protection tube.

### ***Nonstandard Thermocouples***

**The 19 alloy/20 alloy** thermocouple was developed for temperature-sensing and control applications at elevated temperatures in hydrogen or in reducing atmospheres. The positive thermoelement is the 20 alloy, which has a nominal composition of 82Ni-18Mo. The negative thermoelement is the 19 alloy, the nominal composition of which is 99Ni-1Co.

19 alloy/20 alloy thermocouples can be used in hydrogen or in reducing atmospheres over the entire range from 0 to 1260 °C (32 to 2300 °F) with excellent performance. The oxidation resistance of 19 alloy/20 alloy is not good when compared with that of the standard type K couple. 19 alloy/20 alloy thermocouples should not be used in oxidizing atmospheres above 650 °C (1200 °F).

**Iridium-Rhodium.** Three iridium-rhodium thermocouples are commercially available: 60Ir-40Rh/Ir (the most widely used), 50Ir-50Rh/Ir, and 40Ir-60Rh/Ir. Iridium-rhodium couples are suitable for use for limited periods of time in air or other oxygen-carrying atmospheres at temperatures up to approximately 2000 °C (3600 °F) and generally are used for such service at temperatures above the range in which types R, S, and B thermocouples are employed. They can be used in inert atmospheres and in vacuum, but not in reducing atmospheres.

**Platinum-Molybdenum.** The Pt-5Mo/Pt-0.1Mo thermocouple is used for measuring temperatures from 1100 to approximately 1500 °C (2000 to approximately 2700 °F) under neutron radiation (type K couples are employed for temperatures up to 1100 °C).

**Platinel thermocouples** are an all-noble-metal combination. Actually, two combinations have been produced: Platinel I and Platinel II. Both have negative legs of 65Au-35Pd. The positive leg of the Platinel I couple is 83Pd-14Pt-3Au, and the positive leg of the Platinel II couple consists of 55Pd-3/Pt-14Au. Platinel couples can be used unprotected (insulators only) in air to 1200 °C (2190 °F) for extended periods of time and to 1300 °C (2370 °F) for shorter periods.

**Tungsten-Rhenium.** Three tungsten-rhenium thermocouples are commercially available: W/W-26Re, doped W-3Re/W-25Re, and W-5Re/W-26Re. All three couples have been used at temperatures up to 2760 °C (5000 °F), but they usually are employed below 2315 °C (4200 °F). These thermocouples are limited to operation in reducing atmospheres, high vacuum, and inert gases due to their tendency toward oxidation.

## Insulation and Protection

To operate properly, thermocouple wires must be electrically insulated from one another at all points other than the measuring junction and must be protected from the operating environment.

**In conventional thermocouple assemblies,** insulated thermocouple wires are enclosed in protection tubes. For cryogenic application (below 0 °C, and as low as approximately 4 K) varnish or varnish-type coatings are used to insulate thermoelements from one another. At higher temperatures (up to approximately 300 °C), insulating materials include polyvinyl chloride, thermoplastic elastomer, nylon, teflon, and polyimide. At temperatures above 300 °C (570 °F), hard-fired ceramics are used. For base-metal thermocouples, mullite, alumina, and steatite are used. Depending on the temperature and the environment, noble-metal or nonstandard thermocouples can be insulated with quartz, mullite, sillimanite, porcelain, alumina, beryllia, thoria, or hafnia.

Insulated thermocouple elements are used inside protection tubes or wells, which provide mechanical support and protect the thermocouple from the process environment. Protection tubes are made from metal (carbon steel, chromium-molybdenum alloy steels, stainless steels, and nickel alloys) or ceramic materials (porcelain, alumina, or silicon carbide). Wells, which are used to protect thermocouples in liquid or gaseous environments at pressures greater than 345 kPa (50 psi), are metallic.

**Compacted ceramic thermocouples** use a ceramic powder to insulate the thermocouple wires (Fig. 1c). These wires are compacted inside a metal sheath, providing protection from environment. Sheaths, which are selected to suit specific end-use requirements include 300 series austenitic stainless steels, nickel-base alloys (Hastelloy X and Inconel 600 and 702), and tantalum and niobium alloys. Depending on temperature and application, magnesia, alumina, beryllia, or thoria can be used for the insulation.

# Low-Expansion Alloys

## Introduction

LOW-EXPANSION ALLOYS are materials with dimensions that do not change appreciably with temperature. Alloys included in this category are various binary iron-nickel alloys and several ternary alloys of iron combined with nickel-chromium, nickel-cobalt, or cobalt-chromium alloying. Low-expansion alloys are used in applications such as rods and tapes for geodetic surveying, compensating pendulums and balance wheels for clocks and watches, moving parts that require control of expansion (such as pistons for some internal-combustion engines), bimetal strip, glass-to-metal seals, thermostatic strip, vessels and piping for storage and transportation of liquefied natural gas, superconducting systems in power transmissions, integrated-circuit lead frames, components for radios and other electronic devices, and structural components in optical and laser measuring systems.

## Iron-Nickel Alloys

Alloys of iron and nickel have coefficients of linear expansion ranging from a small negative value ( $-0.5 \text{ ppm}/^{\circ}\text{C}$ ) to a large positive ( $20 \text{ ppm}/^{\circ}\text{C}$ ) value. Figure 1 shows the effect of nickel content on the linear expansion of iron-nickel alloys at room temperature. In the range of 30 to 60% Ni, it is possible to select alloys with appropriate expansion characteristics. The alloy containing 36% Ni (with small quantities of manganese, silicon, and carbon amounting to a total of less than 1%) has a coefficient of expansion so low that its length is almost invariable for ordinary changes in temperature. This alloy is known as Invar, which is a trade name meaning invariable.

**Fig. 1** Coefficient of linear expansion at  $20^{\circ}\text{C}$  versus nickel content for iron-nickel alloys containing 0.4% Mn and 0.1% C

After the discovery of Invar, an intensive study was made of the thermal and elastic properties of several similar alloys. Iron-nickel alloys that have nickel contents higher than that of Invar retain to some extent the expansion characteristics of Invar. Alloys that contain less than 36% Ni have much higher coefficients of expansion than alloys containing 36% or more Ni.

## Invar

Invar (UNS number K93601) and related alloys have low coefficients of expansion over only a rather narrow range of temperature (see Fig. 2). At low temperatures in the region from A to B, the coefficient of expansion is high. In the interval between B and C, the coefficient decreases, reaching a minimum in the region from C to D. With increasing temperature, the coefficient begins again to increase from D to E, and thereafter (from E to F), the expansion curve follows a trend similar to that of the nickel or iron of which the alloy is composed. The minimum expansivity prevails only in the range from C to D.

**Fig. 2** Change in length of a typical Invar alloy over different ranges of temperature

In the region between D and E in Fig. 2, the coefficient is changing rapidly to a higher value. The temperature limits for a well-annealed 36% Ni iron are 162 and 271 °C (324 and 520 °F). These temperatures correspond to the initial and final losses of magnetism in the material (that is, the Curie temperature). The slope of the curve between C and D is then a measure of the coefficient of expansion over a limited range of temperature.

Table 1 gives coefficients of linear expansion of iron-nickel alloys between 0 and 38 °C (32 and 100 °F). The expansion behavior of several iron-nickel alloys over wider ranges of temperature is represented by curves 1 to 5 in Fig. 3. For comparison, Fig. 3 also includes the similar expansion obtained for ordinary steel.

**Table 1 Thermal expansion of iron-nickel alloys between 0 and 38 °C**

Ni, %	Mean coefficient, $\mu\text{m/m} \cdot \text{K}$
31.4	$3.395 + 0.00885 t$
34.6	$1.373 + 0.00237 t$
35.6	$0.877 + 0.00127 t$
37.3	$3.457 - 0.00647 t$
39.4	$5.357 - 0.00448 t$
43.6	$7.992 - 0.00273 t$
44.4	$8.508 - 0.00251 t$
48.7	$9.901 - 0.00067 t$
50.7	$9.984 + 0.00243 t$
53.2	$10.045 + 0.00031 t$

**Fig. 3 Thermal expansion of iron-nickel alloys.** Curve 1, 64Fe-31Ni-5Co; curve 2, 64Fe-36Ni (Invar); curve 3, 58Fe-42Ni; curve 4, 53Fe-47Ni; curve 5, 48Fe-52Ni; curve 6, carbon steel (0.25% C)

**Effects of Composition on Expansion Coefficient.** Figure 1 shows the effect of variation in nickel content on linear expansivity. Minimum expansivity occurs at approximately 36% Ni, and small additions of other metals have considerable influences on the position of this minimum. Because further additions of nickel raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve (Fig. 2) also rises with increasing nickel content.

The addition of third and fourth elements to iron-nickel provides useful changes of desired properties (mechanical and physical), but significantly changes thermal expansion characteristics. Minimum expansivity shifts toward higher nickel contents when manganese or chromium is added, and toward lower nickel contents when copper, cobalt, or carbon is added. Except for the ternary alloys with Ni-Fe-Co compositions (Super Invars), the value of the minimum expansivity for any of these ternary alloys is, in general, greater than that of a typical Invar alloy.

Figure 4 shows the effects of additions of manganese, chromium, copper, and carbon. Additions of silicon, tungsten, and molybdenum produce effects similar to those caused by additions of manganese and chromium; the composition of minimum expansivity shifts toward higher contents of nickel. Addition of carbon is said to produce instability in Invar, which is attributed to the changing solubility of carbon in the austenitic matrix during heat treatment.

**Fig. 4** Effect of alloying elements on expansion characteristics of iron-nickel alloys. (a) Displacement of nickel content caused by additions of manganese, chromium, copper, and carbon to alloy of minimum expansivity. (b) Change in value of minimum coefficient of expansion caused by additions of manganese, chromium, copper, and carbon

**Effects of Processing.** Heat treatment and cold work change the expansivity of Invar alloys considerably. Table 2 shows the effect of heat treatment for a 36% Ni Invar alloy. The expansivity is greatest in well-annealed material and least in quenched material.

**Table 2** Effect of heat treatment on coefficient of thermal expansion of Invar

Condition	Mean coefficient, $\mu\text{m/m} \cdot \text{K}$
As forged	
At 17-100 °C (63-212 °F)	1.66
At 17-250 °C (63-480 °F)	3.11
Quenched from 830 °C (1530 °F)	
At 18-100 °C (65-212 °F)	0.64
At 18-250 °C (65-480 °F)	2.53
Quenched from 830 °C and tempered	
At 16-100 °C (60-212 °F)	1.02
At 16-250 °C (60-480 °F)	2.43
Quenched from 830 °C to room temperature in 19 h	
At 16-100 °C (60-212 °F)	2.01
At 16-250 °C (60-480 °F)	2.89

Annealing is done at 750 to 850 °C (1380 to 1560 °F). When the alloy is quenched in water from these temperatures, expansivity is decreased, but instability is induced both in actual length and in coefficient of expansion. To overcome these deficiencies and to stabilize the material, it is common practice to stress relieve at approximately 315 to 425 °C (600 to 800 °F) and to age at a low temperature 90 °C (200 °F) for 24 to 48 hours.

Cold drawing also decreases the thermal expansion coefficient of Invar alloys. The values for the coefficients in the following table are from experiments on two heats of Invar:

Material condition	Expansivity, ppm/°C
<b>Direct from hot mill</b>	1.4 (heat 1)
	1.4 (heat 2)
<b>Annealed and quenched</b>	0.5 (heat 1)
	0.8 (heat 2)
<b>Quenched and cold drawn (&gt;70% reduction with a diameter of 3.2 to 6.4 mm, or 0.125 to 0.250 in.)</b>	0.14 (heat 1)

By cold working after quenching, it is possible to produce material with a zero, or even a negative, coefficient of expansion. A negative coefficient can be increased to zero by careful annealing at a low temperature. However, these artificial methods of securing an exceptionally low coefficient can produce instability in the material. With lapse of time and variation in temperature, exceptionally low coefficients usually revert to normal values. For special applications (geodetic tapes, for example), it is essential to stabilize the material by cooling it slowly from 100 to 20 °C (212 to 68 °F) over a period of many months, followed by prolonged aging at room temperature. However, unless the material is to be used within the limits of normal atmospheric variation in temperature, such stabilization is of no value. Although these variations in heat-treating practice are important in special applications, they are of little significance for ordinary uses.

**Magnetic Properties.** Invar and all similar iron-nickel alloys are ferromagnetic at room temperature and become paramagnetic at higher temperatures. Because additions in nickel contents raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve rises with increasing nickel content. The loss of magnetism in a well-annealed sample of a true Invar begins at 162 °C (324 °F) and ends at 271 °C (520 °F). In a quenched sample, the loss begins at 205 °C (400 °F) and ends at 271 °C (520 °F).

**Electrical Properties.** The electrical resistance of 36Ni-Fe Invar is between 750 and 850 nΩ · m at ordinary temperatures. The temperature coefficient of electrical resistivity is about 1.2 mΩ/Ω · K over the range of low expansivity. As nickel content increases above 36%, the electrical resistivity decreases to approximately 165 nΩ · m at approximately 80% NiFe.

**Other Physical and Mechanical Properties.** Table 3 presents data on miscellaneous properties of Invar in the hot-rolled and forged conditions. Figure 5 illustrates the effects of temperature on mechanical properties of forged 66Fe-34Ni.

### Iron-Nickel Alloys Other Than Invar

Iron-nickel alloys that have nickel contents higher than that of Invar retain to some extent the expansion characteristics of Invar. Because further additions of nickel raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve rises with increasing nickel content. Although this increase in range is an advantage in some circumstances, it is accompanied by an increase in coefficient of expansion. Table 4 and Fig. 6 present information on the coefficients of expansion of iron-nickel alloys at temperatures up to the inflection temperature. They also give data on alloys containing up to 68% Ni. Of significant commercial interest are those alloys containing approximately 40 to 50% Ni such as thermostat alloys 42% Ni iron (UNS K94200) and 45% Ni iron (UNS K94500) and glass sealing alloys such as Dumet (UNS 94101), 51% Ni iron, and 52% Ni iron.

## Special Alloys

**Fe-Ni-Cr Alloys.** Elinvar is a 52Fe-36Ni-12Cr alloy with a zero thermoelastic coefficient (that is, an invariable modulus of elasticity over a wide temperature range). It is used for such articles as hair springs and balance wheels for clocks and watches and for tuning forks used in radio synchronization. Other Fe-Ni-Cr alloys with 40 to 48% Ni and 2 to 8% Cr are useful as glass-sealing alloys.

**Fe-Ni-Co Alloys.** Replacement of some of the nickel by cobalt in an alloy of the Invar composition lowers the thermal expansion coefficient and makes the alloy's expansion characteristics less susceptible to variations in heat treatment. One such alloy is the Super Invar with a nominal 32% Ni and 4 to 5% Co. Its expansion coefficient is lower than that of Invar, but over a narrower temperature range.

Kovar (UNS 94610) is a nominal 29%Ni-17%Co-54%Fe alloy that is a well-known glass-sealing alloy suitable for sealing to a hard (borosilicate) glasses. Kovar has a nominal expansion coefficient of approximately 5 ppm/°C and inflection temperature of approximately 450 °C (840 °F).

**Fe-Co-Cr Alloys.** An alloy containing 36.5 to 37% Fe, 53 to 54.5% Co, and 9 to 10% Cr has an exceedingly low, and at times, negative (over the range from 0 to 100 °C, or 32 to 212 °F) coefficient of expansion. This alloy has good corrosion resistance compared to low-expansion alloys without chromium. Consequently, it has been referred to as "Stainless Invar."

**High-Strength, Controlled-Expansion Alloys.** There is a family of Fe-Ni-Co alloys strengthened by the addition of niobium and titanium that show the strength of precipitation-hardened superalloys while maintaining low coefficients of thermal expansion typical of certain alloys from the Fe-Ni-Co system. Table 5 shows compositions and properties of these alloys. The combination of exceptional strength and low coefficient of expansion makes this family useful for applications requiring close operating tolerances over a range of temperatures. Several components for gas turbine engines are produced from these alloys.

**Table 5 Compositions, thermal expansion coefficients, and room-temperature tensile properties of high-strength controlled-expansion alloys**

# Shape Memory Alloys

## Introduction

THE TERM SHAPE MEMORY ALLOYS (SMA) is applied to that group of metallic materials that demonstrate the ability to return to some previously defined shape or size when subjected to the appropriate thermal procedure. Generally, these materials can be plastically deformed at some relatively low temperature, and upon exposure to some higher temperature will return to their shape prior to the deformation. Materials that exhibit shape memory only upon heating are referred to as having a one-way shape memory. Some materials also undergo a change in shape upon recooling. These materials have a two-way shape memory.

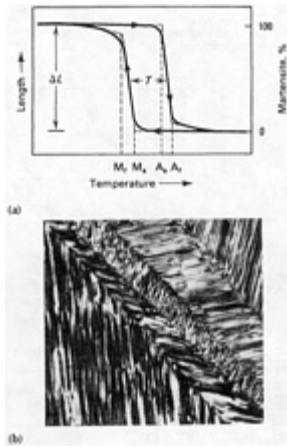

Although a relatively wide variety of alloys are known to exhibit the shape memory effect, only those that can recover substantial amounts of strain or that generate significant force upon changing shape are of commercial interest. To date this has been the NiTi alloys and copper-base alloys such as Cu-Zn-Al and Cu-Al-Ni.

A shape memory alloy is further defined as an alloy that yields a thermoelastic martensite. In this case, the alloy undergoes a martensitic transformation of a type that allows the alloy to be deformed by a twinning mechanism below the transformation temperature. The deformation is then reversed when the twinned structure reverts upon heating to the parent phase.

---

## General Characteristics

The martensitic transformation that occurs in the shape memory alloys yields a thermoelastic martensite and develops from a high-temperature austenite phase with long-range order. The martensite typically occurs as alternately sheared platelets, which are seen as a herringbone structure when viewed metallographically (Fig. 1b). The transformation, although a first-order phase change, does not occur at a single temperature but over a range of temperatures that varies with each alloy system. The typical method of characterizing the transformation and naming each point in the cycle is shown in Fig. 1(a). Most of the transformation occurs over a relatively narrow temperature range, although the beginning and end of the transformation during heating or cooling actually extends over a much larger temperature range. The transformation also exhibits hysteresis in that the transformation on heating and on cooling does not overlap (Fig. 1a). This transformation hysteresis (shown as  $T$  in Fig. 1a) varies with the alloy system.

**Fig. 1** Characteristics of shape memory alloys. (a) Typical transformation versus temperature curve for a specimen under constant load (stress) as it is cooled and heated.  $T$ , transformation hysteresis.  $M_s$ , martensite start;  $M_f$ , martensite finish;  $A_s$ , austenite start;  $A_f$ , austenite finish. (b) Martensitic structure typical of those in copper-aluminum, copper-tin, and copper-zinc alloys.

## Commercial SMA Alloys

Properties of NiTi and Cu-base SMA alloys are quite different. The NiTi alloys have greater shape memory strain (up to 8% versus 4 to 5% for the copper-base alloys), tend to be much more thermally stable, have excellent corrosion resistance compared to the medium corrosion resistance and susceptibility to stress-corrosion cracking of the copper-base alloys, and have much higher ductility. Conversely, the copper-base alloys are much less expensive, can be melted and extruded in air with ease, and have a wider range of potential transformation temperatures. The two alloy systems thus have advantages and disadvantages that must be considered in a particular application.

### Nickel-Titanium Alloys

The basis of the nickel-titanium system of alloys is the binary, equiatomic (49 to 51 at.% Ni) intermetallic compound of NiTi. This intermetallic compound is extraordinary because it has a moderate solubility range for excess nickel or titanium, as well as most other metallic elements, and it also exhibits a ductility comparable to most ordinary alloys. This solubility allows alloying with many of the elements to modify both the mechanical properties and the transformation properties of the system. Excess nickel, in amounts up to approximately 1%, is the most common alloying addition. Excess nickel strongly depresses the transformation temperature and increases the yield strength of the austenite. Other frequently used elements are iron and chromium (to lower the transformation temperature), and copper (to decrease the hysteresis and lower the deformation stress of the martensite). Because common contaminants such as oxygen and carbon can also shift the transformation temperature and degrade the mechanical properties, it is also desirable to minimize the amount of these elements.

**Properties.** Table 1 shows the major physical properties of the basic binary Ni-Ti system and some of the mechanical properties of the alloy in the annealed condition. Note that this is for the equiatomic alloy with an  $A_f$  value of approximately 110 °C (230 °F). Selective work hardening, which can exceed 50% reduction in some cases, and proper heat treatment can greatly improve the ease with which the martensite is deformed, give an austenite with much greater strength, and create material that spontaneously moves itself both on heating and on cooling (two-way shape memory). One of the biggest challenges in using this family of alloys is in developing the proper processing procedures to yield the properties desired.

**Processing.** Because of the reactivity of the titanium in these alloys, all melting of them must be done in a vacuum or an inert atmosphere. Methods such as plasma-arc melting, electron-beam melting, and vacuum-induction melting are all used commercially. After ingots are melted, standard hot-forming processes such as forging, bar rolling, and extrusion can be used for initial breakdown. The alloys react slowly with air, so hot working in air is quite successful. Most cold-working processes can also be applied to these alloys, but they work harden extremely rapidly, and frequent annealing is required. Wire drawing is probably the most widely used of the techniques, and excellent surface properties and sizes as small as 0.05 mm (0.002 in.) are made routinely.

Heat treating to impart the desired memory shape is often done at 500 to 800  $^\circ\text{C}$  (950 to 1450  $^\circ\text{F}$ ), but it can be done as low as 300 to 350  $^\circ\text{C}$  (600 to 650  $^\circ\text{F}$ ) if sufficient time is allowed. The SMA component may need to be restrained in the desired memory shape during the heat treatment; otherwise, it may not remain there.

**Applications** for NiTi alloys can be grouped into four broad categories: actuation devices, constrained recovery devices, superelastic devices, and martensitic devices.

Shape memory actuation devices utilize the shape memory effect to recover a particular shape upon heating above their transformation temperatures. Shape memory actuation devices can act without constraint to freely recover their trained shape, can be fully constrained so that they provide a force, or can be partially constrained so that they perform work. The transformation temperatures of the NiTi alloy can be adjusted to activate at precisely the required temperature. Common actuation temperatures are human body temperature and boiling water temperature. Examples of shape memory actuation devices include blood-cot filters (NiTi wire is shaped to anchor itself in a vein and catch passing clots), vascular stents to reinforce blood vessels, and coffeepot thermostats.

The most successful example of constrained recovery devices is hydraulic pipe couplings. These fittings are manufactured as cylindrical sleeves slightly smaller than the metal tubing they join. Their diameters are then expanded while martensitic, and upon warming to austenite, they shrink in diameter and strongly hold the tube ends. The tubes prevent the coupling from fully recovering its manufactured shape, and the stresses created as the coupling attempts to do so are great enough to create a joint that, in many ways, is superior to a weld.

Superelastic devices are used for applications that demand the extraordinary flexibility of NiTi. Nickel-titanium has the ability to absorb large amounts of strain energy and release it as the applied strain is removed. The elasticity of NiTi is approximately ten times that of steel. Nickel-titanium also has excellent torqueability and kink resistance, which are important for medical guidewires. Further, superelastic NiTi alloys provide a constant force over a large strain range. This

has been exploited in the field of orthodontics (arch wires) where a constant force enhances tooth movement with greater patient comfort. Eyeglass frames represent another important superelastic application.

The martensitic phase of NiTi has some unique properties that have made it an ideal material for many applications. First, the martensitic phase transformation has excellent damping characteristics due to the energy absorption characteristics of its twinned phase structure. Second, the martensitic form of NiTi has remarkable fatigue resistance. Finally, the martensitic phase is easily deformed, yet will recover its shape upon heating above its transformation temperatures. Examples of martensitic devices include vibration dampers, bendable surgical tools for open heart surgery, and highly fatigue resistant wires.

## Copper-Base Alloys

**Compositions and Properties.** Commercial copper-base shape memory alloys are available in ternary Cu-Zn-Al and Cu-Al-Ni alloys or in their quaternary modifications containing manganese. Manganese depresses transformation temperatures of both Cu-Zn-Al and Cu-Al-Ni alloys and shifts the eutectoid to higher aluminum content. It often replaces aluminum for better ductility. Elements such as boron, cerium, cobalt, iron, titanium, vanadium, and zirconium are also added for grain refinement. Compositions of the Cu-Zn-Al alloys usually fall in the range of 10 to 30 wt% Zn and 5 to 10 wt% Al; Cu-Al-Ni alloys contain 11 to 14.5 wt% Al and 3 to 5 wt% Ni. The martensitic transformation temperatures can be adjusted by varying chemical composition. Table 2 lists the major properties of copper-base SMAs.

**Table 2 Properties of copper-base shape memory alloys**

Property	Property value	
	Cu-Zn-Al	Cu-Al-Ni

<b>Hysteresis, <math>\Delta^\circ\text{C}</math> (<math>\Delta^\circ\text{F}</math>)</b>	15-25 (30-45)	15-20 (30-35)

- (a) The Young's modulus of shape memory alloys becomes difficult to define between the  $M_s$  and the  $A_s$  transformation temperatures. At these temperatures, the alloys exhibit nonlinear elasticity, and the modulus is both temperature and strain dependent.

**Processing.** The melting of copper-base shape memory alloys is similar to that of aluminum bronzes. Most commercial alloys are induction melted. Protective flux on the melt and the use of nitrogen or inert-gas shielding during pouring are necessary to prevent zinc evaporation and aluminum oxidation. Powder metallurgy and rapid solidification processing are also used to produce fine-grain alloys without grain-refining additives.

Copper-base alloys can be readily hot worked in air. With low aluminum content (<6 wt%), Cu-Zn-Al alloys can be cold finished with interpass annealing. Alloys with higher aluminum content are not as easily cold workable. Cu-Al-Ni alloys, conversely, are quite brittle at low temperatures and can only be hot finished.

Because copper-base shape memory alloys are metastable in nature, solution heat treatment in the parent  $\beta$ -phase region and subsequent controlled cooling are necessary to retain  $\beta$  phase for shape memory effects. Prolonged solution heat treatment causes zinc evaporation and grain growth and should be avoided. Water quench is widely used as a quenching process, but air cooling can be sufficient for some high-cooling aluminum content Cu-Zn-Al alloys and Cu-Al-Ni alloys. The as-quenched transformation temperature is usually unstable. Postquench aging at temperatures above the nominal  $A_f$  temperature is generally needed to establish stable transformation temperatures.

Cu-Zn-Al alloys, when quenched rapidly and directly into the martensitic phase, are susceptible to the martensite stabilization effect. This effect causes the reverse transformation to shift toward higher temperatures. It therefore delays and can completely inhibit the shape recovery. For alloys with  $M_s$  temperatures above the ambient, slow cooling or step quenching with intermediate aging in the parent  $\beta$ -phase state should be adopted.

**The thermal stability** of copper-base alloys is ultimately limited by the decomposition kinetics. For this reason, prolonged exposure of Cu-Zn-Al and Cu-Al-Ni alloys at temperatures above 150 °C (300 °F) and 200 °C (390 °F), respectively, should be avoided. For high-temperature stability, Cu-Al-Ni is generally a better alloy system than Cu-Zn-Al. However, even for moderate temperature applications, which demand tight control of transformation temperatures, these effects need to be evaluated.

**Applications.** Similar to the NiTi hydraulic coupling described previously, a Cu-Zn-Al coupling for copper and aluminum tubing has been developed. In this application, the Cu-Zn-Al shape memory cylinder shrinks on heating and acts as a driver to squeeze a tubular liner onto the tubes being joined. The joint strength is enhanced by a sealant coating on the liner.

The Cu-Zn-Al shape memory alloys have also found several applications in the force actuation device area. One such example is a fire safety valve that incorporates a Cu-Zn-Al actuator designed to shut off toxic or flammable gas flow when fire occurs.

# Fusible Alloys

## Introduction

FUSIBLE ALLOYS include a group of binary, ternary, quaternary, and quinary alloys containing bismuth, lead, tin, cadmium, and indium. The term fusible alloy refers to any of the more than 100 white-metal alloys that melt at relatively low temperatures, that is, below the melting point of tin-lead eutectic solder (183 °C, or 360 °F). The melting points of these alloys range as low as 47 °C (116 °F). Fusible alloys are used for lens blocking tube bending, for anchoring chucks and fixtures, and for mounting thin sections such as gas turbine blades for machining. The eutectic fusible alloys, which can be tailored to give a specific melting point find application in temperature control devices and in fire protection devices such as sprinkler heads.

## Compositions and Properties

**Compositions.** Many of the fusible alloys used in industrial applications are based on eutectic compositions (Table 1). Under ambient temperature, such an alloy has sufficient strength to hold parts together; at a specific elevated temperature, however, the fusible alloy link will melt, thus disconnecting the parts. In fire sprinklers, the links melt when dangerous temperatures are reached, releasing water from piping systems and extinguishing the fire. Boiler plugs and furnace controls react similarly because an increase in temperature beyond the safety limits of the furnace or boiler operation will melt the plug. When the fusible alloy link melts, pressure or heat in the boiler can be dissipated, or feeding of the fuel supply can be ceased, thereby reducing operation to a safe level.

Table 1 Compositions and melting temperatures of selected eutectic fusible alloys

Composition, %					Melting temperature

In addition to eutectic alloys, each of which melts at a specific temperature, there are numerous noneutectic fusible alloys, which melt over a range of temperatures. Table 2 lists selected eutectic alloy compositions.

**Table 2 Compositions, yield temperatures, and melting temperature ranges of selected noneutectic fusible alloys**

Composition, %					Yield temperature		Melting temperature range

A fusible alloy with a long melting range is useful in staking rods and tubing in assemblies because the alloy is distributed around part surfaces while still molten and provides a firm anchorage after it solidifies.

**Properties of Fusible Alloys.** Fusible alloys are ageable, and thus their mechanical properties often depend on the period of time that has elapsed since casting, as well as on casting conditions and the solidification rate. Test conditions also affect mechanical property values. For example, many fusible alloys can appear brittle when subjected to sudden shock but exhibit high ductility under slow rates of strain.

In certain alloys, normal thermal contraction due to cooling after solidification can be partly, completely, or more than compensated for by expansion due to aging. For example, bismuth alloys containing 33 to 66% Pb exhibit net expansion after solidification and during subsequent aging. Some fusible alloys show no contraction (shrinkage) and expand rapidly while still warm; others show slight shrinkage during the first few minutes after solidification and then begin to expand; in still others, expansion does not commence until some time after the fusible alloy casting has cooled to room temperature.

Each of the three characteristics--net expansion, net contraction, and little or no volume change--can provide specific advantages, depending on the application. For example, a wood pattern used for making molds must be of somewhat greater dimensions than those desired in the casting to compensate for shrinkage of the casting on solidification and during cooling to room temperature. Where metal patterns are cast from a master wood pattern, two such allowances will have to be made unless the alloy used for the metal patterns possesses zero shrinkage. Fusible alloys with eutectic compositions are often used for casting metal patterns from wood masters because they undergo definite growth that is sufficient to allow for cleaning of production castings without reduction dimensions below required values. The growth characteristics of fusible alloys are often used to advantage when a metal part is to be firmly anchored in the lathe chuck. After the part is machined, the fusible alloys is melted away.

In general, the load-bearing capacity of fusible alloys is good, although some deformation will occur under prolonged stress. In addition, hardness and other mechanical properties of many fusible alloys change gradually with time, probably because of the same microstructural changes caused by aging that affect growth or shrinkage.

**Low-melting, fusible alloy solders,** which contain from 44.7 to 58 wt% Bi (see eutectic composition in Table 1), are used for soldering processes that involve temperature-sensitive substrates or devices, as well as step soldering operations where a low temperature is necessary to protect a nearby solder joint. Their ability to melt at low temperatures makes these material ideal for use in such applications as:

- Construction of temperature-overload devices such as safety links, fuses, and plugs where positive-pressure contact is too variable or inconsistent for assembly operation.
- Soldering low-temperature alloys such as pewter
- Machine-soldering operations for through-hole soldering of very thick multilayer printed circuit boards.
- Assembly operations, such as surface mounting, where the integrated circuit packages would be vulnerable to thermal damage at the temperatures required for conventional tin-lead soldering

- Assembly operations using injection-molded circuit boards where the glass transition temperature is too low for the use in tin-lead alloys.

# Hardfacing Alloys

## Introduction

HARDFACING can be broadly defined as the application of a wear-resistant material, in depth, to the vulnerable (or worn) surfaces of a component by a weld overlay or thermal spray process. This article deals with the weld overlay materials used to resist wear; the thermal spray materials are covered in the Section "Surface Engineering" in this Handbook.

Hardfacing applications for wear control vary widely, ranging from very severe abrasive wear service, such as rock crushing and pulverizing (metal-to-earth applications/wear) to applications to minimize metal-to-metal wear, such as control valves where a few thousandths of an inch of wear is intolerable. Hardfacing is used for controlling abrasive wear, such as that encountered by mill hammers, digging tools, extrusion screws, cutting shears, parts of earth-moving equipment, ball mills, and crusher parts. It is also used to control the wear of unlubricated or poorly lubricated metal-to-metal sliding contacts such as control valves, undercarriage parts of tractors and shovels, and high-performance bearings.

Hardfacing is also used to control combinations of wear and corrosion, as encountered by mud seats, plows, knives in the food processing industry, and valves and pumps handling corrosive liquids or slurries. In most instances, parts are made of either plain carbon steel or stainless steel, materials that do not provide desirable wear on their own.

In addition, hardfacing alloys are applied to critical wear areas of original equipment or during reclamation of parts. These alloys, which are referred to as buildup alloys, are not designed to resist wear but to return a worn part back to, or near, its original dimensions and/or to provide adequate support for subsequent layers of more wear-resistant hardfacing alloys.

## Hardfacing Materials

Hardfacing materials include a wide variety of alloys, carbides, and combinations of these materials. Conventional hardfacing materials are normally classified as steels or low-alloy ferrous materials, high-chromium white irons or high-alloy ferrous materials, carbides, nickel-base alloys, or cobalt-base alloys. A few copper-base alloys are sometimes used for hardfacing applications, but for the most part, hardfacing alloys are either iron-, nickel-, or cobalt-base.

Several welding processes are used to apply the hardfacing materials. They range from the traditional (for example, oxyacetylene torch) to more recently developed processes like plasma-transferred arc. To accommodate these different overlay processes, the hardfacing materials are available in a variety of forms. The most popular processes, and the forms most commonly associated with each process, are:

Weld overlay process	Consumable form
<b>Oxyacetylene</b>	Bare cast or tubular rod
<b>Shielded metal arc (SMA)</b>	Coated solid or tubular rod (stick electrode)
<b>Gas tungsten arc (GTA)</b>	Bare cast or tubular rod
<b>Gas metal arc (GMA)</b>	Tubular or solid wire
<b>Open arc</b>	Tubular wire (flux cored)
<b>Submerged arc</b>	Tubular or solid wire
<b>Plasma-transferred arc (PTA)</b>	Powder

In choosing the process to be used, the following factors are important:

- Deposition rate
- Level of dilution (the amount of substrate material intermixed with the overlay material during welding)
- Portability of equipment

To overcome the effects of dilution on wear properties, multiple layers are often employed.

Microstructurally, hardfacing alloys generally consist of hard phase precipitates such as borides, carbides, or intermetallics bound in a softer iron-, nickel-, or cobalt-base alloy matrix. Carbides are the predominant hard phases in iron- and cobalt-base hardfacing alloys. Carbon contents of iron- and cobalt-base hardfacing alloys generally range up to 4 wt%. Borides, as well as carbides, are the predominant hard phases in nickel-base hardfacing alloys. Combined carbon plus boron contents generally range up to 5 wt%. The specific carbide and/or boride phases that form are determined by matrix alloy additions. The matrix alloys in most cobalt-, nickel-, and high-alloy, iron-base hardfacing alloys generally contain up to 35% Cr, up to 30% Mo, and up to 13% W, with smaller amounts of silicon and manganese.

### ***Iron-Base Alloys***

Iron-base hardfacing alloys are more widely used than cobalt- and/or nickel-base hardfacing alloys and constitute the largest volume use of hardfacing alloys. Iron-base hardfacing alloys offer low cost and a broad range of desirable properties. Most equipment that undergoes severe wear, such as crushing and grinding equipment and earthmoving equipment, is usually very large and rugged. Parts subjected to wear usually require downtime for repair. For this reason, there is a general temptation to hardface them with the lowest cost and most readily available materials. As a result, literally hundreds of iron-base hardfacing alloys are in use today.

Due to the great number of alloys involved, iron-base hardfacing alloys are best classified by their suitability for different types of wear and their general microstructures rather than by chemical composition. Most iron-base hardfacing alloys can be divided into the following classes:

- Pearlitic steels
- Austenitic (manganese) steels
- Martensitic steels
- High-alloy irons
- Austenitic stainless steel

**Pearlitic steels** are essentially low-alloy steels with minor adjustments in composition to achieve weldability. These alloys contain low carbon (<0.2% C) and low amounts of other alloying elements (for example, up to 2% Cr), resulting in a pearlitic structure. Pearlitic steels are useful as buildup overlays, primarily to rebuild carbon steel or low-alloy steel machinery parts back to size. Typically, this group of alloys has high impact resistance and low hardness (in the range of 25 to 37 HRC), as well as excellent weldability. Table 1 lists the composition and properties of a typical low-alloy pearlitic steel (EFel) used for buildup applications.

**Table 1 Compositions, hardness, and abrasion data for a pearlitic low-alloy steel (EFe1) and austenitic manganese steels (EFeMn-C and EFeMn-Cr) used for buildup overlays and air-hardening martensitic steels used for metal-to-metal wear applications**

Alloy	Composition, wt%								Hardness, HRC	Abrasion, volume loss			
										Low-stress <sup>(a)</sup>		High-stress <sup>(b)</sup>	
	Fe	Cr	C	Si	Mn	Mo	Ni	mm <sup>3</sup>		in. <sup>3</sup> × 10 <sup>-3</sup>	mm <sup>3</sup>	in. <sup>3</sup> × 10 <sup>-3</sup>	
Buildup weld overlay													
<b>EFe1<sup>(c)</sup></b>	bal	2	0.1	1.0	1	1.5	...	37	88	5.4	49	3.0	
<b>EFeMn-C<sup>(c)</sup></b>	bal	4	0.8	1.3	14	...	4	18	65	4.0	57	3.5

<b>EFe2<sup>(c)</sup></b>	bal	3	0.2	1.0	1	1.0	1	48	54	3.3	66	4.0	
<b>EFe3<sup>(c)</sup></b>	bal	6	0.7	1.0	1	1.0	...	59	60	3.7	68	4.1	
<b>ER420<sup>(d)</sup></b>	bal	12	0.3	1.0	2	...	...	45	84	5.1	62	3.8	

- (a) Dry sand/rubber wheel test (ASTM G 65, Procedure B): load 13.6 kg (30 lb); 200 rev.
- (b) Slurry/steel wheel test (ASTM B 611, modified): load 22.7 kg (50 lb); 250 rev.
- (c) Two-layer shielded metal arc deposit process.
- (d) Two-layer submerged arc welding deposit process

**Austenitic (manganese) steels** are modeled after Hadfield steels. Most commercially available alloys in this category can be broadly subdivided into low-chromium and high-chromium alloys.

Low-chromium alloys usually contain up to 4% Cr and 12 to 15% Mn and some nickel or molybdenum (Table 1). Low-chromium austenitic manganese steels generally are used to build up manganese steel machinery parts subjected to high impact (impact crusher or shovel lips).

High-chromium austenitic steels, which may normally contain 12 to 17% Cr in addition to approximately 15% Mn, are used for the buildup and joining of austenitic manganese steels as well as carbon and low-alloy steels. In addition, the as-deposited hardness of high-chromium steels is higher (~24 HRC) than that of low-chromium steels (~18 HRC). Compositions and properties of austenitic manganese steel hardfacing alloys used for buildup applications are given in Table 1.

**Martensitic steels** are designed to form martensite on normal air cooling of the weld deposit. As a result, these steels are often termed "self-hardening" or "air-hardening," and they resemble tool steels with hardnesses in the range of 45 to 60 HRC. The carbon content of the martensitic steels ranges up to 0.7%. Other elements such as molybdenum, tungsten, nickel, and chromium (up to 12%) are added to increase hardenability and strength and to promote martensite formation. Manganese and silicon usually are added to aid weldability. Table 1 lists compositions and properties of martensitic steels.

The major hardfacing applications for martensitic steels include unlubricated metal-to-metal rolling or sliding parts. The impact resistance of martensitic steels is inferior to that of pearlitic or austenitic alloys, but there is a compensating increase in hardness and resistance to abrasive wear.

In hostile environments, a higher chromium content is beneficial. AWS ER420 and modified versions containing nickel, molybdenum, and niobium (or vanadium) are therefore the natural choice when high temperatures and mildly corrosive environments are encountered. For applications using steel mill hot-work rolls (which demand considerable hot hardness, resistance to oxidation, and resistance to thermal fatigue) both ER420 and EFe3 have been found suitable.

**The high-chromium irons** encompass a wide range of compositions in which chromium may vary between approximately 6 and 35 wt%, and carbon may vary from approximately 2 to 6 wt%. Other possible alloying additions include molybdenum, manganese, and silicon. Table 2 lists typical compositions.

**Table 2 Composition of high-chromium white irons used for metal-to-earth abrasion applications**

Alloy	Composition, wt%							
	Cr	C	Si	Mn	Mo	Ni	B	Fe
<b>ERFeCr-A3</b>	11	2.6	1.3	1.8	1.5	...	...	bal
<b>ERFeCr-A4(Mod)</b>	29	3.5	1.1	0.9	...	2.6	0.7	bal
<b>ERFeCr-A2</b>	28	4.3	0.8	1.7	1.4	...	...	bal

The most important microstructural feature in the high-chromium irons, at least from a wear standpoint, is an  $M_7C_3$  carbide, which forms in abundance during solidification and contains chromium, iron, and (if present) molybdenum. The matrix around these carbide particles can be austenitic, pearlitic, or martensitic.

With regard to industrial applications of the high-chromium abrasion alloys, the low-carbon (2 to 3% C) hypoeutectic materials are usually selected for situations involving moderate abrasion and impact, whereas the higher-carbon (4 to 6% C) hypereutectic alloys are used in applications involving severe abrasion and little or no impact. The hardness range for high-chromium irons is typically 52 to 62 HRC.

**Austenitic stainless steel** hardfacing alloys have been developed, which can be considered alternative materials to the cobalt-base alloys described below. These exhibit similar anti-galling characteristics and possess equal resistance to cavitation erosion. Some of these have been developed for general use and others for specific applications. For example, the cobalt-free composition in Table 3 has been used for hardfacing nuclear plant valves ( $Co^{60}$  produced from cobalt hardfacing wear particles pose a radiation hazard). Cobalt-containing austenitic grades (Table 3) have been used for the repair of the cavitation damage of hydraulic turbines in hydroelectric power plants.

**Table 3 Nominal compositions of austenitic stainless steel hardfacing alloys**

(b) Developed by Hydro-Québec. IRECA denotes Improved REsistance to CAvitation.

## Nonferrous Alloys

Nonferrous hardfacing alloys are used either for high resistance to specific types of wear (other than abrasion) or for wear resistance (including abrasion) in environments that are too corrosive or beyond the service temperature of ferrous alloys. The cobalt-base alloys and bronzes are particularly resistant to galling and to those wear processes involving microfatigue as the degradation mechanism (such as cavitation erosion). The cobalt-base alloys also possess high resistance to deformation at temperatures in excess of 750 °C (1380 °F). Table 4 lists typical compositions of the nonferrous hardfacing alloys.

**Table 4 Composition of selected nonferrous hardfacing alloys**

**Cobalt-Base/Carbide-Type Alloys.** The chief difference between the various cobalt-base/carbide-type alloys is in carbon content (hence, carbide volume fraction, room-temperature hardness, and level of abrasion resistance). Chromium-rich  $M_7C_3$  is the predominant carbide in these alloys, although tungsten-rich  $M_6C$  is evident in those alloys having a high tungsten content, and chromium-rich  $M_{23}C_6$  is common in the low-carbon alloys. Hardness values for cobalt-base/carbide-type alloys range from approximately 40 to 55 HRC. As shown in Fig. 1, the abrasion resistance of these alloys (ERCoCr-A, -B, -C, and -E) increases with increasing carbon content.

**Fig. 1 Comparison of nonferrous hardfacing alloys to tool steel and carbon steel reference materials using ASTM G 65 low-stress, abrasion test. G 65 test parameters: procedure B; room temperature; 13.6 kg (30 lbf) load; quartz grain sand diameter of 212 to 300  $\mu\text{m}$ ; 2000 rev at 200 rev/min; 390 g/min (0.86 lb/min) feed rate**

**Laves Phase Alloy Compositions.** Laves phase is a type of topologically close-packed intermetallic compound. Historically, metallurgists have avoided the presence of Laves phase in most alloys due to its detrimental effect on mechanical properties. However, in the 1960s, the usefulness of Laves phase in resisting metal-to-metal wear was discovered; subsequently, alloys containing Laves phase have become commercially available.

As shown in Table 4, there are two Laves phase cobalt-base alloys available for hardfacing applications (Co-29Mo-9Cr-2.5Si and Co-29Mo-18Cr-3.5Si). Both of these alloys contain at least 50 vol% of Laves phase. Laves phase has a hardness value between 1000 and 1200 DPH, which is less than that of carbides. Consequently, the Laves phase-containing alloys are less abrasive to mating materials than carbide-containing alloys in metal-to-metal wear situations.

Hardness values for cobalt-base Laves phase alloys range from 54 to 64 HRC. The nickel-base Laves phase alloy (Ni-33Mo-16Cr-3.5Si in Table 4) has a nominal macrohardness of 45 HRC. Abrasion data for Laves phase alloys are given in Fig. 1. Although these alloys have been deposited by weld techniques, they are more frequently applied by thermal spray methods.

**Nickel-base/boride-type alloy compositions** represent a progression in terms of iron, chromium, boron, and carbon contents (Table 4). Iron content is largely incidental, allowing the use of ferrocompounds during manufacture. Together with nickel, the other three elements determine the level and type of hard phase within the structure upon solidification, with boron being the primary hard-phase forming element. Hardness values for boride-containing nickel alloys range from 51 to 57 HRC.

Because of the boride and carbide dispersions within their microstructures, the nickel-base/boride-type alloys exhibit excellent resistance to abrasion (ERNiCr-C, ERNiCr-B, and Alloy 40 in Fig. 1). Low-stress abrasion resistance generally increases with boron and carbon contents, hence the hard-phase volume fraction for these materials. Although their performance is not as good under self-mated sliding conditions as the cobalt-base materials, the nickel-base/boride-type alloys possess moderate resistance to galling. Of the nonferrous materials, the nickel-base/boride-type alloys are the least resistant to corrosion. This is attributed to the lack of chromium in the matrix.

**Bronze Type.** The two bronze compositions given in Table 4 fall in the aluminum bronze category. Silicon and other types of bronze also available in welding consumable form for hardfacing.

Components typically protected using the aluminum bronzes include gears, cams, and cold drawing/forming dies. These alloys are not recommended for elevated-temperature use because their mechanical properties considerably decrease at temperatures  $>200\text{ }^{\circ}\text{C}$  ( $>390\text{ }^{\circ}\text{F}$ ).

### ***Tungsten Carbides***

In contrast to the other weld overlay materials, the tungsten carbide composites do not rely on the formation of suitable hard phases during weld pool solidification. Instead, these overlay materials rely on the transfer of tungsten carbide particles from the welding consumable (carbides are inserted in a steel tube) to the overlay. It is important, therefore, to limit the heat input of the welding process in order to prevent melting of the tungsten carbide particles. If the tungsten carbide particles melt, they mix with iron to form much softer iron-tungsten carbides, thus reducing abrasion resistance. For this reason, oxyacetylene deposits usually exhibit higher abrasion resistance than arc-welded tungsten carbide overlays.

An advantage of the tungsten carbide composites is that the size of the hard particles in the overlay can be controlled. This is important because abrasion resistance is dependent upon the size relationship between microstructural features (such as carbides) and the abrading particles. If the abrading particles are large in comparison to the microstructural particles, then, after a running-in period (during which the softer matrix material at the surface is worn down), the abrading particles ride over the hard microstructural outcrops. Conversely, if the abrading particles are small in comparison to the microstructural particles, the opportunity exists for wear of the matrix around the microstructural particles. Eventually, these may drop out, having played only a small role in resisting abrasion.

Several tungsten carbide composites are available in a variety of tubular product forms. Popular compositions are 38, 50, 55, and 60 wt% tungsten carbide, with the carbon steel tube making up the balance. For each composition, several carbide size ranges are available. As an example, for the 60% WC oxyacetylene welding consumable, four mesh size ranges are available:

AWS designation	Mesh size range
<b>RWC-12/20</b>	12-20
<b>RWC-20/30</b>	20-30
<b>RWC-30/40</b>	30-40
<b>RWC-40/120</b>	40-120

The same composition is also available in flux-coated form for shielded metal arc welding (SMAW) and as a continuous wire (with an internal flux) for open arc welding.

Tungsten carbide composites generally possess very high resistance to abrasion and very low impact strength. Performance in a given situation is dependent upon (a) carbide volume fraction, (b) size relationship between the carbides and the abrasive medium, and (c) welding technique applied. Important factors are the distribution of carbides in the overlay (because the particles tend to sink, turbulence in the molten weld pool is an advantage), and the amount of carbide dissolution and reprecipitation in the steel matrix during welding. Impact strength generally decreases with increasing carbide volume fraction.

The tungsten carbide composites have been used to solve a wide variety of industrial sliding and drilling abrasion problems. Table 5 gives abrasion data. For extremely hostile environments, some non-ferrous tungsten carbide products (cobalt- and nickel-base products in the form of bare cast rods) are available. Also, several alternative composite materials, utilizing other carbides (for example, vanadium, titanium, or niobium), are available that have the advantage of creating a more homogeneous deposit because of their lower densities.

**Table 5 Abrasion data for tungsten carbide composites**

Material		Abrasion, volume loss

# Metal-Matrix Composites

## Introduction

METAL-MATRIX COMPOSITES (MMCs) are a class of materials with potential for a wide variety of structural and thermal management applications. Metal-matrix composites are capable of providing higher-temperature operating limits than their base metal counterparts, and they can be tailored to give improved strength, stiffness, thermal conductivity, abrasion resistance, creep resistance, or dimensional stability. Unlike polymer-matrix composites, they are nonflammable, do not outgas in a vacuum, and suffer minimal attack by organic fluids such as fuels and solvents.

In an MMC, the matrix phase is a monolithic alloy (usually a low-density nonferrous alloy) and the reinforcement consists of high-performance carbon, metallic, or ceramic additions. Reinforced intermetallic compounds, such as the aluminides of titanium, nickel, and iron, are also under development. Reinforcements, characterized as either continuous or discontinuous, may constitute from 10 to 70 vol% of the composite. Continuous fiber or filament (f) reinforcements include graphite, silicon carbide (SiC), boron, aluminum oxide ( $\text{Al}_2\text{O}_3$ ), and refractory metals. Discontinuous reinforcements consist mainly of SiC in whisker (w) form, particulate (p) types of SiC,  $\text{Al}_2\text{O}_3$ , and titanium diboride ( $\text{TiB}_2$ ), and short or chopped fibers (c) of  $\text{Al}_2\text{O}_3$  or graphite.

## Aluminum-Matrix Composites

Most of the commercial work on MMCs has focused on aluminum as the matrix metal. The combination of light weight, environmental resistance, and useful mechanical properties has made aluminum alloys very popular; these properties also make aluminum well suited for use as a matrix metal. The melting point of aluminum is high enough to satisfy many application requirements, yet low enough to render composite processing reasonably convenient. Also, aluminum can accommodate a variety of reinforcing agents. Although much of the early work on aluminum MMCs concentrated on continuous fiber types, most of the present work is focused on discontinuously reinforced (particle or whisker) aluminum MMCs because of their greater ease of manufacture, lower production costs, and relatively isotropic properties. As shown in Fig. 1, however, higher performance composites are produced by more expensive, continuous fiber reinforcements. At the opposite end of the cost/performance spectrum are the particle-reinforced molten (or cast) metal composites. In between lie medium-priced composites, including those produced by preform infiltration and powder metallurgy (P/M) techniques.

**Fig. 1** The material cost versus performance of various aluminum-matrix composites. DRA, discontinuously reinforced aluminum

## Aluminum MMC Designation System

Because more aluminum MMCs are produced than MMCs of all other matrix alloys combined, the Aluminum Association (AA) developed a standard designation system for MMCs that has since been adopted by the American National Standards Institute. ANSI 35.5-1992 provides that aluminum MMCs be identified as follows:

matrix/reinforcement/volume% form

For example, 2124/SiC/25w describes the AA-registered alloy 2124 reinforced with 25 vol% of silicon carbide whiskers; 7075/ $\text{Al}_2\text{O}_3$ /10p is the AA-registered alloy 7075 reinforced with 10 vol% of alumina particles; 6061/SiC/47f is the AA-registered alloy 6061 reinforced with 47 vol% of continuous SiC fibers; and A356/C/05C is an AA-registered casting alloy with 5 vol% of chopped graphite fibers.

## Discontinuous Aluminum MMCs

The most commonly used reinforcement materials in discontinuously reinforced aluminum composites are SiC and  $\text{Al}_2\text{O}_3$ , although silicon nitride ( $\text{Si}_3\text{N}_4$ ),  $\text{TiB}_2$ , and graphite have also been used in some specialized applications. For example, aluminum-graphite alloys have been developed for tribological applications because of their excellent antifriction properties, wear resistance, and anti-seizure characteristics. Table 1 lists properties of materials used to reinforce aluminum alloys.

**Table 1 Typical properties of particulate (p), whisker (w), and chopped fiber (c) reinforcements**

Processing methods for discontinuous aluminum MMCs include various casting processes: liquid-metal infiltration, spray deposition, and powder metallurgy. Each of these processes will be briefly reviewed in the following paragraphs.

**Effect of Reinforcement on Properties.** In MMCs, mechanical properties depend on the amount, size, shape, and distribution of the dispersed phase (reinforcement), apart from the mechanical properties of the matrix material, and on the nature of the interface. By definition, a composite material generally requires an amount of dispersed phase (>1 vol%) of a size (>1  $\mu$ m) that allows this constituent to be load bearing and not act merely to control the movement of dislocations, as in dispersion-strengthened materials. The shape of the dispersed phase is so important in determining its load-bearing capacity that composites have been classified on this basis: (a) fiber-reinforced composites with both continuous and discontinuous fibers and (b) particle- or whisker-reinforced composites. The aspect ratio generally characterizes the shape. In continuous-fiber composites, the load is applied directly to both the matrix and the fiber. In discontinuous-fiber composites or particle-reinforced composites, the load is transmitted to the dispersoid through the matrix.

Property predictions of MMCs can be obtained from mathematical models, which require as input a knowledge of the properties and geometry of the constituents. Information on these mathematical expressions, which include simple rule of mixture models, can be found in the selected references listed at the conclusion of this article. In general, however, the influence of hard particle reinforcement (e.g., SiC) on the relevant mechanical and physical properties of discontinuous aluminum-MMCs can be summarized as follows:

- Both the ultimate tensile strength and yield strength increase with an increase in reinforcement fraction. (It should be noted that these properties are decreased with an increase in volume fraction of soft particles, e.g., graphite.)
- The fracture toughness and ductility (percent elongation and strain to failure) decrease with an increase in reinforcement volume fraction.
- The Young's modulus increases with an increase in reinforcement volume fraction.
- The thermal and electrical conductivities as well as the coefficient of thermal expansion decrease with increasing reinforcement volume fraction.

Figure 2 illustrates the effects of SiC volume fraction on the properties of discontinuous aluminum MMCs.

**Fig. 2** Effect of reinforcement volume fraction on the properties of aluminum metal-matrix composite (MMCs). (a) The ultimate tensile strength (UTS), tensile yield strength (TYS), and strain-to-failure ( $\epsilon_f$ ) for 6013/SiC/xxp-T6. (b) Fracture toughness as a function of SiC volume fraction. (c) Young's modulus as a function of  $SiC_w$  and  $SiC_p$  volume fraction. (d) Thermal conductivity for 2009/SiC/xx-T6. (e) Electrical conductivity for 2009/SiC/xxp-T6 and 6061/SiC/xxp-T6. (f) Coefficient of thermal expansion (CTE) for 6061/SiC/xxp-T6.

**Cast Aluminum MMCs.** In the stir casting (or mixing/vortex), the pretreated and prepared reinforcement filler phase is introduced in a continuously stirred molten matrix and then cast by sand, permanent mold, or pressure die casting. Melting under an inert gas cover combined with Ar-SF<sub>6</sub> gas mixtures for fluxing and degassing is essential to avoid the entrapment of gases. Mixing can be affected ultrasonically or by reciprocating rods, centrifuging, or zero-gravity processing.

Matrix alloys include aluminum-silicon compositions specially designed for MMC processing (Table 2). Reinforcements include 10 to 20  $\mu m$  sized SiC or Al<sub>2</sub>O<sub>3</sub> particles in volume fractions ranging from 10 to 20%. Figure 3 shows a typical microstructure. Table 3 lists typical mechanical properties of high-pressure die cast aluminum MMCs. The automotive industry is behind the development of cast aluminum MMCs. Current or potential applications include brake rotors and drums, brake calipers, brake pad backing plates, and cylinder liners.

**Squeeze-Cast Aluminum MMCs.** Squeeze casting is a process by which molten metal solidifies under pressure within closed dies positioned between the plates of a hydraulic press. The applied pressure and the instant contact of the molten metal with the die surface produce a rapid heat transfer condition that yields a pore-free, fine-grain casting with mechanical properties approaching those of a wrought product.

Squeeze casting of aluminum MMCs involves placing a porous ceramic preform in the preheated die, which is later filled with the liquid metal; pressure is then applied. The pressure, in this case, helps the liquid metal infiltrate the porous ceramic preform, giving a sound metal-ceramic composite.

Squeeze casting has attracted much attention because the process minimizes material and energy use, produces net shape components, and offers a selective reinforcement capability. Both discontinuous and continuous aluminum-copper, aluminum-silicon, and aluminum-magnesium alloys reinforced with up to 45 vol% SiC have been produced.

**Rheocast Aluminum MMCs.** Rheocasting, also referred to as compocasting, is similar to the metal stirring route, but instead of the particulates being stirred into a fully liquid metal, it is stirred in the semi-solid (thixotropic) state and subsequently cast under pressure. Particles and discontinuous fibers of SiC,  $\text{Al}_2\text{O}_3$ , TiC,  $\text{Si}_3\text{N}_4$ , graphite, mica, glass, slag, magnesium oxide, and boron carbide have been incorporated into vigorously agitated partially solidified aluminum alloy slurries by this technique.

**Liquid-Metal Infiltration.** The Primex pressureless metal infiltration process is based on material and process controls that allow a metal to infiltrate substantially nonreactive reinforcements without the application of pressure or vacuum. Reinforcement level can be controlled by the starting density of the material being infiltrated. As long as interconnected porosity and appropriate infiltration conditions exist, the liquid metal will spontaneously infiltrate into the preform.

Key process ingredients for the manufacture of reinforced aluminum composites include the aluminum alloy, a nitrogen atmosphere, and magnesium present in the system. During heating to infiltration temperature ( $\sim 750^\circ\text{C}$ , or  $1380^\circ\text{F}$ ), the magnesium reacts with the nitrogen atmosphere to form magnesium nitride ( $\text{Mg}_3\text{N}_2$ ). The  $\text{Mg}_3\text{N}_2$  is the infiltration enhancer that allows the aluminum alloy to infiltrate the reinforcing phase without the necessity of applied pressure or vacuum. During infiltration the  $\text{Mg}_3\text{N}_2$  is reduced by the aluminum to form a small amount of aluminum nitride (AlN). The AlN is found as small precipitates and as a thin film on the surface of the reinforcing phase. Magnesium is released into the alloy by this reaction.

The pressureless infiltration process can produce a wide array of engineered composites by tailoring of alloy chemistry, particle type, shape, size, and loading. Particulate loading in cast composites can be as high as 75 vol%, given the right combination of particle shape and size. Figure 4 shows a typical microstructure.

**Fig. 4** Discontinuous Al/SiC MMC (60 vol% SiC) produced by the liquid-metal infiltration process

The most widely used cast composite produced by liquid-metal infiltration is an Al-10Si-1Mg alloy reinforced with 30 vol% SiC. The 1% Mg present in this alloy is obtained during infiltration by the reduction of the  $\text{Mg}_3\text{N}_2$ . This composite system is being used for all casting processes except die casting. The composite most used for die casting is based on this system, with the addition of 1% Fe. Alloy modifications can be made to the alloy prior to infiltration or in the crucible prior to casting. The only universal alloy restriction for this composite system is the presence of magnesium to allow the formation of the  $\text{Mg}_3\text{N}_2$ . For the SiC-containing systems, silicon must also be present in sufficient quantity to suppress the formation of aluminum carbide ( $\text{Al}_4\text{C}_3$ ). Composites consisting of  $\text{Al}_2\text{O}_3$ -reinforced aluminum that exhibit low excessive wear rates are also produced.

An important application area for pressureless molten metal infiltration is Al/SiC<sub>p</sub> packages, substrates, and support structures for electronic components. Typical requirements include a low coefficient of thermal expansion (CTE) to reduce mechanical stresses imposed on the electronic device during attachment and operation, high thermal conductivity for heat dissipation, high stiffness to minimize distortion, and low density for minimum weight. Compared with conventional aluminum alloys, composites having high loadings of SiC particles feature greatly reduced CTEs and significantly higher elastic moduli, with little or no penalty in thermal conductivity or density (Table 5).

**Table 5 Physical properties of an Al/SiC/xxp MMC for electronic applications**

**Spray deposition** involves atomizing a melt and, rather than allowing the droplets to solidify totally as for metal powder manufacture, collecting the semi-solid droplets on a substrate. The process is a hybrid rapid solidification process because the metal experiences a rapid transition through the liquidus to the solidus, followed by slow cooling from the solidus to room temperature. This results in a refined grain and precipitation structure with no significant increase in solute solubility.

The production of MMC ingot by spray deposition can be accomplished by introducing particulate into the standard spray deposition metal spray leading to codeposition with the atomized metal onto the substrate. Careful control of the atomizing and particulate feeding conditions is required to ensure that a uniform distribution of particulate is produced within a typically 95 to 98% dense aluminum matrix.

A number of aluminum alloys containing SiC particulate have been produced by spray deposition. These include aluminum-silicon casting alloys and the 2xxx, 6xxx, 7xxx, and 8xxx (aluminum-lithium) series wrought alloys. Significant increases in specific modulus have been realized with SiC-reinforced 8090 alloy (Table 6). Products that have been produced by spray deposition include solid and hollow extrusions, forgings, sheet, and remelted pressure die castings.

**Table 6 Properties of conventionally processed aluminum alloys (ingot metallurgy) and spray-deposited aluminum MMCs**

**P/M Aluminum MMCs.** Powder metallurgy processing of aluminum MMCs involves both SiC particulates and whiskers, although  $\text{Al}_2\text{O}_3$  particles and  $\text{Si}_3\text{N}_4$  whiskers have also been employed. Processing involves (1) blending of the gas-atomized matrix alloy and reinforcement in powder form; (2) compacting (cold pressing) the homogeneous blend to roughly 80% density; (3) degassing the preform (which has an open interconnected pore structure) to remove volatile contaminants (lubricants and mixing and blending additives), water vapor, and gases; and (4) consolidation by vacuum hot pressing or hot isostatic pressing. The hot-pressed cylindrical billets can be subsequently extruded, rolled, or forged. Whisker-reinforced aluminum MMCs may experience some whisker alignment during extrusion or rolling (Fig. 5). Control of whisker alignment enables production of aluminum MMC product forms with directional properties needed for some high-performance applications. Cross rolling of sheet establishes a more planar whisker alignment, producing a two-dimensional isotropy.

**Fig. 5** SiC whisker-reinforced (20 vol% SiC) aluminum alloy sheet with the whiskers aligned in the direction of rolling

The mechanical properties of whisker-reinforced aluminum MMCs are superior to particle-reinforced composites at any common volume fraction (Fig. 6). Tables 7 and 8 show the effects of whisker alignment on the properties of aluminum MMCs. Table 9 lists typical mechanical properties for particle-reinforced aluminum alloys.

Fig. 6 Yield strength comparison between whisker- and particulate-reinforced aluminum MMCs

### Continuous Fiber Aluminum MMCs

As shown in Fig. 1, aluminum MMCs reinforced with continuous fibers provide the highest performance/strength. Because of their high cost, however, most applications have been limited to the aerospace industry.

**Aluminum/boron** is a technologically mature continuous fiber MMC (Fig. 7). Applications for this composite include tubular truss members in the midfuselage structure of the Space Shuttle orbiter and cold plates in electronic microchip carrier multilayer boards. Fabrication processes for aluminum/boron composites are based on hot-press diffusion bonding of alternating layers of aluminum foil and boron fiber mats (foil-fiber-foil processing) or plasma spraying methods. Selected properties of aluminum/boron composites are given in Table 10.

Table 10 Room-temperature properties of unidirectional continuous-fiber, aluminum-matrix composites

Property	B/6061 Al	SCS-2/6061 Al <sup>(a)</sup>	P100 Gr/6061 Al	FP/Al-2Li <sup>(b)</sup>

- (a) SCS-2 is a silicon carbide fiber.
- (b) FP is an alpha alumina ( $\alpha$ -Al<sub>2</sub>O<sub>3</sub>) fiber

**Fig. 7** Cross section of a continuous-fiber-reinforced aluminum/boron composite. Shown here are 142  $\mu$ m diam boron filaments coated with B<sub>4</sub>C in a 6061 aluminum alloy matrix

**Continuous SiC fibers** are often used as replacements for boron fibers because they have similar properties (e.g., a tensile modulus of 400 GPa, or  $60 \times 10^6$  psi) and offer a cost advantage. One such SiC fiber is SCS, which can be manufactured with any of several surface chemistries to enhance bonding with a particular matrix, such as aluminum or titanium. The SCS-2 fiber, tailored for aluminum, has a 1  $\mu$ m (0.04 mil) thick carbon rich coating that increases in silicon content toward its outer surface.

Hot molding is a low-pressure, hot-pressing process designed to fabricate Al/SiC parts at significantly lower cost than is possible with a diffusion-bonding/solid-state process. Because the SCS-2 fibers can withstand molten aluminum for long periods, the molding temperature can be raised into the liquid-plus-solid region of the alloy to ensure aluminum flow and consolidation at low pressure, thereby eliminating the need for high-pressure die molding equipment.

The hot-molding process is analogous to the autoclave molding of graphite-epoxy, in which components are molded in an open-faced tool. The mold in this case is a self-heating, slip-cast ceramic tool that contains the profile of the finished part. A plasma-sprayed aluminum preform is laid into the mold, heated to near molten aluminum temperature, and pressure-consolidated in an autoclave by a metallic vacuum bag.

Aluminum/SiC MMCs exhibit increased strength and stiffness as compared with unreinforced aluminum, with no weight penalty. Tensile properties of 6061/SCS-2 composites are given in Table 10. In contrast to the base metal, the composite retains its room-temperature tensile strength at temperatures up to 260 °C (500 °F).

**Aluminum/graphite MMC** development was initially prompted by the commercial appearance of strong and stiff carbon fibers in the 1960s. Carbon fibers offer a range of properties, including an elastic modulus up to 966 GPa ( $140 \text{ psi} \times 10^6$ ) and a negative CTE down to  $-1.62 \times 10^{-6}/^\circ\text{C}$  ( $-0.9 \times 10^{-6}/^\circ\text{F}$ ). However, carbon and aluminum in combination are difficult materials to process into a composite. A deleterious reaction between carbon and aluminum, poor wetting of carbon by molten aluminum, and oxidation of the carbon are significant technical barriers to the production of these composites. Two processes are currently used for making commercial aluminum MMCs: liquid metal infiltration of the matrix on spread tows and hot press bonding of spread tows sandwiched between sheets of aluminum. With both precursor wires and metal-coated fibers, secondary processing such as diffusion bonding or pultrusion is needed to make structural elements. Squeeze casting also is feasible for the fabrication of this composite.

Precision aerospace structures with strict tolerances on dimensional stability need stiff, lightweight materials that exhibit low thermal distortion. Aluminum/graphite MMCs have the potential to meet these requirements. Unidirectional P100 Gr/6061 aluminum pultruded tube exhibits an elastic modulus in the fiber direction significantly greater than that of steel, and it has a density approximately one-third that of steel. Properties are listed in Table 10.

**Aluminum/Al<sub>2</sub>O<sub>3</sub> MMCs** can be fabricated by a number of methods, but liquid or semi-solid-state processing techniques are commonly used. Aluminum oxide fibers, which include Fiber FP (99.5% Al<sub>2</sub>O<sub>3</sub>) and Saffil (96Al<sub>2</sub>O<sub>3</sub>-4SiO<sub>2</sub>) are inexpensive and provide the composite with improved properties as compared with those of unreinforced aluminum alloys. For example, the composite has an improved resistance to wear and thermal fatigue deformation and a

reduced CTE. Continuous fiber Al/Al<sub>2</sub>O<sub>3</sub> MMCs are fabricated by arranging Al<sub>2</sub>O<sub>3</sub> tapes in a desired orientation to make a preform, inserting the preform into a mold, and infiltrating the preform with molten aluminum via a vacuum assist. Reinforcement-to-matrix bonding is achieved by small additions of lithium to the melt. Table 10 gives the room-temperature properties of a unidirectional Al-2Li/Al<sub>2</sub>O<sub>3</sub>.

## Titanium-Matrix Composites

Titanium is selected as a matrix metal because of its good specific strength at both room and moderately elevated temperature and its excellent corrosion resistance. Because titanium retains its strength at higher temperatures than aluminum, it has increasingly been used as a replacement for aluminum in aircraft and missile structures as the operating speeds of these items have increased from subsonic to supersonic.

**Continuous Fiber Titanium MMCs.** Silicon carbide fibers are the reinforcement of choice for titanium MMCs. The SCS-6 fiber is a carbon-cored monofilament that is 142 μm in diameter. A tungsten-cored fiber that has a carbon coating has also been developed with a diameter of 127 μm. A tungsten-cored monofilament with carbon and titanium diboride coatings that is 102 μm in diameter is also available. Fiber contents of 30 to 40 vol% are common (Fig. 8). Conventional matrix alloys include Ti-6Al-4V for low-temperature applications and Ti-6Al-2Sn-4Zr-2Mo (Ti-6242) when higher creep resistance is required or when the temperature is higher than the maximum use temperature for Ti-6Al-4V. The Ti-6242 alloy is used in turbine engine actuator pistons and reinforced fan frames. More recently, titanium aluminide ordered intermetallics such as Ti-22Al-23Nb and Ti-22Al-26Nb have been used as matrix materials. These materials are being developed for rotating blades and impellers. Processing techniques for titanium MMCs used for aerospace applications include fiber-foil-fiber processing and tape casting or wire winding used in conjunction with hot isostatic pressing. Plasma spraying has also been employed to deposit a titanium matrix onto the fibers. Similarly, electron beam physical vapor deposition of metal on fiber has also been demonstrated. Table 11 gives properties for a representative unidirectional SiC/Ti laminate.

**Particle-Reinforced Titanium MMCs** are processed by P/M methods. Although a variety of materials have been studied, the most common combination is Ti-6Al-4V reinforced with 10 to 20 wt% TiC. These composites offer increased hardness and wear resistance over conventional titanium alloys. Properties of unreinforced and reinforced Ti-6Al-4V are compared in Table 12.

## Other MMCs of Importance

**Magnesium-matrix composites** are being developed to exploit essentially the same properties as those provided by aluminum MMCs: high stiffness, light weight, and low CTE. In practice, the choice between aluminum and magnesium as a matrix is usually made on the basis of weight versus corrosion resistance. Magnesium is approximately two-thirds as dense as aluminum, but it is more active in a corrosive environment. Magnesium has a lower thermal conductivity, which is sometimes a factor in its selection. Magnesium MMCs include continuous fiber Gr/Mg for space structures, short staple fiber Al<sub>2</sub>O<sub>3</sub>/Mg for automotive engine components, and discontinuous SiC or B<sub>4</sub>C/Mg for engine components and low-expansion electronic packaging materials. Matrix alloys include AZ31, AZ91, ZE41, QE22, and EZ33. Processing methods parallel those used for the aluminum MMC counterparts.

**Copper-matrix composites** have been produced with continuous tungsten, silicon carbide, and graphite fiber reinforcements. Of the three composites, continuous graphite/copper MMCs have been studied the most.

Interest in continuous graphite/copper MMCs gained impetus from the development of advanced graphite fibers. Copper has good thermal conductivity, but it is heavy and has poor elevated-temperature mechanical properties. Pitch-base graphite fibers have been developed that have room-temperature axial thermal conductivity properties better than those of copper. The addition of these fibers to copper reduces density, increases stiffness, raises the service temperature, and provides a mechanism for tailoring the coefficient of thermal expansion. One approach to the fabrication of graphite/copper MMCs uses a plating process to envelop each graphite fiber with a pure copper coating, yielding MMC fibers flexible enough to be woven into fabric. The copper-coated fibers must be hot pressed to produce a consolidated component. Table 13 compares the thermal properties of aluminum and copper MMCs with those of unreinforced aluminum and copper. Graphite/copper MMCs have the potential to be used for thermal management of electronic components, satellite radiator panels, and advanced airplane structures.

**Table 13 Thermal properties of unreinforced and reinforced aluminum and copper**

Material	Reinforcement content, vol%	Density		Axial thermal conductivity		Axial coefficient of thermal expansion	
		g/cm <sup>3</sup>	lb/ft <sup>3</sup>	W/m · °C	Btu/ft · h · °F	10 <sup>-6</sup> /°C	10 <sup>-6</sup> /°F
Aluminum	0	2.71	169	221	128	23.6	13.1
Copper	0	8.94	558	391	226	17.6	9.7

P120 Gr/Cu	60	4.90	306	522	302	-0.07	-0.04

**Superalloy-Matrix Composites.** In spite of their poor oxidation resistance and high density, refractory metal (tungsten, molybdenum, and niobium) wires have received a great deal of attention as fiber reinforcement materials for use in high-temperature superalloy MMCs. Although the theoretical specific strength potential of refractory alloy fiber-reinforced composites is less than that of ceramic fiber-reinforced composites, the more ductile metal fiber systems are more tolerant of fiber-matrix reactions and thermal expansion mismatches. When refractory metal fibers are used to reinforce a ductile and oxidation-resistant matrix, they are protected from oxidation, and the specific strength of the composite is much higher than that of superalloys at elevated temperatures.

Fabrication of superalloy MMCs is accomplished via solid-phase, liquid-phase, or deposition processing. The methods include investment casting, the use of matrix metals in thin sheet form, the use of matrix metals in powder sheet form made by rolling powders with an organic binder, powder metallurgy techniques, slip casting of metal alloy powders, and arc spraying.

Figure 9 compares the elevated-temperature tensile strength of a nickel-base superalloy (Waspaloy) reinforced with various refractory wires. As this figure indicates, a composite consisting of 50 vol% W-24Re-HfC had the highest strength at 1093 °C (2000 °F).

**Fig. 9** Elevated temperature (1093 °C, or 2000 °F) tensile strength of Waspaloy reinforced with 50 vol% refractory metal wire. 218 CS represents potassium-doped tungsten. ST 300 is a W-1.0ThO<sub>2</sub> alloy. Comparative data are included for unreinforced MarM 246, a nickel-base superalloy.

**Intermetallic-Matrix Composites.** One disadvantage of superalloy MMCs is their high density, which limits the potential minimum weight of parts made from these materials. High melting points and relatively low densities make intermetallic-matrix composites (IMCs) viable candidates for lighter turbine engine materials. Aluminides of nickel, titanium, and iron have received the most attention as matrices for IMCs. Property data on TiB<sub>2</sub>-reinforced titanium aluminides can be found in the article "Structural Intermetallics" in this Section.

# Structural Intermetallics

## Introduction

ALLOYS based on ordered intermetallic compounds constitute a unique class of metallic material that form long-range ordered crystal structures (Fig. 1) below a critical temperature, generally referred to as the critical ordering temperature ( $T_c$ ). These ordered intermetallics usually exist in relatively narrow compositional ranges around simple stoichiometric ratio (see the phase diagrams shown in this article).

**Fig. 1** Atomic arrangements of conventional alloys and ordered intermetallic compounds. (a) Disordered crystal structure of a conventional alloy. (b) Long-range ordered crystal structure of an ordered intermetallic compound

The search for new high-temperature structural materials has stimulated much interest in ordered intermetallics. Recent interest has been focused on nickel aluminides based on  $\text{Ni}_3\text{Al}$  and  $\text{NiAl}$ , iron aluminides based on  $\text{Fe}_3\text{Al}$  and  $\text{FeAl}$ , and titanium aluminides based on  $\text{Ti}_3\text{Al}$  and  $\text{TiAl}$ . These aluminides possess many attributes that make them attractive for high-temperature structural applications. They contain enough aluminum to form, in oxidizing environments, thin films of alumina ( $\text{Al}_2\text{O}_3$ ) that are compact and protective. They have low densities, relatively high melting points, and good high-temperature strength properties (Tables 1 and 2).

**Table 1** Properties of nickel, iron, and titanium aluminides

**Table 2 Attributes and upper use temperature limits for nickel, iron, and titanium aluminides**

Alloy	Attributes	Maximum use temperature, °C (°F)	
		Strength limit	Corrosion limit
<b>Ni<sub>3</sub>Al</b>	Oxidation, carburization, and nitridation resistance; high-temperature strength	1000 (1830)	1150 (2100)
<b>NiAl</b>	High melting point; high thermal conductivity; oxidation, carburization, and nitridation resistance	1200 (2190)	1400 (2550)
<b>Fe<sub>3</sub>Al</b>	Oxidation and sulfidation resistance	600 (1110)	1100 (2010)
<b>FeAl</b>	Oxidation, sulfidation, molten salt, and carburization resistance	800 (1470)	1200 (2190)
<b>Ti<sub>3</sub>Al</b>	Low density; good specific strength	760 (1400)	650 (1200)

Nickel, iron, and titanium aluminides, like other ordered intermetallics, exhibit brittle fracture and low ductility at ambient temperatures. It has also been found that quite a number of ordered intermetallics, such as iron aluminides, exhibit environmental embrittlement at ambient temperatures. The embrittlement involves the reaction of water vapor in air with reactive elements (aluminum, for example) in intermetallics to form atomic hydrogen, which drives into the metal and causes premature fracture. Thus, the poor fracture resistance and limited fabricability have restricted the use of aluminides as engineering materials in most cases. However, in recent years, alloying and processing have been employed to overcome the brittleness problem of ordered intermetallics. Success in this work has inspired parallel efforts aimed at improving strength properties. The results have led to the development of a number of attractive intermetallic alloys having useful ductility and strength.

Figure 2 illustrates the crystal structures showing the ordered arrangements of atoms in several of these aluminides. For most of the aluminides listed in Table 1, the critical ordering temperature is equal to the melting temperature. Others disorder at somewhat lower temperatures, and Fe<sub>3</sub>Al passes through two ordered structures (*D0<sub>3</sub>* and *B2*) before becoming disordered. Many of the aluminides exist over a range of compositions, but the degree of order decreases as the deviation from stoichiometry increases. Additional elements can be incorporated without losing the ordered structure. For example, in Ni<sub>3</sub>Al, silicon atoms are located in aluminum sites, cobalt atoms on nickel sites, and iron atoms on either. In many instances, the so-called intermetallic compounds can be used as bases for alloy development to improve or optimize properties for specific applications.

Fig. 2 Crystal structures of nickel, iron, and titanium aluminides

## Nickel Aluminides

The nickel-aluminum phase diagram shows two stable intermetallic compounds,  $Ni_3Al$  and  $NiAl$ , formed on the nickel-rich end (Fig. 3). The compound  $Ni_3Al$  has an  $L1_2$  crystal structure, a derivative of the face-centered cubic (fcc) crystal structure;  $NiAl$  has a  $B2$  structure, a derivative of the body-centered cubic (bcc) crystal structure (see Fig. 2). Because of the different crystal structures, the two nickel aluminides have quite different physical and mechanical properties.

**Fig. 3** The nickel-aluminum phase diagram showing both NiAl and Ni<sub>3</sub>Al compounds on the nickel-rich end

### Ni<sub>3</sub>Al Aluminides

The aluminide Ni<sub>3</sub>Al is of interest because of its excellent strength and oxidation resistance at elevated temperatures (see Table 2). This intermetallic has long been used as a strengthening constituent in high-temperature, nickel-base superalloys, which owe their outstanding strength properties to a fine dispersion of precipitation particles of the ordered  $\gamma'$  phase (Ni<sub>3</sub>Al) embedded in a ductile disordered matrix. (See the Section "Superalloys" in this Handbook).

Single crystals of Ni<sub>3</sub>Al are ductile at ambient temperatures, but polycrystalline Ni<sub>3</sub>Al fails by brittle grain-boundary fracture with very little plasticity. This effect persists even in very high-purity materials where no grain-boundary segregation of impurities can be detected. The observation of this characteristic turned attention toward a search for segregants that might act in a beneficial way.

Studies of segregants led to the discovery that small ( $\sim 0.1$  wt%) boron additions not only eliminated the brittle behavior of Ni<sub>3</sub>Al but converted the material to a highly malleable form exhibiting tensile ductility as high as 50% at room temperature. The beneficial effect of boron is, however, dependent on stoichiometry, and boron is effective in increasing the ductility of Ni<sub>3</sub>Al only in alloys containing less than 25 at.% aluminum. Since gaining the knowledge that microalloying with boron can ductilize polycrystalline Ni<sub>3</sub>Al, a number of Ni<sub>3</sub>Al alloy compositions have been developed. As shown in Table 3, macroalloying additions include chromium, iron, zirconium, and molybdenum. These alloying additions were made to improve strength, castability, hot workability, and corrosion resistance. The effects of these alloying additions are described in the following paragraphs.

**Table 3** Nominal compositions of selected Ni<sub>3</sub>Al alloys

**Anomalous Dependence of Yield Strength on Temperature.**  $\text{Ni}_3\text{Al}$  is one of a number of intermetallic alloys that exhibit an engineering yield strength (0.2% offset) that increases with increasing temperature. This is shown in Fig. 4, which is a plot of yield stress as a function of test temperature. The anomalous yielding effect, which is lower at lower strains, occurs because of the extremely rapid work hardening. The anomalous yielding behavior makes  $\text{Ni}_3\text{Al}$  stronger than many commercial solid-solution alloys (such as type 316 stainless steel and Hastelloy alloy X) at elevated temperatures (Fig. 4).

Fig. 4 Yield strength versus test temperature for  $\text{Ni}_3\text{Al}$  alloys, two superalloys, and type 316 stainless steel

As with boron-doped  $\text{Ni}_3\text{Al}$ ,  $\text{Ni}_3\text{Al}$  alloys (Table 3) also exhibit rising yield strength with rising temperature. Figure 5 shows that the yield strength of four nickel aluminide alloys tends to rise to a maximum in the temperature range of  $\sim 400$  to  $650^\circ\text{C}$  ( $\sim 750$  to  $1200^\circ\text{F}$ ). Above this temperature range, the yield strength declines.

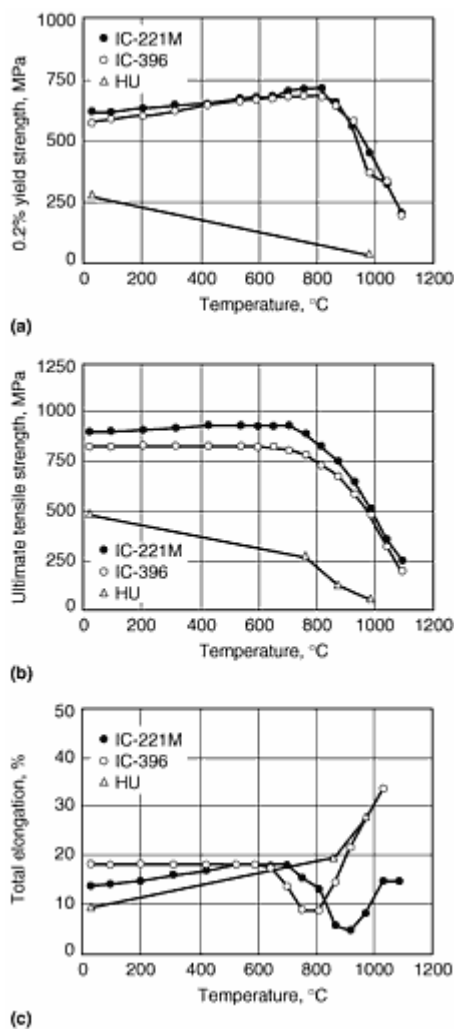

Fig. 5 Variation of yield strength with test temperature for selected nickel aluminide alloys. Strain rate, 0.5 mm/mm per min. See Table 3 for alloy compositions.

**Mechanical Properties.** The study of ductility and strength of  $\text{Ni}_3\text{Al}$  has led to the development of ductile nickel aluminide alloys for structural applications with the following composition range (in atomic percent):

In these aluminide alloys, 6 to 9 at.% Cr is added to reduce environmental embrittlement in oxidizing environments at elevated temperatures. Zirconium and hafnium additions most effectively improve high-temperature strength via solid-solution hardening effects. Molybdenum additions improve strength at ambient and elevated temperatures. Microalloying with boron reduces moisture-induced hydrogen embrittlement and enhances grain-boundary cohesive strength, resulting in sharply increased ductility at ambient temperatures. In some cases, certain amounts (<20 at.%) of cobalt and iron are added to replace nickel, and aluminum and nickel, respectively, in order to further improve hardness and corrosion resistance. The alloys with optimum properties usually contain 5 to 15 vol% of the disordered  $\gamma$  phase, which has the beneficial effect of reducing environmental embrittlement in oxidizing atmospheres and improving creep properties at elevated temperatures.

Figure 6 compares the tensile properties of cast  $\text{Ni}_3\text{Al}$  alloys with cast HU alloy (Fe-20Cr-39Ni-2.5Si). It is clear from this figure that the  $\text{Ni}_3\text{Al}$  alloys are nearly twice as strong at room temperature and six times as strong at 1000 °C (1830 °F). The tensile properties of high-aluminum (4.5 wt% Al) alloy 214 and cast and powder metallurgy (P/M) processed  $\text{Ni}_3\text{Al}$  alloys are compared in Fig. 7. The P/M processed IC-221 alloy in Fig. 7 is significantly stronger than alloy 214 or the cast  $\text{Ni}_3\text{Al}$ -based alloys.

**Fig. 6** Comparison of tensile properties of cast  $\text{Ni}_3\text{Al}$  alloys with cast HU alloy. (a) 0.2% yield strength. (b) Ultimate tensile strength. (c) Total elongation

**Fig. 7** Comparison of tensile properties of cast and P/M  $\text{Ni}_3\text{Al}$  Alloys with Haynes 214. (a) 0.2% yield strength. (b) Ultimate tensile strength. (c) Total elongation

Creep properties of  $\text{Ni}_3\text{Al}$  alloys have been characterized as functions of stress, temperature, and composition. Hafnium and zirconium additions are most effective in improving the resistance of  $\text{Ni}_3\text{Al}$ . Figure 8 shows creep data for the polycrystalline nickel aluminide alloy IC-221. The creep properties of  $\text{Ni}_3\text{Al}$  alloys, like those of nickel-base superalloys, are sensitive to grain size, but the  $\text{Ni}_3\text{Al}$  alloys have better creep resistance for coarse-grain materials (e.g., cast materials). For applications where creep resistance is important, coarse-grain material is more desirable at temperatures greater than 700 °C (1290 °F). Creep properties of single-crystal  $\text{Ni}_3\text{Al}$  alloys containing refractory elements such as tantalum have been studied at temperatures up to 1000 °C (1830 °F). In general, the creep resistance of  $\text{Ni}_3\text{Al}$  is comparable to that of most of the nickel-base superalloys, but it is not as good as that of some advanced single-crystal, nickel-base superalloys used for jet engine turbine blades.

**Fig. 8** Larson-Miller parameter ( $P$ ) plot showing the effect of processing on the creep-rupture properties of IC-221. Tests were conducted in the temperature range of 650 to 870 °C (1200 to 1600 °F) for times ranging from 10 to 12,464 h.

Fatigue and fatigue crack growth are substantially better in  $\text{Ni}_3\text{Al}$  alloys than in nickel-base superalloys in tests below the range of the ductility minimum; see Fig. 9 for room-temperature fatigue crack growth. The good fatigue resistance of  $\text{Ni}_3\text{Al}$  and other ordered intermetallic alloys has been attributed to fine planar slip and superlattice dislocation structure. Dynamic embrittlement in oxidizing environments severely reduces the fatigue resistance of  $\text{Ni}_3\text{Al}$  at temperatures above 500 °C (930 °F); however, this problem has been alleviated by adding moderate amounts (for example, 8 at.%) of chromium to  $\text{Ni}_3\text{Al}$ . Fatigue/creep interactions in single crystals and directionally solidified  $\text{Ni}_3\text{Al}$  alloys have been characterized for temperatures up to 800 °C (1470 °F). Limited results indicate that the performance of single-crystal  $\text{Ni}_3\text{Al}$  alloyed with hafnium and boron is superior to that of Udimet 115 at 760 °C (1400 °F).

**Fig. 9** Crack growth rates of nickel aluminide (Ni-23.5Al-0.5Hf-0.1B, at.%), LRO alloys [(Fe,Ni)<sub>3</sub>(V,Ti)], and several high-temperature alloys tested in air at 25 °C (80 °F)

**Corrosion Resistance.** The oxidation and carburization resistance of Ni<sub>3</sub>Al alloys are compared in Fig. 10 and 11. It is clear from Fig. 10 that the Ni<sub>3</sub>Al alloys that form a protective Al<sub>2</sub>O<sub>3</sub> scale on the surface have significantly better oxidation resistance than aluminum-free alloy 800. Carburization resistance is also high under both oxidizing or reducing environment (Fig. 11).

**Fig. 10** Comparison of the oxidation resistance of Ni<sub>3</sub>Al alloys with that of alloy 800 in air with 5% water vapor at 1100 °C (2010 °F)

(a)

(b)

**Fig. 11** Comparison of the carburization resistance of Ni<sub>3</sub>Al alloys with that of alloy 800. (a) Oxidizing carburizing environment. (b) Reducing carburizing environment

**Processing and Fabrication.** Nickel aluminide parts can be produced by P/M, casting, and ingot metallurgy. Figures 7 and 8 compare the effects of processing on the properties of nickel aluminides.

The nickel aluminide powder can be produced by argon or nitrogen-gas atomization. The nickel aluminide powder can be readily consolidated to 100% density by extruding the powder in a mild steel can at 1100 °C (2010 °F) to a reduction ratio

$\geq 9$  to 1. The powder can also be consolidated by hot isostatic pressing. The extrusion-process consolidated powder has a grain structure that can be superplastic under proper conditions of temperature and strain rate.

Near-net-shape or net-shape casting of parts directly from liquid metal is a highly desirable method for the fabrication of nickel aluminides. Among the near-net-shape methods is the method of sheer fabrication by bringing liquid metal in direct contact with a rotating drum. The sheet thickness is controlled by the speed of the drum. The as-cast sheets are highly ductile, and their strength can be enhanced significantly by cold rolling.

Conventional fabrication techniques (such as hot rolling for large ingots) are ineffective because regions near the surface cool to the range of the ductility minimum, which leads to the formation of large intergranular surface cracks. Isothermal forging offers excellent possibilities for fabrication because the alloys exhibit superplastic behavior above approximately 1000 °C (1830 °F). Conventional hot forging is feasible for fine-grain alloys containing less than 0.3 at.% Zr or Hf. Cold fabrication is effective if the materials can be cast into sheet or rod forms that can be cold formed further without the need for repeated recrystallization treatments.

Alloys based on Ni<sub>3</sub>Al are susceptible to weld cracking; however, if welding is done with care, sound welds can be made in most of the alloys. Welding speed should be reduced and the boron level has to be limited to approximately 0.1 at.% to avoid hot cracking. Oxygen is particularly detrimental: oxide scale on alloy surfaces should be removed prior to welding, and the atmosphere must be controlled to reduce oxygen during welding. Certain alloying additions (iron, for example) have been found to promote weldability. The potential applications (and the properties they would exploit) include:

- Heat-treating furnace parts (superior carburization resistance, high-temperature strength, and thermal fatigue resistance)
- Gas, water, and steam turbines (the excellent cavitation, erosion, and oxidation resistance of the alloys)
- Aircraft fasteners (low density and ease of achieving the desired strength)
- Automotive turbochargers (high fatigue resistance and low density)
- Pistons and valves (wear resistance and capability of developing a thermal barrier by high-temperature oxidation treatment)
- Bellows for expansion joints to be used in corrosive environments (good aqueous corrosion resistance)
- Tooling (high-temperature strength and wear resistance developed through preoxidation)
- Permanent molds (the ability to develop a thermal barrier coating by high-temperature oxidation)

### **NiAl Aluminides**

Nickel-aluminum containing more than approximately 40 at.% Ni starts to form a single-phase *B2*-type ordered crystal structure based on the bcc lattice (Fig. 2). In terms of physical properties, *B2* NiAl offers more potential for high-temperature applications than *L1*<sub>2</sub> Ni<sub>3</sub>Al. It has a higher melting point (1638 °C, or 2980 °F), a substantially lower density (5.86 g/cm<sup>3</sup> for NiAl versus 7.50 g/cm<sup>3</sup> for Ni<sub>3</sub>Al), and a higher Young's modulus (294 GPa, or  $4.27 \times 10^6$  psi, versus 179 GPa, or  $25.9 \times 10^6$  psi). NiAl shows a sharp increase in ductility above 400 °C (750 °F) and becomes very ductile above 600 °C (1110 °F); therefore, fabrication of NiAl at high temperatures presents no major problems.

**Mechanical Properties.** Widespread use of NiAl as a free-standing structural material has not yet been realized because of its poor ductility at ambient temperature and creep resistance at elevated temperatures. Limited tensile ductility has been achieved with cobalt additions. Sufficient iron additions to nickel-rich NiAl, such as Ni-30Al-20Fe (at.%) with a *B2* structure, has resulted in approximately 2% plastic elongation. The same alloy with a fine-grain structure shows 5% elongation when produced by rapid solidification. The alloy Ni-20Al-30Fe, which has a two-phase structure (NiAl + Ni<sub>3</sub>Al), exhibited a tensile ductility of 22% when produced by hot extrusion and a lower ductility (10 to 17%) when produced by rapid solidification.

Creep strength is improved by ternary additions of tantalum, niobium, and hafnium. Replacing some of the nickel with 15 at.% Fe also reduces the creep rate of NiAl.

The creep properties of NiAl can also be greatly improved by solid-solution hardening and particle strengthening. The best creep resistance obtained so far was produced by reinforcing NiAl with AlN dispersoids that were introduced by milling NiAl powder in liquid nitrogen.

For structural use at elevated temperatures in hostile environments, the following alloy composition (at.%) has been identified:

In this case, the alloys were prepared by melting and casting, followed by hot extrusion at 900 to 1050 °C (1650 to 1920 °F). The alloys show a yield strength as high as 700 MPa (102 ksi) at room temperature and 350 MPa (31 ksi) at 1000 °C (1830 °F). The creep rate of the alloys is lower than that of binary NiAl by five to six orders of magnitude at 816 °C in air. Among the alloying elements added to NiAl, zirconium and hafnium improve creep resistance best, but reduce the tensile ductility of the alloys.

**Corrosion Resistance.** NiAl offers excellent oxidation resistance at high temperatures. In the 1950s and 1960s, NiAl alloys were employed as coating materials for hot components in corrosive environments. The oxidation resistance of NiAl can be further improved by alloying with yttrium and other refractory elements such as hafnium and zirconium (Fig. 12).

Fig. 12 Long-term (3000 h) cyclic oxidation behavior of NiAl + 0.1 at.% Zr at 1200 °C (1290 °F)

## Structural Intermetallics

### Iron Aluminides

Iron aluminides form bcc ordered crystal structures over the composition range of 25 to 50 at.%. The aluminide Fe<sub>3</sub>Al exists in the ordered *D0<sub>3</sub>* structure up to 540 °C (1000 °F) and in the *B2* structure between 540 and 760 °C (1000 and 1400 °F); it has a disordered structure above 760 °C (1400 °F). The *D0<sub>3</sub>* → *B2* transition temperature decreases, and the *B2* ordered temperature increases with an increase in aluminum concentration above 25%. Only the *B2* structure is stable at aluminum levels above 36%, and the single-phase field extends to approximately 50 at.% Al (FeAl). Figure 13 shows the iron-aluminum phase diagram.

Fig. 13 The binary iron-aluminum phase diagram

The iron aluminides based on Fe<sub>3</sub>Al and FeAl possess unique properties and have development potential as new materials for structural use. This potential is based on the capability of the aluminides to form protective Al<sub>2</sub>O<sub>3</sub> scales in oxidizing and sulfidizing environments at elevated temperatures. In addition to excellent corrosion resistance, the aluminides offer low material cost, low density, and conservation of strategic elements. However, the major drawbacks of the aluminides are their low ductility and fracture toughness at ambient temperature, their poor strength at temperatures above 600 °C (1110 °F), and their susceptibility to environmental embrittlement.

**Alloying Effects in Fe<sub>3</sub>Al Aluminides.** Grain structure refinement by material processing and alloy additions has been shown to be useful in increasing ductility in Fe<sub>3</sub>Al (Fe-28 Al at.%) aluminides. Additions of titanium diboride (TiB<sub>2</sub>) to Fe<sub>3</sub>Al powders are very effective in reducing grain size, and they increase the tensile ductility of recrystallized materials from 2 to 5 to 7%. Stress relief following hot working of the same materials results in ductilities as high as 18%. The presence of TiB<sub>2</sub> particles increases the recrystallization temperature from 650 to 1100 °C (1200 to 2010 °F), which means that wrought materials will retain room-temperature ductility even after exposure to temperatures as high as 1000 °C (1830 °F). For these materials, ductility is very high at temperatures above 600 °C (1110 °F), and conventional hot fabrication techniques can be employed without difficulty.

Strength properties of these aluminides are also sensitive to microstructure and the level of aluminum. Room-temperature yield strength drops sharply with an increase of aluminum above 25%. Additions of TiB<sub>2</sub>, which reduce the grain size of recrystallized material and stabilize the wrought structure, increase the strength significantly and cause it to be retained to higher temperatures.

A recent alloy design of Fe<sub>3</sub>Al showed that the ductility of the aluminide prepared by melting and casting and fabricated by hot rolling can be substantially improved by increasing the aluminum content from 25 to 28 or 30 at.% and by adding chromium at a level of 2 to 6%. The increase in the aluminum concentration sharply decreases the yield strength of the aluminide. The beneficial effect of chromium may come from modifying the surface composition and reducing the water vapor and aluminum atom reaction, that is, reducing environmental embrittlement. The mechanical properties of the chromium-modified Fe<sub>3</sub>Al alloys can be further improved by thermomechanical treatment and alloy additions of molybdenum and niobium. Some of these alloys show a tensile ductility of more than 15% at room temperature and a yield strength of close to 500 MPa (72.5 ksi) at 600 °C (1110 °F). These ductile Fe<sub>3</sub>Al alloys are much stronger than austenitic and ferritic steels such as type 314 stainless steel and Fe-9Cr-1Mo steel. The refractory elements also substantially enhance the creep properties of the Fe<sub>3</sub>Al alloys.

Table 4 lists several Fe<sub>3</sub>Al alloys that were recently developed. Tensile and creep properties of wrought Fe<sub>3</sub>Al alloys are compared with oxide dispersion strengthened (ODS) MA-956 iron-base superalloy in Fig. 14. The tensile properties of Fe<sub>3</sub>Al alloys are similar to those of the ODS MA-956 alloy; however, its creep properties are significantly lower.

**Table 4 Chemical compositions of selected Fe<sub>3</sub>Al aluminides**

(c)

**Fig. 14 Comparison of tensile properties of wrought Fe<sub>3</sub>Al alloys with those of MA-956 alloy (Fe-20Cr-4.5Al-0.5Ti-0.5Y<sub>2</sub>O<sub>3</sub>). (a) 0.2% yield strength. (b) Ultimate tensile strength. (c) Total elongation. See Table 4 for Fe<sub>3</sub>Al alloy chemical compositions**

**Alloying Effect in FeAl Aluminides.** FeAl aluminides containing 40 at.% or more aluminum fail at room temperature by intergranular fracture with little tensile ductility. Small additions of boron (0.05 to 0.2%) suppress grain-boundary fracture and allow a small increase in ductility ( $\sim 3\%$ ) of Fe-40Al, but not of Fe-50Al. The beneficial effect of boron is not nearly as dramatic in FeAl as it is in Ni<sub>3</sub>Al, but it is nevertheless significant. The ductility of boron-doped FeAl

aluminides remains low because the alloys are still embrittled by the test environment (air). It has been found that boron-doped FeAl (40% Al) exhibits a high ductility (18%) when tested in dry oxygen to avoid environmental embrittlement.

Boron additions also increase the elevated-temperature strength of FeAl, especially in combination with niobium and zirconium. For example, the creep rate can be lowered by an order of magnitude at 825 °C (1520 °F) by the combination of 0.1% Zr and 0.2% B.

More recent alloy development studies have focused on a base alloy of Fe-36Al (at.%) alloyed with the elements listed in Table 5. The most effective elements for increasing high-temperature strength and room-temperature ductility of these FeAl alloys were small additions of molybdenum, zirconium, and boron in combination, with the synergistic effects being much more potent than the single element effects. While zirconium and boron additions were very important for improved room-temperature ductility, Mo + Zr + B additions produced the best tensile and creep-rupture strength at 600 °C (1110 °F) in an alloy designated FA-362 (Table 5). The FA-362 alloy also showed the highest room-temperature ductility in air (11.8%). Preoxidation at 700 °C (1290 °F) further increased the tensile ductility to 14.7%. Figure 15 compares the elevated-temperature yield strengths of various FeAl alloys listed in Table 5 with those of two high-speed tool steels.

**Fig. 15** Yield strength of several FeAl alloys tensile tested at 600 °C (1110 °F) in air. Specimens were punched from thin sheets, hot rolled at 850 to 900 °C (1560 to 1650 °F), and heat treated for 1 h at 700 to 800 °C (1290 to 1470 °F) prior to testing. See Table 5 for alloy compositions.

**Environmental Embrittlement.** For more than 45 years, the iron aluminides have been known to be brittle at ambient temperatures; however, the major cause of the brittleness has only recently been identified. The data in Table 6 indicate the effect of test environment on the room-temperature tensile properties of FeAl (36.5% Al) and Fe<sub>3</sub>Al (28% Al). Yield strength is not sensitive to environment, but ultimate tensile strength is generally correlated with tensile ductility, which depends strongly on test environment. Aluminides tested in air had a ductility of 2 to 4%. FeAl tested in dry oxygen had a ductility of 17.6%, and Fe<sub>3</sub>Al tested in vacuum and dry oxygen had a ductility of 12 to 13%. The water vapor test confirmed the low ductility found in the air tests, indicating that moisture in air is the embrittling agent.

**Table 6** Effect of selected test environments on room-temperature tensile properties of iron aluminides

Test environment (gas pressure)	Elongation, %	Yield strength		Ultimate tensile strength	
		MPa	ksi	MPa	ksi
Fe <sub>3</sub> Al (28% Al) <sup>(a)</sup>					
Air	4.1	387	56	559	81
Vacuum ( $\sim 1 \times 10^{-4}$ Pa)	12.8	387	56	851	123
Argon + 4% H <sub>2</sub> ( $6.7 \times 10^4$ Pa)	8.4	385	55.8	731	106
Oxygen ( $6.7 \times 10^4$ Pa)	12.0	392	56.8	867	126
Water vapor ( $1.3 \times 10^3$ Pa)	2.1	387	56	475	69
FeAl (36.5% Al) <sup>(a)</sup>					
Air	2.2	360	52.2	412	60
Vacuum ( $<1 \times 10^{-4}$ Pa)	5.4	352	51	501	73
Argon + 4% H <sub>2</sub> ( $6.7 \times 10^4$ Pa)	6.2	379	55	579	84
Oxygen ( $6.7 \times 10^4$ Pa)	17.6	360	52.2	805	117

(a) All specimens were annealed 1 h at 900 °C (1650 °F) + 2 h at 700 °C (1290 °F).

Embrittlement is expected to involve the following chemical reaction at metal surfaces:

The reaction of water vapor with aluminum atoms at crack tips results in the formation of atomic hydrogen that drives into the metal and causes crack propagation. The fact that yield strength (Table 6) is insensitive to ductility and test environment is consistent with the mechanisms of hydrogen embrittlement observed in other ordered intermetallic alloys.

**Corrosion Resistance.** As stated earlier, the iron aluminides are highly resistant to oxidation and sulfidation at elevated temperatures. The oxidation resistance generally increases with increasing aluminum content; the major products are  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> and trace amounts of iron oxides when the aluminides are oxidized at temperatures above 900 °C (1650 °F). Cyclic oxidation of Fe-40Al alloyed with up to 1 at.% Hf, Zr, and B produced little degradation at temperatures up to 1000 °C (1830 °F). Aluminide specimens tested at 700 and 870 °C (1290 and 1600 °F) showed no indication of attack in sulfidizing environments, except for the formation of a thin layer of oxides with a thickness in an interference color range. As shown in Fig. 16, the iron aluminum alloys exhibited corrosion rates lower than those of conventional Fe-Cr-Ni alloys (including coating material) by a couple of orders of magnitude when tested in a severe sulfidizing environment at 800 °C (1470 °F). In addition, the aluminides with more than 30% Al are very resistant to corrosion in molten nitrate salt environments at 650 °C (1200 °F). Because of their excellent corrosion resistance, iron aluminides are being considered for use in molten salt systems for chemical air separation, automotive exhaust systems, immersion heaters, heat exchangers, catalytic conversion vessels, chemical production systems, and coal conversion systems.

**Fig. 16** Comparison of the corrosion behavior of iron aluminides with that of conventional iron-base alloys Fe-18Cr-6Al (the coating material) and Fe-25Cr-20Ni. All materials were exposed to a severe sulfidizing environment at 800 °C (1470 °F).

## Titanium Aluminides

Because of their low density, titanium aluminides based on  $\text{Ti}_3\text{Al}$  and  $\text{TiAl}$  are attractive candidates for applications in advanced aerospace engine components (latter stages of the compressor or turbine sections), airframe components, and automotive valves and turbochargers. Table 1 presents the characteristics of titanium aluminides alongside those of other aluminides; the creep behavior of titanium aluminides is compared with that of conventional titanium alloys in Fig. 17. Despite a lack of fracture resistance (low ductility, fracture toughness, and fatigue crack growth rate), the titanium aluminides  $\text{Ti}_3\text{Al}$  ( $\alpha$ -2) and  $\text{TiAl}$  ( $\gamma$ ) have great potential for enhanced performance. Table 7 compares properties of these aluminides with those of conventional titanium alloys and superalloys. Because they have slower diffusion rates than conventional titanium alloys, the titanium aluminides feature enhanced high-temperature properties such as strength retention, creep and stress rupture and fatigue resistance.

**Table 7** Properties of titanium aluminides, titanium-base conventional alloys, and nickel-base superalloys

Property	Conventional titanium alloys	$\text{Ti}_3\text{Al}$	$\text{TiAl}$	Nickel-base superalloys
<b>Density, g/cm<sup>3</sup></b>	4.5	4.1-4.7	3.7-3.9	8.3

(a) At room temperature

Fig. 17 Comparison of the creep behavior of conventional titanium alloys and titanium aluminide intermetallics

Another negative feature of titanium aluminides, in addition to their low ductility at ambient temperatures, is their oxidation resistance, which is lower than desirable at elevated temperatures. The titanium aluminides are characterized by a strong tendency to form  $\text{TiO}_2$ , rather than the protective  $\text{Al}_2\text{O}_3$ , at high temperatures. Because of this tendency, a key factor in increasing the maximum-use temperatures of these aluminides is enhancing their oxidation resistance while maintaining adequate levels of creep and strength retention at elevated temperatures.

### Alpha-2 Alloys

The  $\alpha$ -2 ( $\text{Ti}_3\text{Al}$ ) intermetallic has an ordered  $\text{DO}_{19}$  structure (see Fig. 2). As shown on the titanium-aluminum phase diagram (Fig. 18),  $\text{Ti}_3\text{Al}$  has a wide range of composition stability, with aluminum contents of 22 to 39 at.%. The compound is congruently disordered at a temperature of 1180 °C (2155 °F) and an aluminum content of 32 at.%. The stoichiometric composition, Ti-25Al, is stable up to approximately 1090 °C (1995 °F).

Fig. 18 The titanium-aluminum binary phase diagram

The semicommercial and experimental  $\alpha$ -2 alloys developed are two phase ( $\alpha$ -2 +  $\beta$ /B2), with contents of 23 to 25 at.% Al and 11 to 18 at.% Nb. Alloy compositions with current engineering significance are Ti-24Al-11Nb, Ti-25Al-10Nb-3V-1Mo, Ti-25Al-17Nb-1Mo, and modified alloy compositions such as Ti-24.5Al-6Nb-6(Ta,Mo,Cr,V). Increasing the niobium content generally enhances most material properties, although excessive niobium can degrade creep performance. Niobium can be replaced by specific elements for improved strength (molybdenum, tantalum, or chromium), creep resistance (molybdenum), and oxidation resistance (tantalum, molybdenum). However, for full optimization of mechanical properties, control of the microstructure must be maintained, particularly for tensile, fatigue, and creep performance. Microstructural features, such as primary  $\alpha$ -2 grain size and volume fraction and secondary  $\alpha$ -2 plate morphology and thickness, are varied by thermomechanical processing.

**Typical mechanical properties** for a number of  $\alpha$ -2 alloys are listed in Table 8. Production of two-phase alloys by alloying Ti<sub>3</sub>Al with  $\beta$ -stabilizing elements results in up to a doubling of strength. Interface strengthening of the two-phase mixture appears to be predominantly responsible for the increased strength, but other strengthening factors, such as long-range order, solid solution, and texture effects, also contribute.

**Table 8 Properties of  $\alpha$ -2 Ti<sub>3</sub>Al alloys with various microstructures**

Alloy	Microstructure <sup>(a)</sup>	Yield strength		Ultimate tensile strength		Elongation, %	Plane-strain fracture toughness ( $K_{Ic}$ )		Creep rupture <sup>(b)</sup>

	W + P	705	102	940	136	10.0	...	...	...

(a) E, equiaxed  $\alpha$ -2; W, Widmanstätten; FW, fine Widmanstätten; C, colony structure; P, primary  $\alpha$ -2 grains.

(b) Time to rupture, h, at 650 °C (1200 °F) and 380 MPa (55 ksi)

A fine Widmanstätten microstructure with a small amount of primary  $\alpha$ -2 grains exhibits better ductility than microstructures with a coarse Widmanstätten microstructure or an aligned acicular  $\alpha$ -2 morphology. A detailed investigation into the effect of microstructure on creep behavior in Ti-25Al-10Nb-3V-1Mo has shown that the colony-type microstructure shows better creep resistance than other microstructures. Creep resistance of Ti-25-10-3-1 is raised by a factor of ten in the steady-state regime over that of conventional alloy Ti-1100 (Ti-6Al-3Sn-4Zr-0.4Mo-0.45Si) and two orders of magnitude over that of Ti-6Al-2Sn-4Zr-2Mo-0.1Si. However, 0.4% creep strain in Ti-25-10-3-1 is reached within 2 h.

Additions of silicon and zirconium appear to improve creep resistance, but the most significant improvement is attained by increasing the aluminum content to 25 at.% and limiting  $\beta$ -stabilizing elements to approximately 12 at.%. However, the Ti-24.5Al-17Nb-1Mo alloy exhibits a rupture life superior to that of other  $\alpha$ -2 alloys.

### Orthorhombic Alloys

At higher niobium levels, the  $\alpha$ -2 phase evolves to a new ordered orthorhombic structure that is based on the composition Ti<sub>2</sub>AlNb (O phase). This has been observed in titanium aluminides with compositions near Ti-(21-25)Al-(21-27)Nb (at.%).

Although the orthorhombic alloys have a lower use temperature than the  $\gamma$  aluminides described in the section "Gamma Alloys" (approximately 650 °C, or 1200 °F), they offer much higher absolute strengths. Room-temperature tensile strengths on the order of 1380 MPa (200 ksi) with close to 5% elongation have been reported. In addition, 0.2% yield

strengths in the range of 590 to 690 MPa (86 to 100 ksi) at 700 °C (1290 °F) have also been reported for Ti-21Al-25Nb (at.%) alloy. This material had a room-temperature yield strength of approximately 1070 MPa (155 ksi) with 3.5% elongation.

The ordered orthorhombic alloys having the best combination of tensile, creep, and fracture toughness properties are two-phase O +  $\beta$  alloys such as Ti-22Al-27Nb (at.%). Table 9 lists the elevated-temperature tensile properties of such alloys.

## Gamma Alloys

The  $\gamma$ -TiAl phase has an  $L1_0$  ordered face-centered tetragonal structure (Fig. 2), which has a wide range (49 to 66 at.% Al) of temperature-dependent stability (Fig. 18). The  $\gamma$ -TiAl phase apparently remains ordered up to its melting point of approximately 1450 ° (2640 °F).

They  $\gamma$  alloys of engineering importance contain approximately 45 to 48 at.% Al and 1 to 10 at.% M, with M being at least one of the following: vanadium, chromium, manganese, niobium, tantalum, and tungsten. These alloys can be divided into two categories: single-phase ( $\gamma$ ) alloys and two-phase ( $\gamma$  +  $\alpha$ -2) materials. The ( $\alpha$ -2 +  $\gamma$ )/ $\gamma$  phase boundary at 1000 °C (1830 °F) occurs at an aluminum content of approximately 49 at.%, depending on the type and level of solute M. Single-phase  $\gamma$  alloys contain third alloying elements such as niobium or tantalum that promote strengthening and further enhance oxidation resistance. Third alloying elements in two-phase alloys can raise ductility (vanadium, chromium, and manganese), increase oxidation resistance (niobium and tantalum) or enhance combined properties.

**Material Processing.** Gamma alloys are processed by conventional methods, including casting, ingot metallurgy, and P/M. Important alloying/melting processes include induction skull melting, vacuum arc melting, and plasma melting. Other methods under study include mechanical alloying, spray forming, shock reactive synthesis, physical vapor deposition, and hot pressing and rolling of elemental sheet into multilayer composite sheets. By appropriate thermomechanical processing (TMP), the morphology of the phases in nominally  $\gamma$  alloys can be adjusted to produce either lamellar or equiaxed morphologies, or a mixture of the two.

**Mechanical Properties.** Table 10 lists tensile properties and fracture toughness of  $\gamma$  alloys as functions of processing/microstructure and temperature. Ternary alloys of Ti-48Al with approximately 1 to 3% V, Mn, or Cr exhibit enhanced ductility, but Ti-48Al alloys with approximately 1 to 3% Nb, Zr, Hf, Ta, or W show lower ductility than binary

Ti-48Al. The brittle-ductile transition (BDT) occurs at 700 °C (1290 °F) in Ti-56Al and at lower temperatures with decreasing aluminum levels. Increased room-temperature ductility generally results in a reduced BDT temperature. Above the BDT temperature, ductility increases rapidly with temperature, approaching 100% at 1000 °C (1830 °F) for the most ductile  $\gamma$  alloy compositions. The trend bands for variations in yield strength and tensile ductility with test temperature are shown in Fig. 19. The elastic moduli of  $\gamma$  alloys range from 160 to 176 GPa ( $23 \times 10^6$  to  $25.5 \times 10^6$  psi) and decrease slowly with temperature.

(a)

 $K_q$  = the provisional  $K_{Ic}$  value

**Fig. 19** Ranges of yield strength and tensile elongation as functions of test temperature for  $\gamma$ -TiAl alloys. BDT, brittle-ductile transition

Low-cycle fatigue experiments suggest that fine grain sizes increase fatigue life at temperatures below 800 °C (1470 °F). Fatigue crack growth rates for  $\gamma$  alloys are more rapid than those for superalloys, even when density is normalized. Both fracture toughness and impact resistance are low at ambient temperatures, but fracture toughness increases with temperature; for example, the plane-strain fracture toughness ( $K_{Ic}$ ) for Ti-48Al-1V-0.1C is 24 MPa $\sqrt{m}$  (21.8 ksi $\sqrt{in.}$ ) at room temperature. Fracture toughness is strongly dependent on the volume fraction of the lamellar phase. In a two-phase quaternary  $\gamma$  alloy, a fracture toughness of 12 MPa $\sqrt{m}$  (10.9 ksi $\sqrt{in.}$ ) is observed for a fine structure that is almost entirely  $\gamma$ ;  $K_{Ic}$  is greater than 20 MPa $\sqrt{m}$  (18.2 ksi $\sqrt{in.}$ ) when a large volume fraction of lamellar grains are present. Creep properties of  $\gamma$  alloys, when normalized by density, are better than those of superalloys, but they are strongly influenced by alloy chemistry and TMP. Increased aluminum content and additions of tungsten or carbon increase creep resistance. Increasing the volume fraction of the lamellar structure enhances creep properties but lowers ductility. The level of creep strain from elongation upon initial loading and primary creep is of concern because it can exceed projected design levels for maximum creep strain in the part.

**Composites.** Gamma titanium aluminides also serve as the matrix for titanium-matrix composites. Investment cast Ti-47Al-2Nb-2Mn (at.%) + 0.8 vol% TiB<sub>2</sub> and Ti-45Al-2Nb-2Mn (at.%) + 0.8 vol% TiB<sub>2</sub> XD (exothermic dispersion) alloys have been developed. These alloy form in situ titanium diborides that cause grain refinement and subsequent enhancement of mechanical and physical properties. The XD-type of in situ reinforcements offer better thermal stability than conventional metal-matrix composites and the opportunity to introduce reinforcements in the micron scale range (at 0.8 vol%, the TiB<sub>2</sub> is simply serving as a grain refiner). The XD aluminides offer excellent fatigue properties, with endurance limits in the range of 95 to 115% of the yield strength (non-XD  $\gamma$  alloys exhibit similar behavior). The high fatigue strength is attributed to the microstructural refinement mentioned previously and a strain aging effect that occurs during loading. One major gas turbine engine manufacturer is studying XD  $\gamma$ -aluminide blades for the last stage low-pressure turbine in an aircraft engine that currently uses IN-713 blades. Service temperature is in the range of 650 to 700 °C (1200 to 1290 °F). XD titanium aluminide composites are also being used for applications such as missile fins. Ti-47Al-2V + 7 vol% TiB<sub>2</sub> has a higher strength than 17-4PH steel above 600 °C (1110 °F) and a higher modulus at approximately 750 °C (1380 °F). These improvements extend the operating temperature of the missile wing, which led to a redesign utilizing the XD composite. Table 10 lists tensile properties of XD composites.

**Oxidation Resistance.** Although the  $\gamma$  class of titanium aluminides offers oxidation and interstitial (oxygen, nitrogen) embrittlement resistance superior to that of the  $\alpha$ -2 and orthorhombic (Ti<sub>2</sub>AlNb) classes of titanium aluminides,

environmental durability is still a concern, especially at temperatures approximately 750 to 800 °C (1380 to 1470 °F) in air. This is because, as stated earlier in this article, all titanium aluminides are characterized by a strong tendency to form TiO<sub>2</sub>, rather than the protective Al<sub>2</sub>O<sub>3</sub> scale, at elevated temperature. To improve the oxidation resistance of  $\gamma$  aluminides, two areas are being explored: alloy development and the development of improved protective coatings.

Ternary and higher-order alloying additions can reduce the rate of oxidation of  $\gamma$  alloys. Of particular benefit are small (1 to 4%) ternary additions of tungsten, niobium, and tantalum. When combined with quaternary additions of 1 to 2% Cr or Mn, further improvement in oxidation resistance is gained. However, it is important to stress that these small alloying additions do not result in continuous Al<sub>2</sub>O<sub>3</sub> scale formation. Rather, a complex intermixed Al<sub>2</sub>O<sub>3</sub>/TiO<sub>2</sub> scale is still formed, but the rate of growth of this scale is reduced.

Further improvements in oxidation resistance can be obtained via protective coatings. Three general coating alloy approaches have been taken for protecting titanium aluminides: MCrAlY (M = Ni, Fe, Co), aluminizing, and silicides/ceramics. Protection of titanium aluminides under oxidizing conditions has been achieved with all three approaches; however, the fatigue life of coated material is often reduced to below that of uncoated material.

The degradation in the fatigue life of titanium aluminides by coatings results from three main factors: the formation of brittle coating/substrate reaction zones (chemical incompatibility), the brittleness of the coating alloy, and the differences in the coefficient of thermal expansion (CTE) between the coating and the substrate. MCrAlY coatings, which are successfully used to protect nickel-, iron-, and cobalt-base superalloys, are not chemically compatible with titanium aluminides and form brittle coating/substrate reaction zones at 800 °C. Aluminizing treatments result in the surface formation of the TiAl<sub>3</sub> and TiAl<sub>2</sub> phases, which are brittle and exhibit CTE mismatches with  $\alpha$ -2 orthorhombic, and  $\gamma$  titanium aluminides. Silicide and ceramic coatings are also generally too brittle to survive fatigue conditions.

The ideal oxidation-resistant coating for  $\gamma$  alloys would be Ti-Al based for optimal chemical and mechanical compatibility with  $\gamma$  substrates, be capable of forming a continuous Al<sub>2</sub>O<sub>3</sub> scale for protection from both oxidation and interstitial oxygen/nitrogen embrittlement, and possess reasonable mechanical properties to survive high-cycle fatigue. No ideal combination of these properties exists at present. However, reasonable compromises have been achieved with coating alloys based in the Ti-Al-Cr system. These coatings have been applied by sputtering (Ti-44Al-28Cr on Ti-47Al-2Cr-2Ta), hot isostatic pressing (Ti-44Al-28Cr and Ti-50Al-20Cr coatings), and low-pressure plasma spraying. Figure 20 shows the results of interrupted weight gain oxidation data for Ti-48Al-2Cr-2Nb coated with Ti-51Al-12Cr. These tests showed that the coating successfully protected the substrate at 800 °C (1470 °F) and 1000 °C (1830 °F) in air.

**Fig. 20** The effect of a low-pressure plasma sprayed Ti-51Al-12Cr coating on the (a) 800 °C (1470 °F) and (b) 1000 °C (1830 °F) interrupted oxidation behavior of a Ti-48Al-2Cr-2Nb  $\gamma$ -TiAl alloy in air

## Other Intermetallics of Importance

**Ni<sub>3</sub>Si Alloys.** The silicide Ni<sub>3</sub>Si is the major constituent of the commercial cast alloy Hastelloy D, a corrosion-resistant alloy with the unique ability to resist attack by sulfuric acid solutions (see the Section "Nickel and Nickel Alloys" in this Handbook). Some alloys based on Ni<sub>3</sub>Si, such as Ni-18.9Si-3.2Cr-0.6Hf-0.15B (at.%), are as strong as nickel-base superalloy IN 718 at room and intermediate temperatures and have the potential to be used as structural materials for chemical and petrochemical applications.

**Fe<sub>3</sub>Si Alloys.** A commercial alloy named Sendust based on Fe<sub>3</sub>Si and Fe<sub>3</sub>Al has been developed for soft magnetic applications; its typical composition is Fe-9.6Si-5.4Al (wt%). Sendust has been used as a magnetic head core material because of its superior magnetic properties and its resistance to wear and corrosion. Magnetic properties of Sendust are given in the article "Magnetically Soft Materials" in this Section (see Fig. 9 in that article).

**MoSi<sub>2</sub>** is attractive because of its high electrical and thermal conductivities and excellent oxidation resistance at high temperatures. MoSi<sub>2</sub> has been used commercially for electrical heating elements in high-temperature furnaces under the trade name of Kanthal, which contains roughly 80% MoSi<sub>2</sub> and 20% glass ceramic compounds. Properties of MoSi<sub>2</sub> are given in the article "Electrical Resistance Alloys" in this Section.

**NiTi.** Nitinol, based on the equiatomic NiTi intermetallic, is the major material used for shape memory alloys for industrial, consumer, and medical applications. Detailed information on such alloys can be found in the article "Shape Memory Alloys" in this Section.

**SmCo<sub>5</sub> alloys,** produced by P/M processes, are widely used for magnetic applications. Properties and applications for such cobalt-rare earth alloys are given in the article "Permanent Magnet Materials" in this Section.

**Nb<sub>3</sub>Sn** is an important constituent in superconducting devices. Properties and applications of this compound are described in the article "Superconducting Materials" in this Section.

# Beryllium

## Introduction

BERYLLIUM, because of its unusual combination of physical and mechanical properties, finds its way into specialized applications when its relatively high cost can be justified. It has a very low density ( $1.848 \text{ g/cm}^3$ , or  $0.067 \text{ lb/in.}^3$ ), a moderately high melting point ( $1283 \text{ }^\circ\text{C}$ , or  $2341 \text{ }^\circ\text{F}$ ), and a high elastic modulus ( $303 \text{ GPa}$ , or  $44 \times 10^6 \text{ psi}$ ). It has good electrical conductivity (40% IACS) and thermal conductivity ( $210 \text{ W/m} \cdot \text{K}$ , or  $121 \text{ Btu/ft} \cdot \text{h} \cdot \text{F}$ ).

Unalloyed beryllium is used in weapons, spacecraft, rocket nozzles, structural tubing, optical components, and precision instruments. The specific modulus, that is, the ratio of elastic modulus to density, is higher than that of aluminum, magnesium, or titanium. The high specific modulus and the low thermal expansion ( $11.6 \mu\text{m/m} \cdot \text{K}$ ) translates into good physical stability and low distortion during inertial or thermal stressing, making beryllium useful for critical aerospace components. Its exceptionally good dimensional stability and ability to reflect infrared radiation makes beryllium highly suited for mirrors, either as polished or plated substrate. The near transparency of beryllium to x-rays and other high-energy electromagnetic radiation is responsible for its widespread use in foil gage as windows in x-ray tubes and radiation-detection devices.

Beryllium is an important alloying element in copper and nickel for producing commercially important age-hardening alloys that are used in electrical contacts, springs, spot welding electrodes, and nonsparking tools. It is also added to aluminum and magnesium for grain refinement and oxidation resistance.

## Processing and Product Forms

While beryllium can be melted and cast, the resulting casting has coarse grains ( $>50 \mu\text{m}$ ) that are difficult to process, and attempts to refine them by alloying have been largely unsuccessful. The fine grain size is produced primarily by powder metallurgy (P/M) techniques, from which it inherits the fine grain size (5 to  $15 \mu\text{m}$ ) from the powder processing. Powder consolidation is done by vacuum hot pressing and has also been done by hot isostatic pressing or cold isostatic pressing followed by vacuum sintering.

Consolidated beryllium shows only modest ductility ( $\leq 3\%$  tensile elongation) at room temperature, which is attributed to a large covalent component in its atomic bonding in the *c*-axis direction and to its hexagonal close-packed (hcp) crystal structure, which is limited at room temperature to only one slip direction on two crystal planes, basal and prism. This low ductility is not improved even when impurities are reduced to levels as low as  $\sim 10 \text{ ppm}$ . However, beryllium does show improved ductility at temperatures above 200 to  $250 \text{ }^\circ\text{C}$  ( $392$  to  $482 \text{ }^\circ\text{F}$ ), where more crystal deformation modes are available. At  $400 \text{ }^\circ\text{C}$  ( $750 \text{ }^\circ\text{F}$ ), for example, it shows a tensile elongation as high as 50%. Beryllium transforms to a body-centered cubic (bcc) phase at  $1270 \text{ }^\circ\text{C}$  ( $2318 \text{ }^\circ\text{F}$ ), only  $13 \text{ }^\circ\text{C}$  below its melting point.

Beryllium is flat rolled, extruded into shapes, and forged at elevated temperatures. It is worked warm; the handbooks suggest a temperature range of 800 to  $1100 \text{ }^\circ\text{C}$  ( $1470$  to  $2110 \text{ }^\circ\text{F}$ ) for hot working. Beryllium is commercially available as tube shapes and as plate, sheet, and foil in thickness ranging from 0.013 to 15.2 mm (0.0005 to 0.6 in). Recrystallization annealing is done at 725 to  $900 \text{ }^\circ\text{C}$  ( $1340$  to  $1650 \text{ }^\circ\text{F}$ ). As with other hexagonal close-packed (hcp) metals, beryllium displays anisotropic mechanical properties in wrought forms because of crystallographic texture and grain morphology. The traditional ball-milling method of making powder produces flat, crystallographically oriented powder particles that naturally leads to a crystallographic texture in the initial pressing stage. Newer powder preparation techniques, involving

impact-grinding or atomization methods, produce a more equiaxed product, avoiding the oriented flat powder produced by ball milling and reducing the amount of crystallographic texture during the initial consolidation operation. Even so, care is taken to fabricate beryllium with a fine grain and as random a crystallographic orientation as possible. The room-temperature tensile properties of cross-rolled sheet are 345 to 414 MPa (50 to 60 ksi) yield strength, 483 to 621 MPa (70 to 90 ksi) tensile strength, and 10 to 40% elongation. Both the tensile and the yield strength have been shown to obey the Hall-Petch relationship between yield strength and grain size.

Beryllium shows the machining characteristics of cast iron when the required carbide tools are used. It is commonly brazed and adhesive bonded and with care can be welded.

## Beryllium Grades and Properties

Commercially available grades of beryllium are distinguished by impurity levels and BeO content. The metal, in fact, normally contains 0.7 to 4.25% of BeO, which is unavoidable and increases with the fineness of the beryllium powder used in the consolidation process. It has extremely low solubility for oxygen and readily forms oxide particles that are situated at grain boundaries, which help to control grain growth without being harmful to ductility below 1.2% BeO. Table 1 lists chemical compositions of commercial grades of beryllium.

**Table 1 Chemistry of commercial grades of beryllium**

Beryllium grade	Beryllium components, %		Maximum impurities, ppm					
	Be, min	BeO, max	Al	C	Fe	Mg	Si	Other, each
Structural grades								
<b>S-65B</b>	99.0	0.7	600	1000	800	600	600	400
<b>S-200F and S-200FH</b>	98.5	1.5	1000	1500	1300	800	600	400
Instrument grades								
<b>I-70A</b>	99.0	0.7	700	700	1000	700	700	400
<b>O-50</b>	99.0	0.5	700	700	1000	700	700	400
<b>I-220B</b>	98.0	2.2	1000	1500	1500	800	800	400

**Of the structural grades** (indicated by the S in the designation), S-65B, with 99.0% min Be and 0.7% BeO, offers the most ductility at room temperature: 207 MPa (30 ksi) yield strength, 290 MPa (42 ksi) tensile strength, and 3% min elongation. Grade S-200F, with 98.5% min Be and 1.5% BeO is stronger, but less ductile, at room temperature: 240 MPa (35 ksi) yield strength, 325 MPa (47 ksi) tensile strength, and 2.0% elongation. This grade has usable strength and modulus up to 600 to 650 °C (1110 to 1200 °F), at which temperature the tensile properties are 100 MPa (15 ksi) yield strength, 130 MPa (19 ksi) tensile strength, and 10% elongation.

**Instrument and Optical Grades.** Instrument grades, indicated by the I in the designations I-220B and I-400A, are used for inertial-guidance systems where high geometrical precision and resistance to plastic deformation on a part-per-million scale (microyield strength) are required. In addition to these grades, I-70 was developed for optical components in satellite imaging systems and optical grade O-50 was developed for infrared optical instruments. Table 1 gives compositions of instrument/optical grades.

**Beryllium Alloys.** Beryllium is too reactive to accept alloying elements; it reacts to form stable compounds with most of the other common metals. Most of the research into beryllium-base alloys has been conducted on the beryllium-aluminum system. One alloy that has achieved limited commercial success is Lockalloy (62Be-38Al). This alloy, which has a density of 2.1 g/cm<sup>3</sup> (0.076 lb/in.<sup>3</sup>) and an elastic modulus of 200 GPa (29 × 10<sup>6</sup> psi), has been used in avionics (thermal management) systems, automotive components (brake calipers in race cars), and aircraft and satellite structures. When compared to unalloyed beryllium, beryllium-aluminum alloys offer improved ductility (5 to 7% elongation), yield strength (275 to 310 MPa, or 40 to 45 ksi), and tensile strength 380 MPa, or 55 ksi).

**Corrosion Resistance.** Beryllium forms a thin protective oxide (BeO) coating that provides good corrosion resistance to the atmosphere at room temperature and giving it excellent resistance to pure water up to 300 °C (570 °F). However, corrosion resistance is impaired by impurities. The presence of carbides or chlorides, in particular, can cause a reaction with moist air at room temperature. Above 760 °C (1400 °F), beryllium reacts with oxygen and nitrogen, but not at all

with hydrogen at any temperature. It is attacked by many dilute common acids at room temperature. It can be anodized or chromate coated for improved corrosion resistance.

**Health and Safety Considerations.** The main concern associated with handling beryllium is the effect on the lungs when excessive amounts of respirable beryllium powder or dust are inhaled. Sensitive individuals exposed to airborne beryllium may develop the lung disease berylliosis. Users should comply with occupational safety and health standards applicable to beryllium in Title 29, Part 1910, Code of Federal Regulations.

# Very High Density Metals

Kenneth H. Eckelmeyer, Sandia National Laboratories; Steven G. Caldwell, Teledyne Advanced Materials

## Introduction

VERY HIGH DENSITY METALS are used for applications such as counterweights, radiation shields, and armor-piercing, kinetic-energy penetrators. Though lead is often thought of as the prototype high-density metal, its softness and low melting temperature make it inappropriate for many applications. In addition, the density of lead is substantially lower than numerous other metals, as shown in Table 1. Of these higher-density alternatives, only depleted uranium, tungsten, and tantalum are practical for most commercial applications. Tantalum is discussed in the Section "Refractory Metals and Alloys" in this Handbook. The remainder of this section will discuss the most commonly used very high density materials: depleted uranium and tungsten alloys.

**Table 1 Metals with densities >40% greater than lead**

Metal	Density, g/cm <sup>3</sup>
<b>Tantalum</b>	16.6
<b>Plutonium</b>	19.0-19.7
<b>Uranium</b>	19.1
<b>Tungsten</b>	19.3
<b>Precious metals (gold, platinum, rhenium)</b>	19.3-19.7

Density of lead = 11.35 g/cm<sup>3</sup>

## Depleted Uranium and Uranium Alloys

**Metallurgy.** Naturally occurring uranium makes up 0.0004% of the crust of the Earth; it is 40 times more plentiful than silver, and 800 times more plentiful than gold. Natural uranium contains approximately 0.7% fissionable U<sup>235</sup> and 99.3% U<sup>238</sup>. Isotopic separation is done during chemical processing of uranium ores, resulting in enriched UF<sub>6</sub>, which contains much more than 0.7% U<sup>235</sup> and is reserved for nuclear applications, and depleted UF<sub>6</sub>, which is typically 99.8% U<sup>238</sup> and is available for nonnuclear applications requiring very high density.

Uranium metal is produced by hydrogen reduction of UF<sub>6</sub> to UF<sub>4</sub>, followed by high-temperature reaction of UF<sub>4</sub> with magnesium or calcium to produce uranium derbies. These derbies are vacuum induction remelted, during which alloying elements can be added and poured into either castings of the desired shape or ingots for subsequent metalworking. The ingots are then formed by hot working processes such as rolling, forging, or extrusion, sometimes followed by secondary

warm or cold rolling or swaging. Cast or wrought uranium parts exhibit typical metallic strength and ductility. They can be machined by conventional methods and welded by inert atmosphere processes. They are very prone to oxidation and corrosion, so protective coatings or alloying is frequently used to minimize environmental degradation.

Unalloyed uranium exhibits three polymorphic forms:  $\gamma$  phase (body-centered cubic, or bcc) above 771 °C (1420 °F),  $\beta$  phase (tetragonal) between 665 and 771 °C (1229 and 1420 °F), and  $\alpha$  phase (orthorhombic) below 665 °C (1229 °F). The high-temperature  $\gamma$  phase is very soft and ductile, and dynamic recrystallization occurs when it is plastically deformed. However, metalworking in the  $\gamma$  range is usually avoided because rapid oxidation results in poor surface quality. The intermediate-temperature  $\beta$  phase is brittle and unsuitable for metalworking processes. The  $\alpha$  phase deforms primarily by slip at temperatures above approximately 200 °C (390 °F), but increasing amounts of twinning occur as temperature decreases below that level. The combination of low-flow stress, high ductility, and reduced oxidation rate makes the high- $\alpha$  range ideal for primary hot working. Dynamic recrystallization occurs above approximately 550 °C (1020 °F), but the material work hardens if deformation is continued as the ingot cools to lower temperatures. Below approximately 200 °C (390 °F) the material becomes much stiffer, but secondary rolling and swaging can be done as low as room temperature if periodic recrystallization annealing at about 600 °C (1110 °F) is performed.

The mechanical properties of unalloyed uranium vary substantially with processing history, as shown in Table 2. As-cast uranium typically exhibits very large grains (~1 mm or more). These frequently result in nonuniform localized deformation and cause tensile ductility to be low and varied. Heat treating in the  $\beta$ -phase field is often used to refine the  $\alpha$  grain structure and to increase ductility. When done in a vacuum, high- $\alpha$  or  $\beta$  heat treatment also removes embrittling hydrogen from the material, thus further increasing ductility. Alpha-worked and recrystallized uranium contains much finer grains and exhibits substantially higher ductility. Maximum ductility is obtained in warm-finished wrought material. Alpha-uranium exhibits a ductile-to-brittle transition in the vicinity of room temperature. The presence of even very small amounts of dissolved hydrogen (fractional parts per million) increases the ductile-to-brittle transition temperature. Warm working makes the material more tolerant to hydrogen (perhaps by providing dislocation hydrogen sinks), thus suppressing the ductile-to-brittle transition and increasing room-temperature ductility.

**Table 2 Properties and applications of uranium and uranium alloys**

Alloy	Density, g/cm <sup>3</sup>	Processing	Hardness	Yield strength		Tensile strength		Elongation <sup>(a)</sup> , %	Corrosion resistance	Used for applications requiring	Precautions, comments

<b>U-6Nb</b>	17.3	$\gamma$ - quenched <sup>(f)(h)</sup>	82 HRB	160	25	825	120	31	Excellent	Corrosion resistance, high ductility	Correctly reduced section thickness limitations
<b>U-10Mo</b>	16.4	$\gamma$ - quenched <sup>(f)</sup>	28 HRC	900	130	930	135	9	Excellent	Corrosion resistance, high strength	Minimal section thickness limitations, prone to stress corrosion

- (a) Quenched from 720 °C (1330 °F), reheated to 600 °C (1110 °F), slow cooled; this sequence is often done twice.
- (b) Vacuum heat treated in high- $\alpha$  region; time depends on section thickness.
- (c) Heated in molten salt to 640 °C (1185 °F), then rolled. Dynamic recrystallization occurs above 550 °C (1020 °F); hardness and strength increase if rolling temperature drops below 550 °C (1020 °F).
- (d) Several sequences of rolling at  $\sim$ 300 °C (570 °F) plus vacuum annealing at 600 °C (1110 °F); final anneal at 550 °C (1020 °F).
- (e) Heat treated for 1h at 800 °C (1470 °F) in vacuum (longer if required for removing hydrogen from thick sections), slow cooled.
- (f) Heat treated for 1 h at 800 °C (1470 °F) in vacuum (longer if required for removing hydrogen from thick sections), quenched in water or oil (rate depends on section thickness).
- (g) Age 5 h in vacuum or dry argon.
- (h) Heat treated for 1h at 800 °C (1470 °F) in vacuum, critical quench rate much lower than required for U-0.75Ti; air cool usually sufficient for U-10Mo, but not for U-6Nb.

**Processing and Properties.** Uranium is often alloyed to improve its corrosion resistance and mechanical properties. Alloying elements such as titanium, niobium, molybdenum, zirconium, and vanadium are extensively soluble in the high-temperature phase, much less soluble in the intermediate-temperature  $\beta$  phase, and essentially insoluble in the low-temperature  $\alpha$  phase. Titanium is used primarily to increase strength. Niobium produces the greatest increases in oxidation and corrosion resistance. Small amounts of vanadium can be used to refine  $\alpha$  grain size in castings.

Uranium alloys are typically vacuum induction melted, cast, and fabricated by the same method as unalloyed uranium. The primary exceptions to this are alloys that contain significant amounts of high-melting-temperature niobium; these are frequently vacuum arc melted. Some highly alloyed materials, such as U-6Nb, must also be worked in the  $\gamma$  temperature range.

Virtually all uranium alloys are vacuum solution treated in the  $\gamma$  range ( $\sim$ 800 to 850 °C, or 1470 to 1560 °F) to dissolve the alloying elements and remove hydrogen. The resulting microstructures and properties are strongly influenced by cooling rate from the solution treatment temperature.

Slowly cooled alloys exhibit two-phase microstructures in which the alloying elements are present in the second phases. These second phases are typically intermetallic compounds or alloy-stabilized variations of the  $\gamma$  phase. The second phases increase strength and decrease ductility in the same way that addition of carbon to iron results in strengthening via the formation of increasing amounts of  $\text{Fe}_3\text{C}$ . Because the alloying additions are not in solid solution in the uranium, they have little beneficial effect on oxidation and corrosion resistance.

When alloys are quenched, the equilibrium phase transformations are frequently suppressed, resulting in a variety of nonequilibrium microstructures that are supersaturated with alloying elements and exhibit a wide range of useful properties. Three effects are particularly important. First, because the alloying elements remain in solid solution in the uranium, quenched materials exhibit increased resistance to corrosion and oxidation. In addition, the alloying elements provide solid-solution strengthening. Finally, because these solid solutions are supersaturated, they can be age hardened by subsequent lower-temperature heat treatment. Figure 1 shows how microstructure and properties of as-quenched alloys change with increasing alloy content.

**Fig. 1** Effects of composition on structure and properties of quenched uranium alloys

Very dilute alloys ( $<0.3\%$  alloying addition) typically undergo the equilibrium sequence of phase changes, but the alloying elements tend to retard these diffusional transformations, enabling them to be suppressed to lower temperatures. This can be exploited to reduce  $\alpha$  grain size in castings, particularly via the use of small vanadium additions. U-0.2V castings that are isothermally transformed from  $\beta$  to  $\alpha$  at approximately  $516^\circ\text{C}$  ( $961^\circ\text{F}$ ) exhibit grain sizes 10 to 20 times finer than those in unalloyed uranium castings.

In more concentrated alloys (with alloying additions of  $0.5\%$  to several percent), the equilibrium sequence of phase changes can be completely avoided by quenching; the  $\gamma$  phase then undergoes diffusionless martensitic transformation to a variety of supersaturated variations of the  $\alpha$  phase. In very highly alloyed uranium (approaching  $10\%$  alloying addition), the martensite start ( $M_s$ ) temperatures are below room temperature, so metastable variations of the high-temperature  $\gamma$  phase are retained.

The critical cooling rates needed to avoid diffusional transformations and obtain these supersaturated structures vary in a complex manner with alloy content. In general, however, dilute alloys such as U-0.75Ti require rapid quenching. This restricts the section thicknesses in which they can be used. More concentrated alloys, such as U-6Nb and U-10Mo, require much less severe quenching and thus can be processed in larger sections.

Uranium alloys are susceptible to environmental cracking in ionic chloride and other environments. Dilute alloys are also sensitive to hydrogen, which is readily generated by surface decomposition of atmospheric moisture. Concentrated alloys are more sensitive to atmospheric oxygen. The tensile surface residual stresses that result from quenching of complex-shape parts can be sufficient to cause cracking in these relatively mild environments. The magnitudes of these stresses are limited by the yield strengths of the as-quenched material. Hence, high-strength alloys, such as U-0.75Ti and U-10Mo, tend to be most susceptible to delayed cracking, while low-strength alloys such as U-6Nb are relatively immune.

General oxidation and corrosion resistance increase with increasing the amount of alloy in solid solution. As a result, alloys such as U-6Nb and U-10Mo are often used in applications that require good corrosion resistance.

All previously quenched materials are amenable to subsequent aging. Age hardening occurs at temperatures up to approximately 450 °C (840 °F). This significantly increases strength and decreases ductility. Age-hardened U-0.75Ti is the alloy most commonly selected for applications requiring high strength, but others can also be strengthened in this way. Age-hardened materials retain their enhanced corrosion resistance, as most of the alloying additions remain in solid solution. Residual stresses introduced during the prior quench are also progressively relieved as age hardening progresses.

Overaging occurs by cellular decomposition of the supersaturated solutions at temperatures greater than approximately 450 °C (840 °F). This results in substantially decreased strength. Ductility increases in some cases, but not in others (notably U-0.75Ti) as semicontinuous films of brittle intermetallic develop. Corrosion resistance also decreases dramatically, as the alloying additions are no longer retained in solid solution.

**Machining, Welding, and Corrosion Protection.** Uranium and uranium alloys can be machined by conventional methods and are roughly as machinable as stainless steels. Very soft materials, such as unalloyed uranium and as-quenched U-6Nb, tend to be gummy. Aged materials, such as U-0.75Ti, are somewhat difficult because of their high hardness. Machining is easiest with alloys that have been slowly cooled or overaged to produce relatively soft two-phase microstructures.

Uranium and uranium alloys are inherently weldable by inert atmosphere processes, but subcritical cooling and residual stress development cause difficulties in some composition ranges. U-0.75Ti is difficult to weld because weld cooling rates cause subcritical cooling from the  $\gamma$  phase, resulting in brittle microstructures. U-6Nb is readily weldable because it is much less quench-rate sensitive and because its low as-quenched strength prevents the development of high weld-induced residual stresses. U-10Mo is free from quench-rate sensitivity concerns, but its higher strength permits higher residual stresses to develop, thus increasing susceptibility to delayed cracking.

Uranium and dilute uranium alloys are highly susceptible to oxidation and corrosion. Protective coatings, such as electroplated nickel or ion-plated aluminum, are frequently applied to minimize such environmental effects. More concentrated alloys, such as U-6Nb and U-10Mo, are more resistant to oxidation and corrosion, and thus usually are not coated.

**Design Considerations and Applications.** Several design limitations must be considered in applications of depleted uranium and uranium alloys: susceptibility to oxidation and corrosion, relatively low toughness (particularly at low temperatures), and health and safety considerations associated with processing and use.

Unalloyed uranium is used primarily for radiation shielding, counterweights, and other applications with minimal strength requirements. Nickel electroplating or aluminum ion plating is used to provide corrosion protection where needed. U-0.75Ti is frequently chosen for applications requiring high strength and moderate toughness, such as kinetic-energy penetrators. Quench-rate sensitivity limits the use of this alloy in diameters greater than 30 or 40 mm (1.2 or 1.6 in.). U-6Nb is most frequently used in applications requiring high ductility and inherent resistance to oxidation and corrosion.

**Health and Safety Considerations.** Several health and safety issues must be taken into account when working with depleted uranium. First, finely divided material is pyrophoric. Liberal amounts of machining fluid must be used, and machining chips, saw fines, and grinding residue must be removed frequently from tools and stored submerged in water or oil. Second, heavy-metal poisoning can result if this material is inhaled or ingested. Depleted uranium is roughly as toxic as other heavy metals, such as lead. Inhalation and ingestion are best avoided by avoiding dry grinding where fine airborne particulates could be generated, by cleaning work areas periodically (especially where saw fines or grinding residue is generated or where oxide flakes off during hot working operations), and by applying good personal hygiene practices in uranium work areas. Finally, depleted uranium is mildly radioactive. This low level of radioactivity is generally considered to constitute less of a hazard than chemical toxicity. Working in the vicinity of depleted uranium and

normal handling of this material do not result in exposures that exceed current standards. Nonetheless, unnecessarily close contact (such as carrying depleted uranium around in a pocket) should be avoided.

Public perception sometimes exaggerates these legitimate health and safety issues far beyond what seems technically justified. Such public concern over the radioactivity of depleted uranium has created an environment that is increasingly hostile to its use and is forcing serious consideration of other alternatives, such as tungsten heavy alloys.

## Tungsten and Tungsten Heavy Alloys

**Metallurgy and Applications.** While often considered an uncommon metal, tungsten makes up approximately 0.0069% of the earth's crust, roughly the same as copper. The primary ores--scheelite and wolframite--are typically pulverized and concentrated by flotation. The ore concentrate is then digested and reacted in several steps to form ammonium paratungstate (APT). This is calcined to form blue oxide ( $\text{WO}_3$ ), which is then reduced to metallic tungsten via hydrogen reduction.

Because of the extremely high melting point (3410 °C, or 6170 °F) of tungsten, virtually all commercial production of bulk shapes is done via powder metallurgy. For making tungsten rod stock, metallic powder is compacted at pressures typically between 150 and 600 MPa (20 and 85 ksi) to form a long billet. Following a light  $\text{H}_2$  presinter, the green billet is clamped into water-cooled electrodes for direct sintering in  $\text{H}_2$ . Currents exceeding 1350 A/cm<sup>2</sup> of the initial cross section are commonly required for adequate ohmic heating. Even at temperatures exceeding 3000 °C (5430 °F), full densification does not occur. This is accomplished by subsequent thermomechanical processing (hot swaging and reannealing), during which the stock is reduced to the required diameter. The final deformation step is typically accomplished by hot drawing to provide the desired surface finish.

Tungsten has a bcc crystal structure and is the only elastically isotropic metal known. The Young's modulus of tungsten is approximately 410 GPa (60 psi  $\times 10^6$ ), among the highest of all metals. Bulk tungsten exhibits a ductile-to-brittle transition in the range of 200 to 500 °C (390 to 930 °F), depending on processing history. As a result, it must be worked warm to avoid cracking. Heavily worked tungsten develops a more ductile fibrous microstructure, capable of being bent into tight radii without fracture. The strengths of small-diameter filaments can approach 4.1 GPa (590 ksi).

If heavily deformed tungsten is exposed to temperatures of approximately 1200 °C (2190 °F) or greater for sufficient time, recrystallization and segregation of dissolved impurities to grain boundaries occur, resulting in a return of brittle behavior. This is the principal reason that tungsten is generally considered nonweldable; cracking occurs in the fusion and heat-affected zones. When it is necessary to join tungsten to itself or other metals, mechanical fastening should be considered.

For specialized applications, a number of other alternative technologies exist for forming bulk tungsten shapes: arc melting and casting (sometimes using the skull approach), electron beam melting, chemical vapor deposition, and plasma spraying. Arc casting is often used for components requiring very high purity levels. Plasma spraying is currently utilized for the fabrication of axisymmetric thin-wall parts.

Tungsten provides the materials designer with the highest density of any nonradioactive, nonprecious metal. The extremely high melting point of tungsten also makes it the material of choice for incandescent lamp filaments, high-current electrical contacts, and electrodes for arc lamps and tungsten inert gas welding (also called gas tungsten arc welding, or GTAW). While pure tungsten can be used for all these cited applications, optimum performance is generally realized in doped, alloyed, or composited forms.

Lamp filaments are "AKS" doped with aluminum potassium silicate. This results in potassium bubble formation on grain boundaries, thereby promoting highly interlocking grains and extending useful filament life. Filaments intended for use in high-vibration or shock service contain 1 wt% dispersed thoria, providing boundary pinning points and enhanced high-temperature strength.

Electrical contacts are typically made from tungsten-copper or tungsten-silver composites formed by infiltration. The W-10Cu composite provides an excellent coefficient of thermal expansion match ( $6.5 \times 10^{-6}/\text{K}$ ) with major semiconductor packaging materials and thus is widely used as a high-dissipation, heat-sink material. Low expansion is derived from the tungsten phase, thermal conductivity is derived from the copper phase.

High-intensity, direct-current arc lamps typically utilize tungsten anodes and cathodes containing at least 1 wt% thoria for enhanced thermionic emission and minimization of recrystallization. Electrodes for GTAW likewise contain rare-earth oxides for greater emission, providing improved arc stability and extended life.

**Tungsten Heavy Alloy Processing and Properties.** Tungsten heavy alloys (WHAs) offer a number of advantages over the pure metal for inertial masses and for density-related applications such as radiation shielding. These alloys typically consist of 90 to 98 wt% W in a matrix consisting of nickel, iron, and/or cobalt. While slightly less dense than pure tungsten, WHAs can be readily fabricated into large, full-density components via liquid phase sintering (LPS) in  $H_2$  at temperatures of 1470 to 1580 °C (2680 to 2875 °F)--far below the temperature required to process the pure metal. In addition, virtually all WHAs are readily machinable, allowing the fabrication of complex geometries using common metalworking tools and techniques.

Tungsten heavy alloys are generally ductile, but are susceptible to hydrogen embrittlement by nature of the bcc structure of the principal phase. Consequently, hydrogen removal by vacuum annealing or other means will result in increased quasi-static ductility. Further processing by resolutionization and water quenching locks interstitial impurities in wider distribution for reduced segregation-induced embrittlement, thereby substantially improving fracture toughness.

While hot isostatic pressing and rapid consolidation techniques are applicable, WHAs are most commonly consolidated to full density by solid-state sintering or by liquid phase sintering (LPS). The former process is ideal for parts that require minimal thermal distortion and minimal mechanical properties. Liquid phase sintering provides a superior means of obtaining full density and improved mechanical properties, but much greater distortion ("slumping") occurs during LPS due to capillary action and/or gravity. The LPS process results in a microstructure consisting of spheroids (approximately 40 to 60  $\mu m$  in size) of nearly pure tungsten in an austenitic binder phase of transition metals plus dissolved tungsten, as shown in Fig. 2. This provides better mechanical properties due to less angular grains, lower tungsten-tungsten contiguity, and a greater percentage of metastable tungsten in the solid-solution binder. Tungsten-tungsten contact and interfacial embrittlement are the principal factors limiting mechanical properties of WHAs.

**Fig. 2** Typical microstructure of W-7Ni-3Fe heavy alloy consolidated by liquid phase sintering

The W-Ni-Cu system was the first heavy-alloy system developed and is still used occasionally for components that must exhibit minimal ferromagnetic character. By far the most important alloy system commercially is the W-Ni-Fe ternary. This family of alloys has been used for the full range of WHA applications, having higher mechanical properties than the earlier tungsten-nickel-copper alloys. Binder composition is important in that it strongly influences mechanical properties and determines which, if any, postsinter heat treatments will be needed. Nickel-iron ratios in the range of 2 to 4 are most common, as material in this range can be safely processed without concern for intermetallic precipitation in the binder and consequent embrittlement. Below a nickel-iron ratio of approximately 1.2, there is a risk of forming  $Fe_7W_6$  (a  $\mu$ -phase), depending on the time/temperature profile employed. Once formed, its thermochemical stability prevents its resolution at all practical processing temperatures.

Exceeding a nickel-iron ratio of  $\sim 5$  typically leads to  $Ni_4W$  precipitation for average sintering and cooling cycles. Unlike the iron-rich intermetallic, this nickel-rich compound can be readily resolutionized at approximately 1150 °C (2100 °F), making WHAs with higher nickel-iron ratios practical to process. Tungsten heavy alloys with nickel-iron ratios ranging from 6 to approximately 15 provide noticeably higher properties, but require both vacuum annealing and resolutionization/quenching. All WHAs will benefit from resolutionization/quenching even if not required by composition

for intermetallic control, as this procedure reduces the extent of segregation-induced embrittlement at interfaces caused by interstitials such as carbon, sulfur, and phosphorus, thereby enhancing alloy toughness.

For certain applications, the strength and hardness of unworked material are insufficient. While alternative methods of increasing strength are available (e.g., alloying with molybdenum), WHAs are most commonly swaged, extruded, forged, or upset to enhance strength and hardness (Table 3). Thus, there is a continuous set of mechanical properties available via the trade-off in ductility and toughness for strength and hardness. The greater the initial unworked property set, the greater the range of processing options.

**Table 3 Typical properties for the tungsten heavy alloy W-4.9Ni-2.1Fe**

Condition	Ultimate tensile strength		Elongation, %	Hardness, HRC	Charpy toughness, J
	MPa	ksi			
<b>As sintered</b>	860	125	15	29	...
<b>Vacuum annealed</b>	910	130	25	29	...
<b>Quenched</b>	930	135	32	29	230
<b>Swaged (15% RA)</b>	1115	160	16	39	150
<b>Swaged (25% RA)</b>	1200	175	14	40	110
<b>Swaged (25% RA) + aged 1 h at 500 °C (930 °F)</b>	1400	205	7	44	80

In response to the need for ever higher mechanical properties for heavy alloys (driven primarily by gun-fired, kinetic-energy penetrator requirements), the W-Ni-Co family of alloys was developed in the 1980s. Though requiring postsinter heat treatment, they can provide clearly superior mechanical properties (Table 4).

**Table 4 Property comparison of unworked tungsten heavy alloys**

Alloy	Ultimate tensile strength		Elongation, %	Hardness, HRC	Charpy toughness, J
	MPa	ksi			
<b>W-6.3Ni-2.7Fe</b>	940	135	35	29	300

**WHA Design Considerations and Applications.** The composite nature of the WHA microstructure carries several implications. Perhaps foremost is the mechanical consideration of notch sensitivity. Ideally, practical designs should not contain notches, threads, or corners with radii smaller than approximately 0.5 mm (0.2 in.). Otherwise, stress concentration will reduce mechanical strength. Though WHAs are not particularly susceptible, corrosion can nevertheless occur due to local galvanic activity between the tungsten phase and the electrochemically dissimilar austenitic binder phase if a suitable electrolyte is present. Highly alkaline solutions readily attack the tungsten phase. The mechanical mismatch of the composite structure also directly influences formability limits for metalworking operations. However, the elastic mismatch does serve to attenuate vibration--a valuable factor for high-stiffness, low-chatter WHA boring bars and tool holders.

Due to differences in both chemistry and melting point of the tungsten phase and the binder, WHAs are not readily weldable. Mechanical fastening should be employed whenever possible. Brazing of WHAs to dissimilar metals is possible, but the strength of the joint is typically low due to localized formation of embrittling intermetallics.

Tungsten heavy alloys are used in an increasingly wide array of products, including such diverse end uses as radiation collimation and shielding, balancing weights in aircraft and golf clubs, lead-free waterfowl shot, high-stiffness (modulus of  $\sim 380$  GPa, or  $55 \text{ psi} \times 10^6$ ) boring bars and tooling, kinetic-energy penetrators, gyroscope components, and vibration damping in disk-drive heads. These alloys are an ideal choice for applications requiring a combination of good machinability, high density, excellent thermal stability, moderate cost, and/or freedom from the toxicity considerations of lead and depleted uranium-base materials. As environmental and safety considerations become even more important

drivers in the planning of new products and applications, the fact that WHAs have only a slight percentage of their total weight in slightly toxic metals such as nickel and cobalt provides an incentive for their selection.

# Materials for Sliding Bearings

## Introduction

A SLIDING BEARING (plain bearing) is a machine element designed to transmit loads or reaction forces to a shaft that rotates relative to the bearing. Journal bearings are cylindrical (full cylinders or segments of cylinders) and are used when the load or reaction force is essentially radial (that is, perpendicular to the axis of the shaft). Thrust bearings are ring shaped (full rings or segments of rings) and are used when the load or reaction force is parallel to the direction of the shaft axis. Both radial and axial loads can be accommodated by flange bearings, which are journal bearings constructed with one or two integral thrust bearing surfaces. The sliding movement of the shaft surface or thrust-collar surface relative to the bearing surface is characteristic of all plain bearings. In many applications, plain bearings offer advantages over rolling-contact bearings--such as lower cost, smaller space requirements, the ability to operate with marginal lubricants, resistance to corrosion, and the ability to sustain high specific loads.

## Classifications

Sliding bearings are commonly classified by terms that describe their application, such as:

- Connecting-rod bearing
- Main bearing
- Camshaft bearing or bushing
- Electric motor shaft bushing
- Countershaft thrust washer

The terms "bearing" and "bushing" are used interchangeably and do not have meanings that are significantly different in terms of function or location in a machine.

With respect to size, sliding bearings are frequently classified as either thin wall (that is, thinner than  $\sim 5$  mm, or 0.2 in.) or heavy wall. In general, bearings with diameters  $>150$  mm ( $>6$  in.) are considered to be in the heavy-wall class. Configurations can be further described as half round, full round, flanged, or washer. The Society of Automotive Engineers (SAE) standards classify thin-wall bearings into three groups: sleeve-type half bearings, split-type bushings, and thrust washers.

Sliding bearings are also frequently classified according to material construction, as single-metal (solid), bimetal (two-layer), or trimetal (three-layer) bearings. These terms refer to the number of principal functional layers that are used. Each one of these types of construction is in widespread commercial use and in a wide variety of applications. The use of two or three separate layers provides a means for developing property combinations that cannot be obtained with single-metal bearings.

## Design and Selection

### *Wear Damage Mechanisms*

From the standpoint of bearing material design and selection, some or all of the following wear damage mechanisms must be considered:

- Surface fatigue wear
- Abrasive wear
- Adhesive wear
- Erosive wear
- Corrosion

The potential for wear damage is intimately linked to interactions among operating system characteristics that include:

- Magnitude of bearing loads
- Nature of load (cyclic or steady, unidirectional, or reversing)
- Speeds
- Lubricants and lubrication system characteristics
- Lubricant cleanliness and filtration
- Operating temperatures
- Counterface (shaft) material and finish
- Alignment and rigidity
- Life expectancy

More detailed information is available in articles describing sliding bearings in Volume 11, *Failure Analysis and Prevention*, and Volume 18, *Friction, Lubrication, and Wear Technology*, of the *ASM Handbook*.

### *Properties of Bearing Materials*

**Surface and Bulk Properties.** The conditions under which plain bearings must operate and the wide ranges over which these conditions can vary lead to concern about two kinds of bearing material properties: surface properties (those associated with the bearing surface and immediate subsurface layers) and bulk properties.

Conventional engineering definitions of material properties do not adequately describe the distinctive properties that are needed in materials for sliding bearings. Although there is no universally accepted system, of nomenclature, measurement or testing for these properties, they can be defined and studied in terms of the following characteristics:

- *Compatibility*: the antiwelding and antiscoring characteristics of a bearing material when operated with a given mating material
- *Conformability*: the ability of a material to yield to and compensate for slight misalignment and to conform to variations in the shape of the shaft or of the bearing-housing bore
- *Embeddability*: the ability of a material to embed dirt or foreign particles and thus prevent them from scoring and wearing shaft and bearing surfaces
- *Load capacity*: the maximum unit pressure under which a material can operate without excessive friction, wear, and fatigue damage
- *Fatigue strength*: the ability of a material to function under cyclic loading below its elastic limit without developing cracks or surface pits
- *Corrosion resistance*: the ability of a material to withstand chemical attack by uninhibited or contaminated lubricating oils
- *Hardness*: the ability to resist plastic flow under high unit compressive loads, conventionally measured by indentation hardness testing
- *Strength*: the ability to resist elastic and plastic deformation under load, conventionally measured by compression, shear, and tensile testing

Table 1 lists some of the more important relationships between bearing material properties and wear damage mechanisms. Compatibility can be regarded as a purely surface characteristic. Conformability and embeddability involve the surface and immediate subsurface and are strongly related to the bulk properties of strength and hardness. The other characteristics relate principally to bulk properties.

**Table 1 Influence of bearing material properties on wear damage mechanisms**

Bearing material property	Damage mechanisms counteracted	Causes
<b>Compatibility</b>	Adhesive wear	Asperity contact, surface roughness, inadequate oil film
<b>Conformability</b>	Adhesive wear, surface fatigue wear	Misalignment, edge loading, faulty assembly, geometric errors
<b>Embeddability</b>	Abrasive wear, adhesive wear	Dirt particles in oil, scoring
<b>Fatigue strength</b>	Surface fatigue wear	Excessive dynamic load, localized overload (for example, misalignment)
<b>Hardness</b>	Extrusion, erosive wear	Overheating, excessive load, cavitation effects
<b>Corrosion resistance</b>	Corrosive wear	Lubricant deterioration (overheating), lubricant contamination (water, fuel, refrigerant, combustion products)

**Measurement and Testing.** Of the six characteristics listed in Table 1, only hardness can be measured satisfactorily by standard laboratory test methods. Many special dynamic test rigs and test methods have been developed by the plain bearing industry to evaluate and to measure the other characteristics and their interactions. Most of these testing systems are designed to subject specimen bearings to operating conditions that are qualitatively similar to the conditions of intended service, but quantitatively more severe with respect to one or several parameters, such as: magnitude of load, surface speed, operating temperature, lubricant supply, and lubricant cleanliness.

Although much useful information has been developed through laboratory rig testing, it still is often necessary to test bearing materials and designs in full-size operating machines to clearly establish their overall suitability. Such testing is necessarily expensive and time consuming. It should be undertaken only after careful study both of the conditions under which the bearing will operate and of prior experience in similar applications.

**Bearing Material Microstructures.** All commercial significant bearing metals, with the exception of silver, are polyphase alloys. As indicated below, these polyphase alloys can be classified according to basic microstructural types.

- *Type I: Soft Matrix with Discrete Hard Particles.* Lead and tin babbitts are of this type.
- *Type II: Interlocked Soft and Hard Continuous Phases.* Many copper-lead and leaded bronze alloys are of this type.
- *Type III: Strong Matrix with Discrete Soft-Phase Pockets.* Low-lead bronzes and some aluminum-tin

alloys are of this type.

- *Mixed microstructures* that combine the characteristics of types I and III are exhibited by Al-Si-Sn alloys and Al-Si-Pb alloys.

**Effects of Multilayer Construction.** One of the most useful concepts in bearing material design came in 1941 with the recognition that the effective load capacities and fatigue strengths of lead and tin alloys are sharply increased when these alloys are used as thin layers intimately bonded to strong bearing backs of bronze or steel. Use is made of this principle (Fig. 1) in two-layer constructions using a surface layer of lead or tin alloy, usually no more than 0.13 mm (0.005 in.) thick. Unimpaired compatibility is provided by such a layer, together with reasonably high levels of conformability and embeddability. Other useful compromises can be effected between surface and bulk properties by employing an intermediate copper or aluminum alloy layer between the surface alloy layer and a steel back. In these three-layer constructions, use of a surface layer thickness as low as 0.013 mm (0.0005 in.) offers even more favorable compromises between surface and bulk properties than are possible with two-layer constructions.

**Fig. 1** Plot of bearing fatigue life versus thickness of a lead alloy babbitt surface layer as a function of the number of layers used. Bearing load, 14 MPa (2 ksi)

**Heat and Temperature Effects.** The reduced mechanical strength of bearing liner materials at elevated temperatures is an important consideration in the selection of a bearing material for a given application. Fatigue strength, compressive yield strength, and hardness decrease significantly with increased bearing operating temperature. Low-melting, lead-base, and tin-base bearing alloys are most severely limited in this respect, and copper alloys are limited the least. Aluminum alloys have high-temperature bearing properties intermediate to those of lead/tin and copper alloys (Fig. 2).

**Fig. 2** Strength retention at elevated temperatures for aluminum-base bearing alloys

## Bearing Material Systems

Because of the widely varying conditions under which bearings must operate, commercial bearing materials have evolved as specialized engineering materials systems rather, than as commodity products. They are used in relatively small tonnages and are produced by a relatively small number of manufacturers. Much proprietary technology is involved in alloy formulation and processing methods, the latter of which includes casting processes (strip, continuous, and centrifugal casting), powder metallurgy (continuous sintering, impregnation and infiltration, and powder rolling), and roll bonding. Successful selection of bearing material and/or processing methods for a specific application often requires close technical cooperation between the user and the bearing producer.

### ***Single-Metal System***

Most single-metal sliding bearings are made from either copper alloys or aluminum alloys. Some use is also made of cast zinc-base alloys, which serve as lower-cost substitutes for solid bronze.

Single-metal systems do not exhibit outstandingly good surface properties, and their tolerance of boundary and thin-film lubrication conditions is limited. As a result, the load capacity rating for a single-metal bearing usually is low relative to the fatigue strength of the material from which it was made. Because of their metallurgical simplicity, these materials are well suited for small-lot manufacturing from cast tubes or bars, using conventional machine shop processes.

**Copper Alloys.** Except for commercial bronze and low-lead tin bronze, copper alloys in single-metal systems are almost always used in cast form. This provides thick bearing walls ( $\geq 3.20$  mm, or 0.125 in.) that are strong enough so that the bearing is retained in place when press fitted into the housing.

Commercial bronze and medium-lead tin bronze alloys C83420 and C83520 are used extensively in the form of wrought strip for thin-wall bushings, which are made in large volumes by high-speed press forming. The relatively poor compatibility of these alloys can be improved by embedding a graphite-resin paste in rolled or pressed-in indentations, so that the running surface of the bushing consists of interspersed areas of graphite and bronze. Such bushings are widely used in automotive engine starting motors.

The lead in leaded tin bronzes is present in the form of free lead that is dispersed throughout a copper-tin matrix so that the bearing surface consists of interspersed areas of lead and bronze. In general, the best selection of materials from this group for a given application will be the highest-lead composition that can be used without risking excessive wear, plastic deformation, or fatigue damage.

**Aluminum Alloys.** Virtually all solid aluminum bearings used in the United States are made from alloys containing from 5.5 to 7% Sn, plus smaller amounts of copper, nickel, silicon, and magnesium. Starting forms for bearing fabrication include cast tubes as well as rolled plate and strip, which can be press formed into half-round shapes. As is the case with solid bronze bearings, relatively thick bearing walls are employed in solid aluminum alloy bearings.

The tin in these alloys is present in the form of free tin that is dispersed throughout an aluminum matrix so that the bearing surfaces consist of interspersed areas of aluminum and tin. Surface properties are enhanced by the free tin in much the same way that those of bronze are improved by the presence of free lead.

The high thermal expansion of aluminum poses special problems in maintaining press fit and running clearances. Various methods are employed for increasing yield strength (for example, heat treatment and cold work) to overcome plastic flow and permanent deformation under service temperatures and loads.

**Zinc Alloys.** During the past 20 years, Zn-Al-Cu casting alloys have been used to replace cast bronze alloys in certain low-speed machinery bearing applications. These alloys do not contain any soft microconstituents that correspond to the lead used in bearing bronzes and to the tin in cast aluminum bearing alloys. To a considerable degree, compatibility of the zinc-base alloys seems to derive from their chemical behavior with hydrocarbon lubricants.

**Porous Metal Bushings.** Oil-impregnated porous metal bushings (self-lubricating bearings) can also be included in the single-metal systems category. The materials used for these bushings include unleaded and leaded tin-bronze, bronze-graphite, iron-carbon, iron-copper, and iron-bronze-graphite compositions.

### ***Bimetal Systems***

All bimetal systems employ a strong bearing back to which a softer, weaker, relatively thin layer of a bearing alloy is metallurgically bonded. Low-carbon steel is by far the most widely used bearing-back material, although alloy steels, bronzes, brasses, and (to a limited extent) aluminum alloys are also used. When steel bearing backs are employed, load-capacity ratings for both copper and aluminum alloys are sharply increased above those of the corresponding single metals without degrading any other properties.

Bronze-back materials do not exhibit combinations of performance characteristics substantially different from those of steel-back bearings. The practical advantages of bronze as a bearing-back material lie partly in the economics of small-lot manufacturing and partly in the relative ease with which worn bronze-back bearings can be salvaged by rebabbiting and remachining. From the standpoint of performance, the advantage of bronze over steel as a bearing-back material is the protection bronze affords against catastrophic bearing seizure in case of severe liner wear or fatigue. Similar protection is provided by using an aluminum alloy bearing back.

Although the surface properties of bronze bearing-back materials are not impressive, they are superior to those of steel, and these "reserve" bearing properties can be of considerable practical importance in large expensive machinery used in certain critical applications.

**Trimetal Systems**

Virtually all trimetal systems employ a steel bearing back, an intermediate layer of relatively high strength, and a tin alloy or lead alloy surface layer. Most of these systems are derived from steel-backed bimetal systems by the addition of a lead-base or tin-base surface layer.

The strengthening effects of thin-layer construction are notable in those systems that incorporate electroplated lead alloy surface layers  $\leq 0.025$  mm ( $\leq 0.001$  in.) thick. Comparison of fatigue strength and load capacity ratings of these systems with those of the corresponding bimetal systems shows that the thin lead alloy surface layer upgrades not only surface properties but also fatigue strength. The increase in fatigue strength can be attributed at least in part to the elimination of stress raisers, from which fatigue cracks can propagate.

Trimetal systems with electroplated lead-base surface layers and copper or aluminum alloy intermediate layers provide the best available combinations of cost, fatigue strength, and surface properties. Such bearings have high tolerances for boundary and thin-film lubrication conditions, and thus can be used under higher loads than can any of the bimetal systems.

**Bearing Materials**

**Tin-Base Alloys**

Tin-base bearing materials (babbitts) are alloys of tin, antimony, and copper that contain limited amounts of zinc, aluminum, arsenic, bismuth, and iron. The compositions of tin-base bearing alloys, according to ASTM B 23, SAE, and ISO specifications, are shown in Table 2.

**Table 2 Designations and nominal composition of tin-base bearing alloys**

Designation <sup>(a)</sup>			ASTM (B 23)	Composition, %				Product form	Applications

(a) UNS, unified numbering system; SAE, Society of Automotive Engineers; ISO, International Organization for Standardization; ASTM, American Society for Testing and Materials

The presence of zinc in these bearing metals generally is not favored. Arsenic increases resistance to deformation at all temperatures; zinc has a similar effect at 38 °C (100 °F) but causes little or no change at room temperature. Zinc has a marked effect on the microstructures of some of these alloys. Small quantities of aluminum (even <1%) will modify their microstructures. Bismuth is objectionable because, in combination with tin, it forms a eutectic that melts at 137 °C (279 °F). At temperatures above this eutectic, alloy strength is decreased appreciably.

Table 3 shows bulk mechanical properties of ASTM grades 1 to 3. These properties have some value for initial materials screening comparisons of alloys; but they are not reliable predictors of the performance of thin layers bonded to a strong backing, which is the manner in which tin-base babbitts are usually used in modern bearing practice. Layer thickness effects (Fig. 1) and temperature effects (Fig. 2) are more important practical considerations than the mechanical property differences among the various alloy compositions.

Compared with most other bearing materials, tin alloys have low resistance to fatigue, but their strength is sufficient to warrant their use under low-load conditions. These alloys are commercially easy to bond and handle and they have excellent antiseizure qualities. Their excellent corrosion-resistant properties make these alloys especially well-suited for bearing applications in compressors, electric motors, and food-processing equipment.

### Lead-Base Alloys

Lead-base bearing materials (lead babbitts) are alloys of lead, tin, antimony, and in many cases arsenic. Many such alloys have been used for centuries as type metals and were probably first employed as bearing materials because of the properties they were known to possess. The advantage of arsenic additions have been generally recognized since 1938. Table 4 lists nominal compositions of the most widely used lead babbitts according to ASTM, SAE, and ISO specifications. Mechanical properties of some of these alloys are given in Table 5.

For many years, lead-base bearing alloys were considered to be only low-cost substitutes for tin alloys. However, the two groups of alloys do not differ greatly in antiseizure characteristics, and when lead-base alloys are used with steel backs and in thicknesses <0.75 mm (<0.03 in.), they have fatigue resistance that is equal to, if not better than, that of tin alloys. Bearings of any of these alloys remain serviceable longest when they are  $\leq 0.13$  mm ( $\leq 0.005$  in.) thick (see Fig. 1).

In the absence of arsenic, the microstructures of these alloys comprise cuboid primary crystals of SbSn or of antimony embedded in a ternary mixture of Pb-Sb-SbSn in which lead forms the matrix. The number of these cuboids per unit volume of alloy increases as antimony content increases. If antimony content is >15%, the total amount of the hard constituents increases to such an extent that the alloys become too brittle to be useful as bearing materials.

Arsenic is added to lead babbitts to improve their mechanical properties, particularly at elevated temperatures. All lead babbitts are subject to softening or loss of strength during prolonged exposure to the temperatures (95 to 150 °C, or 200 to 300 °F) at which they serve as bearings in internal combustion engines. Addition of arsenic minimizes such softening. Under suitable casting conditions, the arsenical lead babbitts--for example, SAE 15 (ASTM grade 15)--develop remarkably fine and uniform structures. They also have better fatigue strength than arsenic-free alloys.

Pouring temperature and rate of cooling markedly influence the microstructures and properties of lead alloys, particularly when they are used in the form of heavy liners for railway journals. High pouring temperatures and low cooling rates, which typically result from the use of overly hot mandrels, promote segregation and formation of a coarse structure. A coarse structure may cause brittleness, low compressive strength, and low hardness. Therefore, low pouring temperatures (325 to 345 °C, or 620 to 650 °F) usually are recommended. Because these alloys remain relatively fluid almost to the point of complete solidification ( $\sim 240$  °C, or 465 °F, for most compositions), they are easy to manipulate and can be handled with no great loss of metal from drossing.

**Lead-Base Electroplated Overlays.** The improvement in fatigue life that can be achieved by decreasing babbitt layer thickness has already been noted. Economically as well as mechanically, it is difficult to consistently achieve very thin uniform babbitt layers bonded to bimetal shells by casting techniques. Therefore, the process of electroplating a thin precision babbitt layer on a very accurately machined bimetal shell was perfected. Specially designed plating racks allow the thickness of the plated babbitt layer to be regulated so accurately that further machining is usually not required.

Electroplated tin alloys were found to be generally inferior to lead alloys, and only lead alloys are in commercial use as electroplated bearing overlays. SAE alloy 192 (88Pb10Sn2Cu) is the most frequently used. Tin in alloys 191 (90Pb10Sn), 192 and 193 (80Pb18Sn2Cu) and indium in alloy 194 (93Pb7In) imparts corrosion resistance. Tin also increases wear resistance. Both copper and indium enhance fatigue resistance. Plated overlays generally range in thickness from 0.013 to 0.05 mm (0.0005 to 0.002 in.), with fatigue life increasing markedly as overlay thickness decreases.

## Copper-Base Alloys

Copper-base bearing alloys comprise a large family of materials with a wide range of properties. They include commercial bronze, copper-lead alloys, and leaded and unleaded tin bronzes. They are used alone in single-metal bearings, as bearing backs with babbitt surface layers, as bimetal layers bonded to steel backs, and as intermediate layers in steel-backed trimetal bearings.

The moderate strength and hardness of pure copper are readily increased by alloying, most commonly with tin (with which copper forms a solid solution). Lead is present in cast copper-base bearing alloys as a nearly pure, discrete phase, because its solid solubility in the matrix is practically nil. The lead phase, which is exposed on the running surface of a bearing, constitutes a site vulnerable to corrosive attack under certain operating conditions.

The antifriction behavior of copper-base bearing alloys improves as lead content increases, although at the same time strength is degraded because of increased interruption of the continuity of the copper alloy matrix by the soft weak lead. Thus, through judicious control of tin content, lead content, and microstructure, a large family of bearing alloys has evolved to suit a wide variety of bearing applications.

Table 6 gives specification numbers and nominal compositions of copper-base bearing alloys, as well as the forms in which the alloys are used and general notations on typical product applications. Table 7 shows the ranges of mechanical strength properties that are exhibited by copper-base bearing alloys.

**Commercial Bronze.** Lead-free copper alloys are characterized by poor antifriction properties but fairly good load-carrying ability. Wrought commercial bronze strip (SAE 795) with 10% Zn can be readily press formed into cylindrical bushings and thrust washers. Strength can be increased by cold working this inexpensive material.

**Unleaded Tin Bronze.** The unleaded copper-tin alloys are known as phosphor bronzes because they are deoxidized with phosphorus. They are used principally in cast form as shapes for specific applications, or as rods or tubes from which solid bearings are machined. They have excellent strength and wear resistance, both of which improve with increasing tin content, but poor surface properties. They are used for bridge turntables and trunnions in contact with high-strength steel and in other slow-moving applications.

**Low-Lead Tin Bronzes.** The inherently poor machinability of tin bronzes can be improved by adding small amounts of lead. Such additions do not significantly improve surface properties, however, and applications for these alloys are essentially the same as those for unleaded tin bronzes.

**Medium-Lead Tin Bronzes.** The only wrought strip material in this group of alloys is SAE 791, which is press formed into solid bushings and thrust washers. C83600 is used in cast form as bearing backs in bimetal bearings. SAE 793 is a low-tin, medium-lead alloy that is cast or sintered on a steel back and used as a surface layer for medium-load bimetal bushings. SAE 792 is higher in tin and slightly higher in lead; it is cast or sintered on a steel back and used for heavy-duty applications such as wrist pin bushings and heavy-duty thrust surfaces.

**High-Lead Tin Bronzes.** These contain medium-to-high amounts of tin and relatively high lead contents to markedly improve antifriction characteristics. SAE 794, widely used in bushings for rotating loads, has the same bronze matrix composition as SAE 793 (4.5% Sn) but three times as much free lead. It is cast or sintered on a steel back and used for somewhat higher speeds and lower loads than alloy 793. The bronze matrix of SAE 794 is much stronger than that of a

plain 75-25 copper-lead alloy. Alloy 794 can be used as the intermediate layer with a plated overlay in heavy-duty trimetal bearing applications such as main and connecting-rod bearings in diesel truck engines. This construction provides the highest load-carrying ability available in copper alloy trimetal bearings.

**Copper-Lead Alloys.** These are used extensively in automotive, aircraft, and general engineering applications. These alloys are cast or sintered to a steel backing strip from which parts are blanked and formed into full-round or half-round shapes depending on final application. Copper-lead alloys continuously cast on steel strip typically consist of copper dendrites perpendicular and securely anchored to the steel back, with an interdendritic lead phase. In contrast, sintered copper-lead alloys of similar composition are composed of more equiaxed copper grains with intergranular lead phase.

High-lead alloy SAE 48 can be used bare on steel or cast iron journals. Tin content in this alloy is restricted to a minimum value to maintain a soft copper matrix, which together with the high lead content improves the antifriction/antiseizure properties of the alloy. Bare bimetal copper-lead bearings are used infrequently today because the lead phase, present as nearly pure lead, is susceptible to attack by corrosive products that can form in the crankcase lubricant during extended oil-change periods. Therefore, most copper-base alloys with lead contents >20%, including both SAE alloy 48 and alloy 49, are now used with plated overlays in trimetal bearings for automotive and diesel engines.

SAE 485 is a special sintered and infiltrated composite material. By these methods, it is possible to combine a very strong continuous copper alloy matrix structure with a very high lead content and to alloy the lead-rich constituent with sufficient tin to make it resistant to corrosion. SAE 485 is used principally for bushing and bearing applications that involve alignment, shaft surface finish, or unusual dirt contamination problems.

### Aluminum-Base Alloys

Successful commercial use of aluminum alloys in plain bearings dates back to about 1940, when low-tin aluminum alloy castings were introduced to replace solid bronze bearings for heavy machinery. Production of steel-backed strip materials by roll bonding became commercially successful about 1950, permitting the development of practical bimetal and trimetal bearing material systems using aluminum alloys in place of babbits and copper alloys.

The ready availability of aluminum and its relatively stable cost have provided an incentive for continuing development of its use in plain bearings. Aluminum single-metal, bimetal, and trimetal systems can now be used in the same load ranges as babbits, copper-lead alloys, and high-lead tin bronzes. Moreover, the outstanding corrosion resistance of aluminum has become an increasingly important consideration in recent years and has led to widespread use of aluminum alloy materials (in the place of copper-lead alloys and leaded bronzes) in automotive engine bearings.

**Designations and Compositions.** Alloy designations and nominal compositions of aluminum-base alloys in most extensive commercial use are listed in Table 8. In these alloys, additions of silicon, copper, nickel, magnesium, and zinc function to strengthen the aluminum through solid-solution and precipitation mechanisms. Fatigue resistance and the opposing properties of conformability and embeddability are largely controlled by these elements and by the use of appropriate heat treatments. Tin and lead are instrumental in upgrading the inherently poor compatibility of aluminum. Cadmium is also used as an alloy addition for this reason. Silicon has a beneficial effect on compatibility in addition to its moderate strengthening effect. Although not well understood theoretically, this compatibility-enhancing mechanism is of considerable practical value. Silicon is used effectively in many alloys for this reason (usually in conjunction with tin, lead, or cadmium).

**Mechanical properties** are of more value in predicting the fabrication behavior of aluminum-base bearing alloys than in predicting their bearing performance. With the exception of solid aluminum alloy bearings, in which there is no steel back and where press-fit retention depends entirely on the strength of the aluminum alloy, mechanical properties of finished bearings are rarely specified, usually for control purposes only. Consideration of some of these properties (Table 9) does, however, contribute to an understanding of these alloys as a family of related engineering materials and of their relationship to the better-known structural aluminum alloys in addition to the copper-base, tin-base, and lead-base bearing alloys discussed previously.

**Product Applications.** The majority of the current commercial applications of aluminum-base bearing alloys involve steel-backed bimetal or steel-backed trimetal bearings. To determine the most cost-effective aluminum material for any specific application, consideration should be given to the economic advantages of bimetal versus trimetal systems. The higher cost of the high-tin and high-lead alloys usually is offset by eliminating the cost of the lead alloy overlay plate. If the higher load capacity of a trimetal material is required, it then becomes important to select an aluminum liner alloy that provides adequate but not excessive strength, so that conformability and embeddability are not sacrificed unnecessarily. The tin-free alloy group (alloys 16 to 20 in Table 8) offers a wide range of strength properties, and the most economical choice usually is found in this group.

### **Other Bearing Materials**

**The zinc-base alloys** that have been used successfully for machinery bearings are standard zinc foundry alloys of the Zn-Al-Cu-Mg, high-performance type (alloys ZA-12 and ZA-27). Tubular shapes made by conventional sand, permanent mold, and pressure die-casting methods are machined into bearings in the same way that solid bronze bearings are made. Most applications have been direct substitutions for solid bronze bearings; the substitutions are made primarily to reduce costs. Maximum recommended running temperatures for zinc-base bearing alloys range from 95 to 120 °C (205 to 250 °F), which is approximately 100 °C (180 °F) below the temperature limits for copper-base and aluminum-base bearing alloys.

**Silver-Base Alloys.** Use of silver in bearings is largely confined to unalloyed silver (AMS 4815) electroplated on steel shells, which then are machined to very close dimensional tolerances and finally precision plated to size with a thin overlay of soft metal. The overlay can be lead-tin, lead-tin-copper, lead-indium, or in some cases, pure lead. As a bearing material, plated silver is invariably used with an overlay. Silver on steel with an overlay is regarded as the ultimate fatigue-resistant bearing material.

**Gray cast irons** are standard materials for certain applications involving friction and wear (for example, brake drums, piston rings, cylinder liners, and gears). Cast irons perform well in such applications and thus should be given consideration as bearing materials.

**Cemented Carbides.** Extremely hard materials, including cemented tungsten carbides, titanium carbides, and other combinations have been used successfully for various specialized bearing and seal applications. In terms of the bearing performance characteristics listed in Table 1, these materials exhibit essentially zero conformability and embeddability, but rank high in strength, hardness, corrosion resistance, and compatibility.

**Nonmetallic bearing materials** are widely used for a variety of applications. They have many inherent advantages over metals, including better corrosion resistance, lighter weight, better resistance to mechanical shock, and the ability to function with very marginal lubrication or with no lubricant present at all. The major disadvantages of most nonmetallics

are their high coefficients of thermal expansion and their low thermal conductivity characteristics. For many years, carbon-graphites, wood, rubber, and laminated phenolics dominated the field of nonmetallic bearing materials. In the early 1940s, development of nylon and polytetrafluoroethylene (PTFE, or Teflon) gave engineering designers two new nonmetallics with very unique characteristics, particularly the ability to operate dry.

A wide variety of polymer composites is now being used very successfully in bearing applications. The addition of fiber reinforcements and fillers such as solid lubricants and metal powders to the resin matrix can significantly improve the physical, thermal, and tribological properties of these plastics.

## Introduction

BIOMATERIALS are the man-made metallic, ceramic, and polymeric materials used for intracorporeal applications in the human body. Intracorporeal uses may be for hard tissue or soft tissue replacement. Metallic materials are the primary focus in this section; limited information is provided on ceramics, polymers, composites, cements, and adhesives, especially where they interact with metallic materials.

Metals frequently are used in the body for orthopedic purposes--such as hip stems and balls, knees, and so on--where hard tissue (bony structures) must be repaired or replaced. Metals also find application as stents (in angioplasty), leads and cases (in pacemakers), and surgical clips or staples. Dental applications of metals center around amalgam or gold to repair cavities or replace broken teeth, titanium alloys for posts on which to fix crowns or bridges, and nickel-chromium alloys and cobalt-chromium alloys for crowns and bridgework, partial dentures, or as the basis for porcelain-coated alloy teeth. Stainless steel and a few other alloys find use as wires and sheet in orthodontics.

Ceramics are used as the ball in the articulating region of a hip joint, as bioactive coatings on implants, and in certain aspects of dental use--for example, as fillers or for porcelain enameling (a ceramic process). Carbon finds use in heart valves and dental implants. As for polymeric materials, silicone has been used in joint replacement, polymethyl methacrylate (PMMA) as a cement (grout), and ultrahigh molecular-weight polyethylene (UHMWPE) as the acetabular cup in hip joints. Composite materials, particularly polymeric material composites, are used in dental applications, but their use is limited elsewhere in the body. Composites or ceramics intended to resorb in the body have been shown to have potential application. Resorbable materials in the body are not new; resorbable sutures have been in use for many years.

**Body Conditions.** Temperature conditions are not extreme for the materials used, body temperatures being a little less than 38 °C (100 °F). However, the chemical physiological environment and biomechanical environment can be extreme. For structural implants used to repair the hip, it is estimated that the average nonactive person may place  $1$  to  $2.5 \times 10^6$  cycles of stress on his or her hip in a year. For a person 20 to 30 years of age, with a life expectancy of 70 to 80 years, that is the equivalent of approximately  $10^8$  cycles of loading in a lifetime. The actual loads and cycles are a function of the weight and activity level of the person, but the need for longtime cyclic capability in fatigue is obvious. Other applications in the body also impart many millions of fatigue cycles to the device or component implanted.

In considering the parameters of materials for intracorporeal applications, several factors are of major importance. It is generally agreed that the material must:

- Be nontoxic and noncarcinogenic, cause little or no foreign body reaction, and be chemically stable and corrosion resistant. This is known as biocompatibility.
- Be able to endure large and variable stresses in the highly corrosive environment of the human body
- Be able to be fabricated into intricate shapes and sizes

Many structural applications of materials in the body require that the replacement material fit into a space perhaps only one-fourth the area of the part being permanently or temporarily replaced or assisted. Consequently, the implant may have to withstand loads up to 16 or more times that which the human bone must withstand. In restorative dentistry, high compressive biting forces are combined with large temperature changes and acidity to produce a challenging environment. It is clear that there can be very great mechanical loading demands on biomaterials used for structural purposes.

The chemical structure of the body can cause corrosive attack, which may degrade the implant and/or cause release of ions that may adversely affect the body. This chemical interaction is described in terms of the biocompatibility of the biomaterial. Biocompatibility must consider the release of ions or molecules, the mobility of released species, and the interaction of released species or material surfaces with the body. Some ions or molecules are severely detrimental to the body. Among other things, a material might be carcinogenic, be thrombogenic (cause clotting), cause cell mutations, produce a fever, or cause sensitization. Ions released could cause tissue necrosis. The essence of developing a biomaterial has been to find a material with the necessary mechanical and/or physical properties that cause no damage, or a limited amount, to the human body.

**Mechanical Behavior.** Metals generally are required to have both high static and cycle-dependent properties. Tensile yield and ultimate strength, modulus of elasticity, and fatigue endurance limit are the principal metallic strength attributes that must be determined. Temperature is not an issue. For dental materials, which experience very high point forces in the mouth, creep and compressive yield strengths are important. Ceramics offer excellent compressive yield, and thus are often used for such applications. Tension and bending or tension fatigue are not primary strength attributes for study in ceramics because tensile loads cause relatively rapid nonductile crack propagation.

Important mechanical properties of polymeric materials include tensile strength, creep strength, modulus, and fatigue strength. Creep can be important because the operating temperature of the body is a significant fraction of the melting or glass transition temperature for polymers. The first polymeric material (Teflon) used for an acetabular cup failed because of extreme distortion due to creep.

Wear resistance is also an important criterion for all biomaterials. Excessive wear can lead to premature mechanical failure of the replacement component. More importantly, wear debris may not be biocompatible with the body.

Under ideal conditions, mechanical property tests would be made in environments identical to that in the human body (i.e., in vivo). Practically, mechanical property tests are run either in normal air environments or, where the degrading effects of environment must be evaluated, in simulated human physiological solutions.

**Corrosion.** Metals used as biomaterials must be either noble or corrosion resistant to the body environment. Many types of corrosion have been observed on biomaterials used in the body, including general corrosion, pitting and crevice corrosion, stress-corrosion cracking, corrosion fatigue, and intergranular corrosion. None of these forms, with the exception of general corrosion, can be tolerated in surgical implant materials. For a material to be considered resistant to corrosion in the body, its general corrosion rate usually must be less than 0.01 mil/year (0.00025 mm/year). For comprehensive discussions of corrosion testing procedures and results, see the articles "Corrosion of Metallic Implants and Prosthetic Devices" and "Tarnish and Corrosion of Dental Alloys" in *Corrosion*, Volume 13 of the *ASM Handbook*.

Corrosion testing of ceramic materials is not common practice because the corrosion of oxide ceramics used for structural implants is very low. However, ceramics do show degradation of properties in vivo. Polycrystalline ceramics of the alumina type show loss in static strength when exposed to body fluids. This strength loss is a form of environmental degradation. Generally, the greater the purity and the greater the density (lesser porosity) of a ceramic, the more resistant it is to strength loss in the body. Bioactive ceramics represent a different aspect of corrosion because they are expected to transform into bony structures by gradually releasing their cations and anions to be incorporated in the growing bone or tissue structure. Corrosion testing is not implicitly required for bioactive ceramics.

Polymeric materials are not necessarily subjected to what is normally defined as corrosion; nevertheless, they do break down in the body. The result can be tissue interaction with residual monomers remaining after polymerization, chemical degradation of molecular structure of the polymer, and leaching of additives such as plasticizers, fillers, and colorants. Some polymers are designed to degrade (resorb) in the body; others degrade but are not intentionally designed to do so. The deterioration of polymers can affect the main polymer chain, cross links, and side groups. Sometimes, undesirable cross linking can occur and degrade a linear polymer, while in other cases a desired cross link is broken by interaction of thermal energy or other elements (e.g., oxygen) with the polymer. Some polymers absorb lipids or interact with proteins; hydrolysis occasionally can occur.

The body environment is quite hostile to man-made materials, and polymers will start to degrade as soon as they are implanted. Hydroxyl ( $\text{OH}^-$ ) ion attack or interactions with dissolved oxygen are the principal chemical sources of polymer degradation. The degradation of polymers in the body is much more complex than the attack of metals and ceramics.

**Regulatory Issues.** Biomaterials cannot be separated from the regulatory processes that govern their use. It can take years to gain approval for new materials if they are substantially different from any used and approved previously. Because the approval process can be costly, biomaterials development and application tend to follow existing tracks or at least claim to be doing so when regulatory approval is requested.

## Metallic Biomaterials for Implants

Metals have been successfully used as biomaterials for many years. Figures 1, 2, and 3 show typical implant applications for orthopedic purposes. Figure 4 shows intramedullary rods and illustrates their use for fracture fixation. There are numerous other structural metallic implants.

**Fig. 1** Diagram of total hip and knee replacements showing component shape and location of implantation

**Fig. 4 Intramedullary rods and locking nails applied to tibia or femur**

Hip arthroplasty generally requires that the upper femur (thigh bone) be replaced and the mating pelvis (hip bone) area replaced or resurfaced. Femoral components usually are manufactured from cobalt-chromium or titanium alloys. The ball (articulating portion of the femoral component) is made either of highly polished cobalt-chromium alloys or of ceramic. Modular designs where the stem and ball are of two different materials are common. Similarly, the polymeric socket of the common acetabulum replacement can be implanted directly in the pelvis or be part of a modular arrangement wherein the cup is placed into a metal shell. Design variations include the modular approach, straight stems, curved stems, platforms and no platforms, holes and no holes in the femoral stem, and so on.

Relatively few metals in industrial use are biocompatible and capable of long-term success as an implant in the body. For structural applications in the body, the principal metals are AISI 316L stainless steel, cobalt-chromium alloys originating from modifications of the alloy Vitallium (Haynes Stellite Alloy No. 21), and Ti-6Al-4V. There are limited uses for gold. Tantalum finds use as cranial plates or surgical staples (along with stainless steel), as do four grades of commercial-purity titanium. Table 1 lists the compositions of alloys used as implantable biomaterials; Table 2 indicates relative strengths for these alloys. The overall chemistry and properties of metallic materials generally are covered by ASTM specifications. Table 3 lists selected ASTM specifications dealing with implantable biomaterials.

**Table 3 Selected ASTM specifications dealing with biomaterials**

ASTM No.	Biomaterial
----------	-------------

<b>F 55, F 138</b>	Low-carbon stainless steels (type 316L)
<b>F 75, F 90</b>	Cobalt-chromium alloys
<b>F 67</b>	Commercially pure titanium
<b>F 136</b>	Ti-6Al-4V
<b>F 451</b>	Acrylic bone cement
<b>F 560</b>	Unalloyed tantalum
<b>F 603</b>	High-purity dense aluminum oxide
<b>F 648</b>	Ultra-high molecular-weight polyethylene (UHMWPE)
<b>F 881</b>	Silicone gel and solid silicone

Fatigue and yield strengths vary not only by alloy type (e.g., stainless steel versus titanium) but also with processing. The modulus, however, is more or less set by the alloy type. The lowest moduli (110 to 125 GPa, or  $16$  to  $18 \times 10^6$  psi) are for titanium alloys, while stainless steels have moduli near 205 GPa ( $30 \times 10^6$  psi), and cobalt-chromium alloys have moduli even higher, approximately 240 GPa ( $35 \times 10^6$  psi). The modulus is an important concern in the orthopedic application of biomaterials. Bone has a modulus on the order of 17 GPa ( $2.5 \times 10^6$  psi). The discrepancy between the modulus of bone and that of the alloys used to support structural loads means that the metallic devices implanted in the body take a disproportionate share of the load (stress). Bone adapts to applied stress (Wolff's Law). Because alloys cause stress shielding one result of the adaptation is that the bone associated with the implant does not become or remain as strong as it would in the absence of an implant. The ideal alloy would have the modulus of magnesium, the strength of cobalt-chromium alloys, the corrosion resistance and biocompatibility of titanium, and the fabricability of stainless steel.

Alloys used in articulating prosthesis applications are often used in conjunction with other biomaterials such as UHMWPE, polyoxymethylene (Delrin-150), or aluminum oxide ceramics. A typical hip prosthesis consists of the stem, a ball, and a socket with a metallic backing.

The chemistry and manufacturing processes for metallic biomaterials are not necessarily unique to the biomedical device industry. Control of undesired elements is an important aspect of the successful application of metallic biomaterials. The principal requirement for each alloy is that it be corrosion resistant when inserted in the body and that it have optimum mechanical properties. For a discussion of the physical metallurgy of stainless steel, cobalt-chromium, and titanium alloys, consult the appropriate Sections in this Handbook.

One of the unique aspects of the biomaterials and biomedical device industry is that, despite the general adherence to the ASTM or other standards, materials are marketed and discussed in trade names. Thus, an alloy that has chemical origins which can be traced to a common cobalt-chromium alloy might have the following names: Vitallium, Alivium, Endocast, Orthochrome, Protasul, and Zimaloy. It is necessary for each trade-marketed alloy to be reviewed to determine its underlying composition--that is, to which ASTM or other specification it is being made and sold.

Stainless steels and cobalt-chromium alloys depend for their general corrosion resistance on the presence of chromium and its ability to render the alloys passive. Additions of other alloy elements enhance resistance to nonuniform types of corrosion (e.g., pitting). Titanium and titanium alloys develop passivity without chromium. Surface passivity is the most important criteria, but surface finish also can affect performance. Highly polished surfaces perform better in terms of corrosion and wear.

**Stainless steels** are popular because they are relatively inexpensive, they can be formed with common techniques, and their mechanical properties can be controlled over a wide range for optimum strength and ductility. Stainless steels are used as wrought alloys. Passivity of stainless steel implants is enhanced by nitric acid passivation before the implant is sterilized and packaged for delivery to a medical facility.

Stainless steels are not sufficiently corrosion resistant for long-term use as an implant material. They find use as bone screws, bone plates, intramedullary rods, and other temporary fixation devices with a number of applicable ASTM specifications. For example, ASTM F 55 describes stainless steel that contains 17 to 19% Cr, 12 to 14% Ni, 2 to 3% Mo, a maximum of 0.03% C, and maximum limits on several other elements. AISI 316L, which is covered by ASTM F 55 and F 138, is the most commonly used stainless biomaterial because it resists pitting corrosion better than other stainless alloys. Despite its improved resistance to pitting, type 316L can be susceptible to crevice corrosion, as are most stainless steels.

The stainless steels used for implants are austenitic, which accounts for their good formability. Vacuum melting improves the fatigue capabilities of the alloys (AISI 316LVM, which is ASTM F 138). Cold working increases strength and fatigue resistance. Type 316L stainless steel can be welded, but care must be taken not to sensitize the component. Types 302,

304, 304VAR (vacuum arc remelted), and 316L have been used as wire for limited-duration applications in the body. Welding and soldering are used to join one wire section to another or to form smooth tips on guide wires.

As noted, the corrosion resistance of stainless steel is not sufficient for long-term use in the body; plates, screws, and other components implanted during reconstructive surgery are invariably removed after bones have knit and sufficient bone strength has been achieved. Early hips implanted in the 1960s used stainless steel, but cobalt-chromium or titanium alloys are now the metallic materials of choice for long-term implants.

**Cobalt-chromium alloys** were first used in the 1930s. The alloy Vitallium was used as a cast dental alloy and then adapted to orthopedic applications starting in the 1940s. The corrosion resistance of cobalt-chromium-base alloys is more than an order of magnitude greater than that of stainless steels, and they possess high mechanical property capability.

These alloys were first used as cast components. Later, wrought cobalt-chromium alloys came into use. Although a number of ASTM specifications exist for cobalt-chromium-base biomaterials, the two main alloys used are Co-28Cr-6Mo (ASTM F 75), a casting alloy, and Co-20Cr-10Ni (ASTM F 90), a wrought alloy. Wrought processing has been applied to modified compositions that fall under F 75.

The metallurgy for cobalt-chromium alloys is the same as that for cobalt-base superalloys. Strengthening is produced by solid-solution elements and the presence of carbides. In wrought alloys where working is possible, cold work enhances strength. In order to produce wrought cobalt-chromium alloys, carbon must be reduced compared to the level in cast alloys (0.05% versus about 0.25% or higher). Low carbon contents mean that less strengthening is produced by carbides. To enhance fabricability, chromium contents generally are reduced and nickel added. Wrought alloys can be hot worked and some can be cold drawn. Yield strengths vary with grain size and the degree of cold work imparted from the wrought fabrication process.

Alloys produced for structural applications such as hip prostheses can be forged if optimum properties are desired. The forging process results in maximum strength and toughness for cobalt-chromium alloys but may not produce uniform grain sizes. Data have been reported on forging of a modified F 75 composition wherein finer grain size occurred in the distal end (tip of the femoral stem, farthest from the ball) than in the proximal end. Strength (fatigue, yield) was correspondingly better in specimens taken from the distal end.

Cobalt-chromium alloys are difficult to machine. Closed-die forging can minimize machining requirements, but wrought processed components still may require more machining than cast components. Consequently, investment casting often is used to produce cobalt-chromium implants at the lowest cost. The grain size of cast components is invariably greater than that of comparable wrought components, so strength properties of castings do not approach those of wrought cobalt-chromium alloys. Porosity can be a problem in castings but can be controlled by improved mold design and by application of hot isostatic pressing (HIP) in postcast treatment of vacuum investment cast alloys. Powder metallurgy has been used to make some cobalt-chromium components. Hot isostatic pressing of powder is claimed to result in very fine grains and exceptional properties, but costs may be higher.

The preferred method of producing cobalt-chromium alloy implants will be a function of the trade-off between cost and properties. Where the properties of castings are sufficient, castings will dominate. When maximum strength is required, hot pressing and/or forging will rule. Table 2 shows that forged cobalt-chromium alloys have substantial mechanical property advantages over the cast alloy. Because of the significant differences in chemistry between the cast and wrought compositions, concern may arise that the strengths of wrought alloys are a function of chemistry. Table 4 compares the strengths of virtually identical cobalt-chromium alloys (low carbon and slightly lower chromium in wrought) tested in the cast and forged conditions. The strength advantage of forging is obvious.

**Table 4 Effect of forging on Vitallium alloy mechanical properties**

Material condition	Tensile strength		0.2% yield strength		Elongation, %	Fatigue strength (10 <sup>6</sup> cycles implied, R = -1)	
	MPa	ksi	MPa	ksi		MPa	ksi
<b>Forged</b>							
<b>Proximal stem</b>	1406.6	204.0	889.5	129.0	28.3	792.9	115.0

<b>Cast (typical)</b>	790	115	520	75	15	310	45

**Titanium and its alloys** used for implant devices have been designed to have excellent biocompatibility, with little or no reaction with tissue surrounding the implant. Titanium derives its corrosion resistance from the stable oxide film that forms on its surface, which can reform at body temperatures and in physiological fluids if damaged. Although many titanium alloys have been developed, primarily for industrial application, Ti-6Al-4V alloy and the four grades of commercially pure titanium have found the most use in the body. Other titanium alloys such as Ti-6Al-17Nb and Ti-15Mo also have biomaterials applications.

The mechanical properties of commercial-purity titanium are a function of oxygen level. Increasing oxygen levels increase yield strength and decrease ductility. Ti-6Al-4V has much greater yield and ultimate strengths than the pure metal, as well as good ductility (Table 2), and offers one of the best combination of properties among all structural implant metals. The alloy generally is produced by forging but can be cast; it can be strengthened by controlling the composition and by adjusting the manufacturing process. Titanium alloys undergo a transition in crystal structure on heating. The transition temperature (to the high-temperature, body-centered cubic phase,  $\beta$ ) is called the  $\beta$ transus. Processing in various methods in the vicinity of the  $\beta$ transus can refine the microstructure. By appropriate processing, it is possible to increase fatigue life by a factor of two or more.

The friction and wear properties of titanium are quite different from those of most other metals. This is a result of its tenacious oxide film. The film will remain intact under low loads and slow sliding speeds in articulating conditions. However, if the film is worn away and not regenerated promptly, galling will cause metal-to-metal contact and cold welding. This process leads to very high friction and wear rates; consequently, titanium-to-titanium (or to other metal) articulating joints are not used. Methods such as ion beam implantation and nitriding can be useful for improving wear.

The wear properties of titanium probably prevent its more widespread use in orthopedic prostheses. For the most part, however, titanium is not articulated against other metallic materials or itself, but is used for components of modular construction where a titanium femoral stem will be used with a cobalt-chromium or a ceramic ball to articulate against a UHMWPE liner (e.g., in a total hip replacement).

**Shape memory effect (SME) alloys** are able to "remember" a prior shape even if the component undergoes significant deformation. The shape memory alloy component will stay in its deformed shape until the material is heated to a transition temperature, at which point the component will spontaneously return to its original shape.

One class of SME alloys is represented by nickel-titanium alloys of roughly equiatomic composition. It was reasoned that nickel-titanium alloys should be reasonably biocompatible and corrosion resistant and could be used for temporary fracture fixation. Applications of nickel-titanium alloys include osteosynthesis plates, jaw plates, and dental braces.

To illustrate the application of SME alloys, consider osteosynthesis plates. These are attached to a bone to stabilize a fracture and promote healing. The plate is produced in its desired final geometry using a SME alloy, then is stretched 8% and cooled. Screw attachment holes are drilled without heating the plate. Then the plate is attached to the patient's fractured bone. A local heat source (warm water or hot air) is applied to raise the temperature to above the transition temperature; the plate reverts to its original dimensions, contracting and pulling the fractured surfaces together.

## Coatings for Use on Implants

One of the great debates in orthopedic implant surgery has been over the question of attachment of bone to prosthetic devices. The principal reason for revision operations on implants (especially now that corrosion problems have been largely overcome by removing stainless steels from articulating prostheses) has been loosening of the prosthesis. Improved bonding of the prosthesis to the bone should enhance the stability of a prosthesis and reduce the chances for loosening. Various procedures have been developed in an attempt to increase the bond strength of joints. Some of these procedures tried to promote bony ingrowth into the implant using porous coatings, with varying degrees of success.

One procedure consisted of attaching, to the implant surface, fibers of an alloy compatible with the basis alloy to produce a porous metal coating. Titanium fibers were used on Ti-6Al-4V implants. An alternate procedure was to attach metal powder particles (often spherical). Powder metallurgy techniques were used to put Co-Cr-Mo on a Co-Cr alloy implant, and commercial-purity titanium powders were plasma sprayed on Ti-6Al-4V implants. Results from these trials have been mixed, but many implants are available with a porous metallic surface coating on part of the implant surface. In addition to concern about the efficacy of the attachment process, for titanium alloys (which are subject to notch-induced fatigue failure) it was felt that reduced fatigue life might arise due to the notches produced by powders on the surface.

The most effective processes for promoting improved attachment have used calcium phosphate ceramics (calcium hydroxyapatite, HA), which provide elements found in bone. The concept involves bonding a thin layer of a biologically active calcium HA coating to the implant. The coating must be capable of being resorbed by the body, which then substitutes natural bone for the calcium phosphate. A high-strength bond is maintained with the metallic implant by avoiding the fibrous tissue layer often encountered between implant and bone.

Hydroxyapatite coatings have been applied by the plasma spray process. Because the bond between an HA coating and the substrate is a mechanical one, the implant surface must be roughened; the degree of roughness influences interfacial strength. Variations in coating composition and stability affect clinical success. Hydroxyapatite coatings are considered useful in producing enhanced bond strengths, but results vary.

## Metallic Biomaterials for Dentistry

**Dental amalgam** has been in use since the 1800s, generally with limited known detrimental effects on humans. Dental amalgam is made by mixing mercury and a powdered alloy containing silver, tin, copper, and zinc. The amalgam has a composition close to the  $\text{Ag}_3\text{Sn}$   $\gamma$  phase. The amalgamation reaction produces a solidified alloy over a short time range, allowing the dentist to manipulate the pasty amalgam in the tooth cavity. Dental amalgam is used to restore chewing surfaces and is subject to heavy forces. The aim of the amalgam is to develop an acceptable compressive strength in the restoration within several hours without compromising the manipulative ability of the amalgam. The dimensional stability of the amalgam during setup is important for its clinical application. Longtime phase changes can occur in amalgam, which may affect performance. Table 5 lists the properties of some alloys used in dentistry.

When a tooth cavity is restored by using an amalgam, there is no adhesion between the amalgam and the tooth material. This can cause marginal leakage of the restoration (filling). The dimensional stability of the amalgam during setup and its ability to reproduce the convolutions of the cavity walls, along with the technique of the dentist in mixing and applying the amalgam, affect leakage. Deterioration of fillings can occur by localized or crevice corrosion in crevices, pores, and cracks or at margins.

Dental amalgam is brittle, which can lead to failure in tension or creep. Dentists avoid this by feathering edges and minimizing chances for high tensile loads. Dental amalgam creeps under load; the mercury content of the amalgam affects creep resistance.

Amalgam chemistry has changed over the years. Production of improved spherical powder shapes enhanced setup of the amalgam restoration. In addition, copper was introduced to modify the phase reaction by eliminating the so-called  $\gamma_2$  phase, which is the tin-mercury phase responsible for most long-term corrosion of fillings.

**Gold alloys** are typically used for crowns and bridgework, although persons concerned about the health aspects of mercury in silver-tin amalgams have opted for gold cavity restorations. In this latter instance, the malleability of gold is used to good advantage. Thin foils of pure gold are produced and mechanically deformed into the tooth cavity to produce a filling.

Pure gold is used in wrought form for fillings or as a cast material for bridges and crowns. In some circumstances gold also is used for dental wires and in alloyed form as a dental solder. Because gold is not particularly strong, alloys have been developed to improve strength for castings. Gold foil, although soft when applied, hardens due to the cold work it receives during insertion into the cavity. The hardness of a properly compacted gold foil filling is about twice that of cast gold. Gold fillings are claimed to so closely adapt to the contours of the cavity that no marginal leakage occurs.

Gold alloys used for castings fall into four categories according to hardness and strength. Type I alloys use solid-solution additions. The type II to IV alloys contain varying elements to produce hardening reactions by solution hardening and by heat treatment. As the alloy type number increases, the percentage of gold in the alloy decreases, so that type IV alloys are relatively low in tarnish resistance. Commercial dental alloys usually range in gold content from approximately 50 to 88%.

**Other Metallics.** Cast cobalt-chromium alloys are used in dentistry for fixed bridges and for partial dentures as the framework for attachment of teeth (Fig. 5), as are nickel-chromium alloys. Austenitic stainless steels are used for partial dentures and, occasionally, as mesh frameworks to strengthen full dentures. Wrought cobalt-chromium, nickel-chromium, and stainless steel are available as wires for orthodontic use. All these alloys are less dense than gold alloys. In the case of cobalt-chromium alloys, improved mechanical properties (compared to gold), coupled with decreased density, permit the manufacture of lighter and thinner dental prostheses.

**Fig. 5** Removable partial dentures showing cobalt-chromium alloy uppers and lowers (a and b) plus completed partial denture set with teeth attached (c)

Titanium alloys seem uniquely suited for dental implant applications, particularly as single or multiple posts on which to attach a few teeth (Fig. 6) or a permanent denture. Use of implants inserted into the mandible (lower jaw) or maxilla (upper jaw) provides an anatomically satisfactory way to transfer the stresses of chewing to the bone. Threaded and smooth implants have been used with success, although threaded implants seem to be superior. Titanium dental implants have remarkably good integration with the bony structure of the jaw.

**Fig. 6** Illustration of uncoated dental implant and its use. The posts function as a support for replacement teeth.

# Extractive Metallurgy

B. Mishra, Department of Metallurgical & Materials Engineering, Colorado School of Mines

## Introduction

THE REVERSION of metals into compounds is a natural phenomenon also known as corrosion or oxidation. Over time, a piece of steel will turn into rust; this process of reversion is natural because it results in the metal lowering its free energy. Thus, spontaneous or natural reversion is associated with a release of energy. The more active or reactive the metal, the higher its tendency to return to its natural state.

The science of preventing metals from undergoing this natural process is known as corrosion protection or oxidation protection. Because a metal desires to be in a stable compound form, its natural state must therefore be an oxidized form, such as an oxide, sulfide, carbonate, sulfate, chloride, or nitrate. This natural state is called an ore or a mineral. The process of dissociating these compounds and converting them into a metal (and a nonmetal) is known as extraction. The dissociation of the compound into metals and nonmetals is called reduction.

Naturally, the process of extraction requires that energy be spent in order to force the metal to disengage from its compound. When the form of this energy is primarily thermal, the process is known as pyrometallurgy. Processes that use electrical or chemical energy to perform the reduction are known as electrometallurgy and hydrometallurgy, respectively.

The extractive metallurgy applied to the production of a particular metal may involve one or more of these distinct metallurgical processes. Although hydrometallurgy implies processing through an aqueous medium, it may involve heat for enhanced kinetics and/or favorable thermodynamics. The size and concentration of ore suitable for each of these processes differ widely. Electrometallurgy usually is not used directly on the ore concentrate in the scheme of metal extraction. Generally, a purer metal compound feed is required for metal extraction through electrometallurgy, whereas hydrometallurgical and pyrometallurgical techniques are suitable for treating a beneficiated ore. This Section will discuss the basic principles of these major types of metallurgical processes in further detail, and will show the path of metal extraction from an ore to the finished metal.

Until recently, the field of extractive metallurgy was concerned mainly with producing metals from their oxidized/combined state or natural ore, which is known as primary metal production. However, like everything else, metals have a limited life. Once a metal becomes part of an engineered system--as an alloy, intermetallic, or surface-modified product--its usefulness depends on the continued usefulness of the entire system, which is generally cut short at some point, often by corrosion. In the present industrial environment, valuable metals cannot be discarded. Regeneration or recycling of metals back into a useful form, which is known as secondary metal production, often requires the same extractive metallurgy principles and sophisticated separation methods as does the reduction of ore. The entire field of waste minimization, remediation, recovery, and recycling is fast becoming an integral part of extractive metallurgy.

The development of radically new methods for extraction of metals is rare. In recent times, research and development efforts in extractive metallurgy have focused on managing existing processes more efficiently. Small improvements in processing methods have yielded large gains in productivity and profitability. New recycling methods also are under development, since recycled metal and extracted metal have different properties. The aluminum, zinc, lead, copper, and precious metals industries have made great strides in secondary production over the last two decades. All of this technology development now takes into account environmental concerns, such as air and water pollution and health hazards.

## Mining of Minerals and Ores

More than 98 wt% of the earth's crust comprises eight elements: oxygen, silicon, aluminum, iron, calcium, sodium, potassium, and magnesium. These elements are not distributed uniformly, but occur as concentrated ore deposits of one mineral form or the other. These ore deposits form by (1) magmatic segregation, (2) solution and precipitation, and (3) physical phenomena, such as erosion and concentration. Geophysical, geochemical, and extraterrestrial methods are available for locating a useful mineral deposit and estimating its commercial worth.

An ore can be defined as "a naturally occurring aggregate of minerals from which a metal or metals may be extracted at a profit." Several factors are considered in the decision to exploit a mineral deposit: extent of the deposit, required mining

method, grade or rank of the deposit, available facilities for mining, cost of mining with respect to metal price, metal demand forecast, ore processing and extraction costs, and the socioeconomic as well as environmental impact of the mining activity. This decision is also time sensitive, being strongly influenced by changing technological, economic, and social constraints.

The ore minerals that are most simple to treat are those where the valuable metal occurs in its elemental or native form; in such cases physical separation or liberation is sufficient for metal production. However, chemical and thermal means are often necessary to liberate the metal due to its low concentration. Not many metals occur naturally as elements; the chief examples are gold, silver, and platinum. Other metals have been found in elemental form, but not to the extent needed for economic exploitation. The metals found in their elemental form are usually noble metals, since they are inherently non-reactive or inert. Most metals occur in the earth's crust combined with other nonmetallic elements in the form of minerals. There are relatively few minerals of economic importance. Also, a particular mineral deposit may be used to extract several metals as they are often found together, such as copper, gold, lead, zinc, antimony, bismuth, molybdenum, and arsenic.

Most common minerals of high tonnage metals (iron, aluminum, copper, titanium, nickel, chromium, magnesium, zinc, and others) are either an oxide or a sulfide deposit. Several of the oxides or sulfides are present together in a chemically combined form in the deposit. While the oxide or sulfide of a particular metal (usually the highest weight percent) is the primary component being extracted, it must be separated from the others. These other oxides or sulfides comprise the gangue of the ore. The composition and nature of the gangue material accompanying the valuable mineral is of great concern. The type of process required for extraction depends largely on the nature of the gangue in terms of its basicity or acidity. The amount and composition of gangue dictates the type of flux required for preparing a proper slag to enable the metal extraction.

Thus, an ore can be relatively simple or exceedingly complex, but in essence will consist of: (a) the primary valuable mineral, (b) the predominant gangue content, (c) valuable by-products, and (d) detrimental impurities. The composition of the valuable mineral dictates to some extent the type of metallurgical reduction process used. The composition of the gangue will also influence the reduction processes that can be used. Valuable by-products may increase the economic return from a given ore, such as the occurrence of gold in copper ores, the presence of silver in lead ores, and the recovery of molybdenum from copper ores. Finally, the presence of certain impurities may increase the cost of treatment or even make processing unfeasible; examples are arsenic in copper ores and bismuth in lead ores. For further information on the mining methods and common ore and mineral types for metal extraction, see Ref 1 and 2.

## Mineral Processing

Mineral processing refers to a group of physical and chemical steps that make the ore amenable for metal extraction by creating a concentrate of the metal compound of interest. *Mineral beneficiation* and *ore dressing* are terms used interchangeably for mineral processing. Mineral processing steps also allow the valuable by-products to preferably segregate with the concentrate while rejecting some of the predominant gangue. It should be realized that mineral processing, in certain cases, can provide two or more separate streams, each forming a source of value. The chemical changes affected to the ore are no more than superficial. Physical separation processes are based on the exploitation of the gravimetric, magnetic, and electrostatic properties of various ore fractions. This is often enhanced by sizing, sieving, and washing. The most commonly used flotation processes utilize the differences in surface properties that can be altered by surface chemistry. Mineral processing separates some of the gangue in natural ores by operations that do not change the mineralogical status of the valuable metal. As a result mineral processing increases the percentage of the valuable mineral by lowering the gangue content. The rejected material is referred to as tailings or tails.

Mineral processing is economically justified by the early removal of partial gangue so that a smaller volume of concentrate has to be shipped for extraction rather than the bulky low-grade ore. In the majority of installations, the

mineral processing facilities--such as crushers, grinders, concentrators, separators, and flotation devices--are near the mine, while the reduction plant may be in a more central location some distance away. It is desirable to ship concentrates to the reduction plant where other ancillary equipment and facilities required for down-line processing are readily available. Direct-smelting ores existed in the past when the upper portions of veins were being mined and the ore was rich and relatively low in gangue. Such resources are now rare.

### ***Crushing, Grinding, and Classification***

The chunky crude ore must first be broken down in size to release the valuable mineral from its physical bonds with the gangue. The extent of the subdivision of the ore to obtain a reasonable degree of liberation depends on the characteristics of the individual ore. Ores are referred to as fine grain or coarse grain to describe the average natural particle size of the valuable mineral constituents as well as that of the gangue. Ore samples are crushed and ground to varying extents and the product is separated into size fractions by sieving on set of laboratory screens with elutriation of the subsieve fraction. The size fractions are examined under the microscope to determine the extent of liberation, and concentration tests are run on size fractions to determine the degree of concentration that can be obtained. The extent of comminution to obtain the higher degree of concentration through greater liberation must be justified by the increased cost of grinding. When the particle size is very small, concentration processes do not work as efficiently and tailing losses are high. In addition, fine ore is unsuitable for several pyrometallurgical processes, such as the blast furnace smelting. Particle size reduction is achieved by two- or three-stage procedures referred to as crushing and grinding; the combination of the two is known as comminution. Three basic types of crushing and grinding circuits are shown in Fig. 1.

**Fig. 1** Three basic types of crushing-and-grinding circuits. (a) Conventional. (b) Autogenous. (c) Autogenous with separate fine grinding

**Crushing** reduces ore pieces 1 to 2 ft in diameter or larger to pieces averaging 100 to 150 mm (4 to 6 in.) in diameter. Schuhmann has shown a linear relationship between successive screen sizes and the logarithm of cumulative percent retained on each size of screen (Ref 3). Many devices have been proposed for coarse crushing, but jaw or gyratory crushers are mostly used for the normal ores. Sometimes short-head cone crushers are used for intermediate reduction of the size of the gyratory- or jaw-crusher product (Ref 4).

**Grinding** follows coarse crushing, and possibly intermediate crushing, to take the ore from a maximum size of a few inches to smaller sizes needed for reasonable liberation. Of the many devices and procedures invented for grinding, most

plants use a tumbling grinding mill in which the grinding media are steel or ceramic balls, steel rods, or pieces of the ore itself. This latter process is called "autogenous" grinding. The grinding operation can be conducted either wet or dry, but normally in ore mills wet grinding is used because the subsequent concentration process is also wet. Avoidance of severe dust problems and the merits of wet classification lot particle-size control are other advantages of wet grinding.

A mill can be operated in the open-circuit mode, where the ore is added at the feed end and the entire product is accepted at the discharge end. In this case, the reduction in particle size for all of the ore is essentially completed in one pass that produces considerable overgrinding of most of the feed. An alternative scheme is to put the grinding mill in the closed-circuit mode with a classifying device. The mill is operated so that not all of the ore is sufficiently reduced in size, but the mill discharge is fed to a classifier which returns the oversize particles to the mill feed and permits the undersize particles to continue on to the next step in the process.

**Classification** is defined as separation of particles according to their settling rates in a fluid, normally water, although dry classifiers are commonly used for collecting dust from crushing operations. Wet classifiers used in conjunction with grinding can be subdivided into mechanical and hydraulic classifiers. A spiral (mechanical) classifier, to which pulp from a grinding mill is fed, forces the larger and heavier particles to settle to the bottom of the pool which are then conveyed by the spiral for more grinding. The smaller and lighter particles overflow and are ready for the next step in the process. In a hydraulic classifier (hydrocyclone), the fine particles in the overflow are discharged from the top, and the coarse particles in an underflow are discharged at the bottom.

### **Concentration Devices**

**Gravity Devices.** Minerals are usually higher in density than the gangue, and therefore, various devices can be used for separation. The classical miner's pan and rocking cradle have been replaced by more sophisticated shaking tables or a jig that can be mechanized to handle larger quantities of material and to achieve better separation. However, these installations are unable to treat the fine particles generated by the extent of grinding necessitated by fine ore-gangue textures.

**Magnetic Devices.** Separation based on magnetic properties is widely used for concentration of iron ores. If the iron mineral is magnetite, the magnetite particles can be attracted by permanent magnets or electromagnets to separate them from the gangue, as shown in Fig. 2. If the iron ore is predominantly hematite ( $\text{Fe}_2\text{O}_3$ ), a partial reduction can convert the hematite to the magnetic magnetite ( $\text{Fe}_3\text{O}_4$ ), making magnetic separation feasible. For a successful magnetic separation it is imperative that the mineralogy of the magnetic and nonmagnetic fractions of the ore are distinct and separable.

**Fig. 2** Wet-drum low-intensity magnetic separator tanks. (a) Concurrent. (b) Counter-rotation. (c) Counter-

current. (Courtesy of Eriez Magnetics)

**Electrostatic Devices.** The separation on the basis of differences in electrostatic properties requires the ore be in a limited size range like sand. The ore is fed onto a conducting and grounded rotor and is exposed to an ionizing electrode. The particles pick up a charge and then those that are conducting lose the charge to the rotor and are thrown off. The nonconducting particles retain their charge, cling to the rotor, and are brushed off into a separate container. This procedure has been successful in the treatment of beach sands. In conjunction with magnetic and gravity separation, electrostatic devices can separate rutile, ilmenite, chromite, garnet, magnetite and silica fractions.

**Flotation** is the most widely used method for concentrating nonferrous ores, particularly sulfides. It can also be applied to oxidized forms of minerals with limited efficiency. The separation is based on whether or not mineral surfaces are wettable. The finely ground ore in an aqueous pulp is fed to a flotation machine with an impeller that provides vigorous agitation. Air is introduced into the cell either from a compressed-air line or by the pumping action of the impeller. The air bubbles, distributed by the agitation, rise through the pulp and attach to the nonwetted mineral particles, carrying them to the surface where a froth is formed that can be scraped from the cell. The wetted particles, usually the gangue, do not attach to the bubbles, and hence remain in the pulp to be discharged as tailings. A single one-pass separation is usually not sufficient, and the rougher concentrate may be recleaned. Likewise, the tailings from the first separation may be scavenged to avoid discarding valuable minerals. The retreatment, regrinding, and other elaborate steps lead to a complex flow sheet. These flow sheets have been optimized by mathematical modeling, and sensitive instrumentation has resulted in greater efficiency and a high degree of control.

Only graphite and molybdenite have nonwetable surfaces necessary for particles to adhere to bubbles and be carried to the surface. Usually, reagents must be added to the pulp to change the surface properties. Oils were used at one time to give sulfides an oily surface that would make them float without affecting the gangue remaining in the pulp. Today, selective reagents, which can distinguish among various sulfides, are used. These reagents, called *collectors*, are added along with other agents that will stabilize the froth, depress or activate selected minerals, control pH, and generally improve the collection and selection of desired minerals.

### ***Disposal of Tailings***

The concentrate products from any of the wet concentrating processes require dewatering. The initial step is thickening in a large cylindrical tank. The stream of concentrate and water enters the tank where the mineral particles settle to the bottom, and slowly revolving rakes move the mud-like deposit to a center discharge. The overflow, practically devoid of solids, can be returned to the process if dissolved reagents are not detrimental. The thickened underflow pumped from the concentrate thickeners is normally sent to a vacuum filter of a drum or disk type, which reduces the moisture content of the cake to about 10% or less.

The tailings from the mill may be further thickened if there is a need to recover more of the mill water. Otherwise, the tailings are discharged through pipes or flumes to the tailing pond where the remaining particles settle out over a period of time allowing the top clear water to be discarded.

### **Flow Diagrams of Extraction Processes**

As mentioned earlier, the final combination of unit processes to form the complete flow sheet for the extraction of any metal from its ore depends on the type and cost of raw materials, cost of processing, and the demand for the metal. The cost of energy is a major factor in the cost of processing; as higher purity metal is required, more energy is required to produce it. However, the unit processes are essentially classified as pyro-, hydro-, or electrometallurgical. Figures 3, 4, and 5 show flow diagrams for copper, iron, and zinc (Ref 5), which clearly indicate a combination of these three types of basic metallurgical unit steps. For example, the two alternative routes for zinc production are either completely

pyrometallurgical (Fig. 5, left) or a combination of all three (Fig. 5, right). The flow sheet for copper (Fig. 3) shows a combination of pyro metallurgical and electrometallurgical steps. The iron extraction flow sheet (Fig. 4) is essentially a combination of pyrometallurgical unit processes. The purity of the metal product also depends on the chosen route. Electrolytic refining as the final step in extraction yields a product of higher purity. Pyrometallurgical processes generally yield a product with impurities unless the product is further refined. For complete description of thermodynamic and kinetic characteristics of these unit processes, see Ref 6, 7, and 8.

## Pyrometallurgical Processes

The mineral concentrate produced from crude mined ores is a complex mixture of minerals and some residual gangue and is usually not suitable for direct reduction. Notable exceptions are the direct reduction of iron or the iron-carbide process, which rely on an ore feed of very high-purity iron oxide (that is, containing a very small amount of associated gangue). Some preliminary treatment is necessary depending on the reactivity of the major metal. The ore concentrate of highly reactive metals, such as aluminum, magnesium, titanium, and calcium, must be pretreated to get a high-purity feed, which would yield a high-purity metal upon reduction because the refining of reactive metals is difficult. In some cases, a pretreatment is necessitated by the fact that the concentrate is a rich source of not just one metal compound, but two or three. On the other hand, the raw feed for production of low-reactive metals, such as iron, chromium, and nickel, is not pretreated extensively; hence, upon reduction it results in an impure metal requiring subsequent refining. Therefore, before the primary reduction occurs, ore concentrate needs to be prepared.

## Preparation Processes

The pyrometallurgical pretreatments include drying, calcination, roasting to oxides or sulfates, reduction roasting, chlorination or carbo-chlorination, and other exotic processes.

**Drying.** The objective of drying operations is the removal of bulk water and volatiles, which together usually comprise 20 to 30 vol%. This evaporation of water can be accomplished either by heating the solid material or by using a vacuum system. Vacuum systems are used in the removal of organics that would decompose at high temperatures. The percent of weight lost is known as *loss on ignition* (LOI). Sufficient time at temperature must be allowed for complete drying. Because the evaporation of water is endothermic (the heat of vaporization of water is 44 kJ/mol), energy must be supplied for the evaporation of water as well as to bring the material up to drying temperature. Drying is conducted at temperatures close to the boiling point of water, which allows the use of low-quality fuels, such as hot combustion gases from other processes or cheap producer-gas fuel. Also, the low temperature used for the drying process puts no special demand on the equipment material.

Fixed-bed furnaces, rotary kilns, and fluidized-bed furnaces are commonly used for drying. Fixed-bed furnaces or shaft furnaces are most suitable for drying coarse materials. Rotary kilns are usually used with feed material of a mixed size. Fluidized-bed furnaces are used for drying predominantly fine-grained material. If the concentrate is to be roasted on multihearth roasters, drying and preheating occur on the upper hearths utilizing the ascending heat from the roasting hearths. Some flash roasters also dry the concentrate on the upper hearths, take it out, grind it to eliminate lumps, and then inject the fine, dry material into the combustion chamber. Wet concentrates can be fed into a fluid-bed roaster, and they rapidly dry in the hot, turbulent bed. Wet concentrates can also be fed into reverberatory furnaces as long as the feed does not build up on the sides of the furnace and then drop into the hot bath causing explosions. A separate drying step is usually expensive. In most reactors, drying occurs as the charge is descending or waiting for the final roasting, reduction, or smelting process.

**Calcination** is a high-temperature operation used for removal of chemically bound water or for decomposition of carbonates to remove carbon-dioxide gas. The most common example of calcination in the metallurgical industry is the decomposition of metal carbonates to form metal oxides, such as lime from limestone. In one atmosphere, the temperatures required for decomposition of carbonates or hydroxides range from 1000 to 1500 °C (1832 to 2732 °F). A typical decomposition reaction at 1000 °C (1832 °F) and 1 atm pressure is:

The rate of decomposition is a function of the heat input (Ref 9) because calcination is a gas-solid reaction, and the rate of the process is controlled by conduction of heat through the product oxide layer. To increase calcination rates in industrial furnaces, a large amount of excess heat is commonly used. The excess heat increases the calcination rate, but it also causes rather high temperatures in the oxide-product layer. Calcium oxide, which sinters readily at temperatures just above the calcination temperature, has lower pore volume, specific surface area, and reactivity if excess heat is used (Ref 10).

Fixed-bed or shaft furnaces are commonly used for calcination of lump carbonate material. However, because of the long residence times and high surface temperatures, the oxide products tend to be less reactive, or *hard-burned*. Rotary kilns produce oxides that are more reactive, or *soft-burned*, but have lower fuel efficiency and higher maintenance, operation, and capital costs than the shaft furnaces. Like drying, calcination is also achieved as a part of the primary metallurgical process of roasting or prereduction.

Roasting is the process in which the mineral mixtures are heated to temperatures just below the melting or sintering point of the mineral in the presence of air or other reactive gas to achieve a chemical change. Roasting is a prominent step in the extraction of copper. Common roasting temperatures are between 500 and 900 °C (932 and 1652 °F), where reaction kinetics are fast. The roasting process is carried out by contacting the sulfide with air at elevated temperatures. Once the roasting has started it is autogenous, that is, no external fuel is required, because of the exothermicity of the roasting reactions. The burning of the sulfides often provides more heat than required to self-sustain the process.

The equilibrium relationships of the metal-oxygen-sulfur system are used to determine which solid phase, metal, oxide, sulfide, or sulfate will be present as a product. It is possible to show the equilibrium relationships of the system on a predominance area diagram. See Fig. 6 for Cu-O-S and Fe-O-S systems at 700 °C (1292 °F) (Ref 11). Specifying two gas compositions, such as oxygen and sulfur dioxide, fix the stable solid phases possible. Partial pressure of sulfur or sulfur trioxide gas could also be used as one of the axes on the graph. Generally, pyrometallurgical plants seek to produce oxides from sulfides during roasting for subsequent reduction by carbon or other reducing agents. Production of sulfates by roasting would be desirable if subsequent leaching (hydrometallurgical process) were to take place. The production of metal directly in roasting is a phenomenon observed in sinter-roasting of lead concentrates.

**Fig. 6** Predominance area diagram for roasting of iron and copper sulfides at 700 °C (1292 °F). Solid lines: iron compounds. Dashed lines: copper compounds. Dotted lines: gases. Ternary compounds are disregarded.

As mentioned earlier, roasting in a reducing atmosphere is normally used for partial reduction, such as the conversion of  $\text{Fe}_2\text{O}_3$  to  $\text{Fe}_3\text{O}_4$  for subsequent magnetic separation. Roasting in a chlorine atmosphere or in the presence of chlorides is a method for producing metal chlorides from metal oxides, which can then be volatilized or leached. Addition of carbon is sometimes necessary during chlorination for thermo-dynamic considerations when the oxide is more stable than chlorides under normal temperature conditions.

Modern roasters are equipped with temperature control, atmosphere control, and heat conservation devices. In addition, provisions are made for greater exposure of mineral surfaces to the gas by frequent rabbling or by dispersion of the solids into a particle/gas suspension. Modern equipment is limited to multihearth, flash, and fluidized-bed roasters. Multihearth roasters are cylindrical in plan with 4 to 12 superimposed hearths. The feed enters at the top and is rabbled first to the center, where it drops to the second hearth to be rabbled to the outer edge, where it drops to the third hearth. The process continues until the roasted material exits from the bottom hearth of the roaster. The gases rise countercurrent to the material movement and are usually removed at the second hearth and sent to flues, dust collectors, or possibly an acid plant. The rising gas also dries the descending charge.

A flash roaster has a larger capacity than a multihearth roaster of similar dimensions because exposure of mineral surfaces to the reacting gas is greater. The top-injected charge gets dried and preheated before free-falling through the combustion

chamber where rapid oxidation occurs. In later models the drying hearths are at the bottom of the cylindrical structure. A fluid-bed roaster reverses the concept of a flash roaster by blowing the gases through a turbulent bed of mineral particles. The charge is lifted up by the gas pressure, which expands the bed and allows more intimate contact between the gas and the fine material.

**Sintering.** The process used to cause partial reduction and agglomeration of relatively fine ore concentrate is known as sintering. In sintering, high temperature is used to obtain partial fusion of particles to form a *sinter*. Sintering is an integral part of the modern day ironmaking. Sintering of iron ore concentrates results in the coalescence of small particles into larger prereduced prefluxed agglomerates that will not blow out of the furnace. Drying, calcining, and roasting are simultaneously achieved. Sintering of nonferrous sulfide concentrates of lead, copper, zinc, and other metals has the dual function of particle-size control and simultaneous roasting, but the roasting is of even more importance because the final sulfur content may be critical.

A sintering machine comprises a grate on which the charge is spread and then ignited. Air is either blown up through the grate and the bed or sucked down through the bed and grate. High-sulfide ores generate enough heat to reach the temperature needed for sintering. Low-sulfur ores or iron ores with no fuel value require fuel additions usually in the form of carbon (coke breeze). Continuous sintering machines can be controlled to a greater extent and also simplify feeding of the charge and discharging of the finished sinter. Most continuous sintering machines run on a downdraft principle; however, in lead smelting, the updraft sintering makes a sinter with higher lead content and eliminates most of the windbox lead. The properties of a sinter are critical to the operation of the smelter, that is, the iron blast furnace. These properties are related to the sinter charge composition, sizes of the constituents, sintering temperature, grate speed, and suction velocity.

Sinter-roasting is the customary method of preparing feed for lead blast furnaces, and in rare cases, for copper blast furnaces. It is also the method for treating zinc sulfide concentrates before smelting either in electrothermic furnaces or in the imperial smelting furnace.

### ***Pyrometallurgical Reduction***

The metal content in ore concentrates after preparatory processes is mostly in the form of metal oxides or sulfides in much higher concentrations than the original ore; thus it is suitable for reduction and smelting into the desired metal product. This procedure can be represented by the general equation:

where M is any metal, X is the nonmetallic element or elements originally combined with M, and RX is the reaction product. When the metal compound, MX, decomposes at moderately high temperatures with or without air to yield the metallic element, the reducing agent, R, may not be required. This is the case in the heating of mercuric sulfide (cinnabar) in air to yield mercury and sulfur dioxide as it is during the thermal decomposition of zirconium and hafnium tetraiodide to produce the metals.

**Reducing Agents.** Figures 7 and 8 show the important Ellingham-Richardson diagrams for the metal-metal oxide and metal-metal sulfide systems, respectively. These equilibrium diagrams--along with the vapor-phase diagrams and the isothermal stability or predominance area diagrams for various metal(s)-non-metal(s) systems (Ref 12)--form the basis for selecting the appropriate reducing agent in pyrometallurgy. The thermodynamic principles for the generation of these graphs have been fully described in Ref 13 and 14. Such processing conditions need to be created where the metal is stable on these diagrams.

Fig. 7 Ellingham-Richardson diagram showing standard free energy of formation as a function of temperature for metal oxide systems

**Fig. 8** Ellingham-Richardson diagram showing standard free energy of formation as a function of temperature for metal sulfide systems

Figure 7 is a plot of the standard free-energy change for metal oxide formation as a function of temperature. The relative positions of the individual lines on this plot show the relative tendency of the metal to form the oxide. Following Fig. 7 from top to bottom reveals an increase in tendency to form an oxide for the metal because a higher negative change in free energy (a desired state due to higher stability) is indicated. In other words, the oxides at the bottom of the plot are stable and, therefore, are more difficult to reduce to the element. Since the standard free energy change decreases with an increase in temperature, it is easier to reduce at a higher temperature. For a given line, the metal is stable below and the metal oxide is stable above the line. It should be noted that all the lines are plotted for one mole of oxygen gas, which allows for a ready comparison of different metal oxide stabilities. Figure 7 shows which metals would preferentially oxidize if several pure metals were exposed to the same amount of oxygen (activity or partial pressure) in the environment. For example, if iron and aluminum are exposed to ambient air at high temperature, aluminum will preferentially oxidize. It is easy to determine the partial pressure of oxygen at any temperature below which metal would be stable.

The oxygen potentials of the reducing gas mixtures of CO/CO<sub>2</sub> and H<sub>2</sub>/H<sub>2</sub>O can also be determined, which indicate the reducing ability of an oxide by CO or H<sub>2</sub> atmospheres, respectively. Some other important lines in Fig. 7 are the carbon, carbon monoxide, and hydrogen stabilities because these are the most common reducing agents in pyrometallurgy. These

processes are known as carbothermal or hydrothermal reduction. These reducing agents are stable below their respective lines; therefore, they cannot reduce an oxide that is below it. For example, carbon cannot reduce alumina at reasonable temperature conditions. It can be readily seen that the relative stabilities of oxides can change as a function of temperature, making such a reduction feasible at very high temperature. Likewise, the principle of metallothermic reduction can be appreciated. A metal with the tendency to form a more stable oxide can reduce a less stable oxide. For example, magnesium can reduce silica or titania. On a practical note, while carbon and hydrogen produce gases upon reduction, metallothermic reductions usually result in a solid oxide product, which can pose serious kinetic concerns, forcing the reduction reaction to completely seize. For example, if calcium metal is used to reduce a less stable metal oxide, the resultant calcium oxide must be fluxed off or the reaction will stop. This can apply in comparing the behavior of two compounds of the same metal. Figures 7 and 8 can be compared to evaluate the relative stabilities of a metal oxide and a sulfide, that is, the compound with a higher negative free energy change is more stable. In certain cases, reduction of metal from metal compounds can be achieved. For example, lead can be produced by reacting lead oxide and lead sulfide at a temperature where sulfur dioxide is more stable than the metal compounds combined.

Using the Ellingham-Richardson or any other equilibrium diagram requires caution. These diagrams provide no knowledge about the reaction kinetics. Rarely the case in a real system, standard states (unit activities) are assumed for elements and their compounds. Pyrophorosity of fine metal powders or the passivating effects of a compound are ignored in determining reactivities. Possible reactions between the elements are also not considered in the thermodynamic analysis. Free energy change data for individual compounds are also quite different. This must be kept in mind when selecting the reducing agent for pyrometallurgical treatments for metal compound reduction. In addition to the theoretical thermodynamic bases, cost, the nature of the reaction by-product, the solubility of the reducing agent in the metal produced, and the possibility of reaction of the metal with the reducing agent should also be considered when selecting a reduction agent.

Carbon is a relatively cheap reductant, which has to be carbonized or converted into coke for strength and reducibility. The resulting CO/CO<sub>2</sub> by-product escapes from the reacting mass, and the change in the standard free energy of the reaction given in Eq 2 with carbon as the agent becomes more negative with increasing temperature. Most compounds in Fig. 7 and 8 show a less negative free energy change with increasing temperature. This means that even the most refractory oxides will be decomposed by carbon if the mixture is heated to a high enough temperature. The drawbacks of using carbon as the reductant are that the metal is usually a strong carbide former and reacts with carbon to yield an impure metal at high temperatures, for example, it produces pig-iron in blast furnaces with 4 to 5 wt.% carbon in solution. A low-temperature process can lower the amount of carbon that can join the reduced iron. Molybdenum, tungsten, and vanadium are also produced with appreciable carbon contents if reduced from mixtures of metal oxide and carbon. A high temperature is required to separate the balance gangue in the ore calling for smelting temperatures rather than plain solid-state reduction. Carbon may also be able to reduce some of the other compounds present in the gangue.

If oxygen is soluble in the metal being produced, the activity of the oxygen is reduced such that the most effective reducing conditions cannot reduce the oxygen content below an equilibrium condition. This interferes particularly for titanium and zirconium, which cannot be reduced from their respective oxides using carbon to obtain a low enough oxide content for commercial requirements.

Hydrogen can be used to reduce metal oxides if carbon reduction is not suitable due to carbide stability or oxygen activity in equilibrium with carbonaceous gases; for example, tungsten oxide may be reduced by hydrogen to meet performance specifications. The cost of hydrogen will be higher than carbon if the metal oxide has a large negative free energy of formation, which in turn would lead to an equilibrium composition of the reaction gas high in hydrogen and low in water vapor. In this case, the moisture content of the reaction gas must be reduced prior to recirculation.

An example of a metallothermic reduction of an oxide with another metal having a greater affinity for oxygen is the Goldschmidt reaction. In this reaction, iron oxide mixed with aluminum powder produces a molten iron and a cloud of finely divided alumina. Vacuum reduction of calcined dolomite with ferrosilicon depends on the magnesium oxide being reduced by the silicon, followed by the reaction of the resulting silica with calcium oxide content of the calcined dolomite to form a calcium silicate, thus avoiding reaction of some of the magnesium oxide (MgO) with silica. Note that straight reduction of MgO with silicon is not feasible (Fig. 7). In general, the reduction of metal oxides with other metals is adopted only when carbon or hydrogen cannot be used due to thermodynamic considerations. Metallic reductants are generally expensive and tend to form an intermetallic alloy with the reduced metal.

**Reduction of Nonoxide Compounds.** Nonferrous metals that occur as sulfides also require direct reduction. Separation concerns similar to those about oxides exist for sulfide reduction, due to the presence of gangue and the possibility of simultaneous reduction of two metal sulfides. Metal oxides such as uranium, titanium, or zirconium oxides

( $\text{UO}_2$ ,  $\text{TiO}_2$ , and  $\text{ZrO}_2$  respectively) that, due to low oxygen activity, do not yield all of their oxygen even to strong reducing agents, have to be reduced from their halides with calcium, lithium, sodium, or magnesium, which are stronger halide formers than the refractory metals. Conversion of oxides into chlorides prior to thermal reduction can occur by chlorination or by carbo-chlorination. Note that the reaction shown below in Eq 3 is not feasible under lower temperatures, but the reaction shown in Eq 4 is. Similar reactions occur with zirconium.

Alternatively, metal can be produced by reacting two metal compounds, such as lead oxide and lead sulfide. First, there is a roasting reaction in air where lead oxide and lead sulfate are produced, followed by a reaction between these oxidation products and some of the remaining lead sulfide to produce metallic lead and  $\text{SO}_2$  gas:

The reaction in Eq 5 requires that the free energy of formation of  $\text{SO}_2$  must exceed the free energy required to decompose the lead oxide and the lead sulfide. This reaction is not commercially practiced. Copper converting utilizes the same sequence of partial oxidation followed by reaction to produce blister copper from copper matte (Ref 6). Conversion of copper sulfide is conducted at temperatures high enough so that all constituents are liquid and the reactions are rapid. Similarly, nickel sulfide can be converted to metallic nickel by using high temperatures, which can be achieved in a top-blown converter using oxygen.

**Slags.** The reduction reactions on impure metal ores usually require formation of a slag to dispose the gangue material in the feed. For example,  $\text{Fe}_2\text{O}_3$  reduced with carbon yields impure metallic liquid iron and a  $\text{CO}/\text{CO}_2$  mixture that can escape from the furnace. However, the accompanying gangue comprising alumina, silica, magnesia, and others must be converted to a form that melts and is separable. This molten liquid of oxides is the slag. Sometimes, it is preferable to add fluxes, such as calcined lime, which will react with the gangue to produce a fluid slag. Other desirable features of the slag are low melting point, low viscosity, low tendency to react with refractories or to dissolve the metal, and low density to obtain good separation. Since slags do not have appreciable utility, they must also be of low value. If the gangue is primarily acidic, basic fluxes are required as opposed to a basic gangue which can be neutralized by an acidic flux.

## ***Pyrometallurgical Process Equipment***

**Reverberatory furnaces** comprise a large rectangular refractory-lined hearth area and an arched roof. These furnaces are gas, oil, or coal fired where combustion occurring in the furnace space "reverberates" the heat off the roof down onto the hearth. Reverberatory furnaces are commonly used for matte smelting of finely divided copper sulfide concentrates. However, reduction of liquid baths by charcoal or coke is difficult because slag often prevents contact with the bath. Recent advances in process control and refractory development allow the blowing of mixtures of gases through protected tuyeres submerged in the bath or by top blowing. These furnaces can be of the reverberatory type or can be more like kilns with a mechanism for partial rotation.

**Blast furnaces** are used for reducing the metal oxides that are not highly reactive, such as iron, zinc, and lead. The size and shape of the blast furnace differs for different metals. The iron blast furnace operation has been described in the article "Steelmaking Practices and Their Influence on Properties" in this Handbook. In short, it consists of continuously charging the solid material from the top and blowing hot air from the bottom, causing a counter current flow of solid and gas where heat is exchanged. Air oxidizes carbon in the coke to carbon monoxide, which reduces the oxides of iron through various oxidation states. The reduced iron melts in the hearth and, as the heavier liquid, rests under the layer of molten slag, which consists of unreduced oxides from the gangue. Slag melting occurs with the assistance of appropriate flux addition. A typical product from the iron blast furnace has the chemical composition of 4% C, 0.8 to 2% Si, 0.01 to 0.03% S, 0.3 to 0.5% P, and some manganese depending on the content of the feed material.

Lead blast furnaces are much smaller than iron blast furnaces because of the lower volume of material treated at a lead smelter. The cross-sectional plan of the lead furnace is rectangular rather than circular to allow the penetration of low-pressure blast to the center of the charge. The furnace is top-charged with lead sinter, which also contains most of the fluxes and coke to adjust the final slag composition. As the charge descends in the shaft it moves counter-current to the ascending hot reducing gas generated by the combustion of coke in the tuyere zone, similar to the iron operation. The

charge is dried, the carbonates are calcined, and the metal oxides are reduced by the carbon monoxide (CO) in the gases as the descending charge gets hotter. At the same time, the siliceous gangue reacts with the lime and iron oxide flux to form droplets of slag. Finally, the whole charge is melted with the molten lead on the bottom of the crucible and the slag floating on the lead. The residual sulfur in the charge combines with copper, iron, and lead to form an artificial mixture of sulfides known as matte. Usually this matte is sold to the copper smelter as it contains precious metals as well. Both slag and metal are tapped continuously into a forehearth where the slag overflows and the lead accumulates to be tapped periodically.

Copper blast furnaces are similar to lead furnaces but are not prevalently the equipment of choice. Reduction of copper oxide in a blast furnace is accompanied by simultaneous reduction of some of the iron oxide in the charge, yielding a mixed iron-copper alloy referred to as black copper. If reducing conditions are made less intense in the furnace to avoid iron contamination, more copper is lost through the slag.

Imperial furnace or lead-zinc blast furnace smelting of zinc oxide requires that the gas mixture be kept at a high enough temperature to prevent the oxidation of zinc. The imperial furnace has no cold zones, the charge is preheated before entering the furnace, and the gases are kept hot in the condensers. The zinc is captured from the gas mixture by absorption on small drops of liquid lead created by violent mixing of a lead bath in the condenser. Subsequent cooling of the zinc-lead alloy yields two immiscible liquid layers: the upper one high in zinc, which can be sent to a refining column, and the lower one high in lead, which is recirculated to the condenser. If the furnace is fed a mixture of lead and zinc oxides, the lead can be reduced and tapped from the furnace while the zinc vapors issued from the upper part of the furnace move to the condenser. The lead reduction does not require an additional reducing agent.

**Converters** are essentially refractory-lined vessels holding a molten bath of metal or metal sulfide into which air or oxygen can be blown to achieve rapid oxidation and refining. The shape and construction depend on the material to be treated. Converters are the equipment of choice for making steel from pig iron and are described in the article "Steelmaking Practices and Their Influence on Properties" in this Handbook. Copper refining uses a side-blown converter with provision for tuyere punching, which is known as the Pierce-Smith converter.

**Electric furnaces** of direct and indirect arc types, as well induction melters, have fast become the most used equipment for pyrometallurgical processes for pure metals and alloys production, as well as for melt refining. The source of energy is mostly electrical and external, since little exothermic process heat is realized in these furnaces. Electric-arc furnaces are also very popular for melting and refining recyclable scrap metals. A schematic of the electric-arc furnace is shown in this Handbook in the article "Steelmaking Practices and Their Influence on Properties."

**Retorts** are used to produce metals that can only be reduced at temperatures above their vaporization points so that these metals emerge from the reacting mass in the vapor state and require condensation. For example, a zinc oxide and carbon mixture is smelted in horizontal retorts, which are refractory cylinders closed at one end and heated from the outside. The charge of oxide sinter and coke or coal is charged from the open end, which is then closed with a refractory condenser. Upon heating, the zinc vapors and CO enter the condenser where the temperature is lowered to condense the vapors to liquid zinc. Due to its lower operating cost, the vertical retort process has replaced horizontal retort furnaces. Vertical units are much larger with semicontinuous operation utilizing periodic feeding of hot batches of sinter and coke. The vapors are condensed in a large spray condenser and the zinc is tapped periodically. Production of magnesium by the reduction of calcined dolomite with ferrosilicon is also carried out in alloy steel retorts. A vacuum is maintained in the retort to assist migration of the magnesium vapor to the cold zone where the metal condenses as solid "muff" of magnesium.

## ***Pyrometallurgical Refining***

Thermodynamic conditions prevailing in pyrometallurgical reduction processes and the constituency of the charge material do not allow selective preparation of a pure metal through direct smelting. In addition, the reducing agent and the vessel lining add to the contamination of the metal produced. The purpose of refining, therefore, is to remove various impurities until the metal can meet the purity specifications.

**Liquation** is the process where impurities are frozen out by reducing the temperature of the bath. For example, in a binary alloy system of gold and silver showing a continuous solid solution, cooling the melt will freeze out an alloy higher in gold (higher melting-point element). Subsequent treatment is required since there is no clear separation of the two metals. In the lead-silver eutectic system, cooling the mixture freezes out almost pure lead. Alloy systems that form

two immiscible layers upon cooling, such as lead-zinc, can be used to yield two usable products, as described in the imperial furnace discussion.

**Refining with gaseous reagents** is the method for effective and selective removal of impurities using solid and gaseous reagents. Refining with oxygen presumes that the impurity is more readily oxidized than the host metal and that the resulting impurity oxide is not soluble in the host metal. Removal of silicon, manganese, carbon, and phosphorus from pig iron to produce steel is the best example of the use of oxygen gas for refinement. Resulting oxides combine with lime to form a fluid removable slag. High-temperature oxidation of impure lead by injection of air into a molten bath eliminates arsenic, antimony, and tin as oxides which combine with PbO to form a slag. This process is selective: gold, silver, and bismuth are not oxidized.

In copper converting, the resulting blister copper carries some iron and sulfur, which are eliminated by fire refining process where air is blown into the molten blister and the remaining iron and sulfur are oxidized. Silica sand is added to the bath to react with iron oxide and form a slag. The slag contains a high amount of copper, which is returned to the process for its recovery. Oxidation can be achieved with air, oxygen, or steam injections. These represent oxygen at different activities and may be the basis for obtaining more selectivity in oxidation.

Although zinc can be selectively oxidized from molten lead by air injection, a fairly high temperature is necessary, and the mixed zinc-lead oxide skimmings are not easily treated. However, removal of zinc as a chloride can be achieved at a lower temperature by injecting chlorine gas into the lead-zinc alloy in a closed kettle. The mixed chloride slag may also undergo commercial processing for further recovery. In a similar way, iodine can be reacted with impure titanium, zirconium, or hafnium to form a volatile iodide that leaves the impurities behind. The volatile iodide is brought into contact with a hot filament which decomposes the iodide, leaves the pure metal to deposit on the filament, and releases the iodine to return and react again with the feed metal.

Application of solid reagents for impurity removal depends on their ability to react selectively with the impurities and to form an insoluble phase that can be removed from the parent metal. Common examples are additions of sulfur to remove copper from lead, additions of zinc to remove gold and silver from lead, and additions of calcium and magnesium to remove bismuth from lead.

## Hydrometallurgical Processes

Similar to pyrometallurgical processing, hydrometallurgy may not be directly applicable without a pretreatment. Drying, calcination, and roasting, as discussed previously, may be required to upgrade the ore and prepare it for hydrometallurgical processing. The hydrometallurgical steps may be broadly classified into leaching, purification and metal deposition using aqueous solutions. Although these process steps are predominantly conducted at ambient temperatures, higher temperatures near the boiling point of water or above it (as in pressure leaching) may be necessary for faster kinetics. It should be noted that the same thermodynamic principles apply here as have been discussed for molten metals and slags.

## Leaching Processes

Leaching is a separation process that uses aqueous solutions. A suitable aqueous environment is selected which can decompose the mineral containing the valuable metal. The objectives of leaching are:

- Production of a compound for further processing by pyrometallurgical techniques
- Production of a metal from impure metal or metal compounds that have been prepared by a pyrometallurgical process
- Direct production of a metal from an ore or concentrate

Selection of a particular objective depends on economic factors and the involved thermodynamic and kinetic conditions of the system. The theoretical possibility is limited by thermodynamic constraints, whereas kinetic constraints relate to the overall time required and affect the reactor size and design.

The thermodynamics of leaching are concerned with the ability to decompose a particular compound so that it will selectively dissolve and become stable in the aqueous solution used for leaching. Proper calculations can predict the maximum amount of mineral that can be leached until the system reaches equilibrium. The rate of dissociation and dissolution is kinetically controlled. Figures 9 and 10 are schematic diagrams of a mineral/water interface on a microscopic scale. The concentration of the active chemical in the bulk of the solution is greater than the concentration near the surface of the mineral. This occurs because the active chemical is removed from solution by reaction at the mineral surface. Figure 9 shows that the rate at which the reaction or decomposition of the mineral will occur is determined by: (1) the diffusion of reactant, R, from the bulk of the solution to the surface of the mineral; (2) the reaction of the reagent with the surface to form a soluble species; and finally, (3) the diffusion of the product metal species, M, away from the surface. In Fig. 10, diffusion of R through the porous product layer and diffusion of M through the product layer are also possible (Ref 15).

Fig. 9 Schematic diagram of a mineral surface showing complete dissolution in water

Fig. 10 Schematic diagram of a mineral surface showing decomposition in water and generation of a porous layer of residue on the surface

The leaching of a compound in an aqueous environment can take several forms. Simple dissolution reactions in water, acid, and alkali can be represented by Eq 6, 7, and 8 respectively:

Anionic base exchange, oxidation-reduction, and water-soluble complex formation reactions can be shown by the reactions shown in Eq 9, 10, and 11, respectively:

Oxygen pressure and pH are the most important parameters for determining the chemical properties of aqueous solutions. Predominance area diagrams can be plotted for a metal/H<sub>2</sub>O system in the form of a pH/log *p*O<sub>2</sub> diagram showing regimes of stability for the metal, ions, and insoluble metallic compounds, such as hydroxides (Ref 16).

The leaching method used depends on the physical condition of the ore and the inherent mineralogy. Simple leaching processes include in situ leaching, heap leaching, and agitation leaching. In situ leaching refers to mineral dissolution with the ore "in place" underground. In situ leaching is usually done in worked-out stops of high-grade mines, support pillars left behind after mining, or low-grade deposits. This type of treatment requires the surrounding rock to be tight and impermeable to solution flow in order to contain the leaching solution. This process is very time consuming but has low treatment costs, low equipment requirements, low capital costs, and the ability to treat low-grade ores.

**The heap-leaching process** is similar to in situ leaching since it does not require extensive leaching equipment, such as tanks, slurry pumps, and thickeners; hence, heap leaching requires low capital and maintenance costs. Therefore, the principal feed materials for heap leaching are low-grade ores, ores not amenable to flotation, and discarded waste rock from previous processing with metal values below milling grade. The leachant is sprayed or pumped over a heap of ore. As it percolates through the heap, it dissolves the desirable compounds from the ore. An agglomeration step prior to leaching of the fine ore has shown significant improvement in precious metals recovery (Ref 17).

**Agitation leaching** is usually used with well-disseminated, fine-grained, high-grade ores. This requires extensive crushing and grinding before leaching in order to expose the solution to the minerals where agitation improves the process kinetics. Because of the extensive amount of equipment required for agitation leaching, recoveries of over 90% and short residence times are requirements of the process. Agitation is accomplished by either bubble action using compressed air or by mechanical agitation using impellers. Pachuka tanks are commonly used in air-agitated leaching processes (Ref 18). When high-intensity agitation is required mechanical agitation with impellers is usually used. Marine propellers produce an axial flow, paddles cause a tangential flow, and turbine impellers produce a combined radial and axial flow pattern (Ref 19).

**Pressure leaching** is similar to agitation leaching except that the process is done at elevated pressures and temperatures. Agitation leaching under normal pressure is limited to 100 °C (212 °F). As pressure on the solution is raised, the boiling point of water can be elevated. Thus, higher leaching temperatures can be employed by increasing the pressure. Therefore, the main objective of pressure leaching is to enhance the kinetics of metal dissolution by permitting higher operating temperatures and by increasing the solubility of gaseous species that may take part in the leaching reaction. The oxidation of sulfides in aqueous solutions exemplifies the need for increased gas solubility. At atmospheric pressure metal sulfides are insoluble even in strong acidic solutions. Increasing the temperature and pressure of the system increases the solubility of oxygen in solution. The increase in oxygen solubility and temperature causes rapid oxidation of some metal sulfides to sulfates making them soluble in acid solutions. This ability to achieve oxidation in the leaching step by increasing the pressure can eliminate the need for pretreatment steps, such as oxidation roasting of sulfide ores.

Pressure leaching is generally done in a stainless steel or titanium autoclave for high strength and corrosion resistance at higher temperature and pressure. Linings of glass, lead, or refractory brick may be used under severe corrosion conditions. Most autoclaves are equipped with agitators for mixing. Both vertical and horizontal autoclaves are used in hydrometallurgy. The Sherritt-Gordon process (Fig. 11) uses pressure leaching during the production of nickel and cobalt metals (Ref 20).

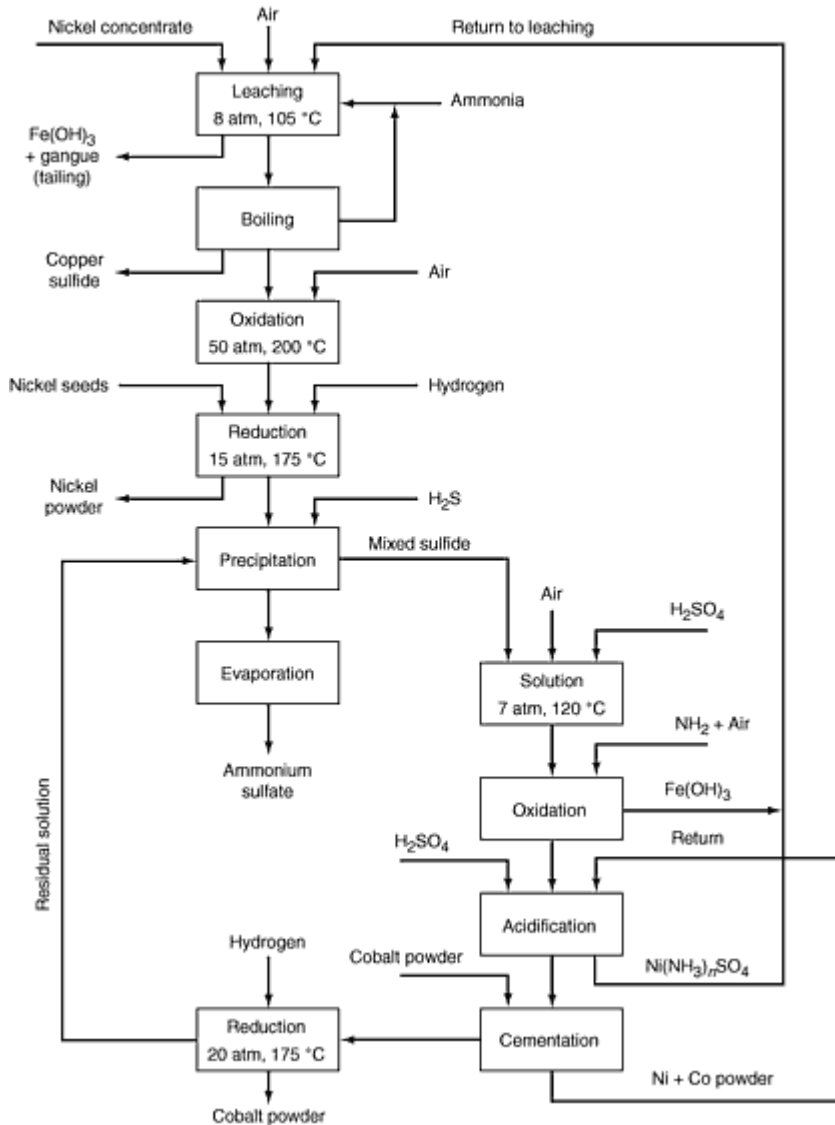

Fig. 11 Sherritt-Gordon process flow diagram for nickel and cobalt production

## Solution Purification

Leaching with strong solutions usually produces an aqueous stream containing the desired metal values as well as some impurities due to the complexity of the mineral ore. Processes for the purification of the leaching solution prior to metal recovery include precipitation, solvent extraction, and ion exchange.

**Precipitation** involves the removal of ionic species from solution as compounds. Precipitation is accomplished by making adjustments to the solution which cause formation of compounds that are no longer soluble in the solution. The concept of the solubility product is used to predict, and to perform calculations concerning, precipitation from solution. The solubility product for a given compound is defined as the product of the concentrations of cation and anion of the compound of interest, each raised to the power of its proportion in the compound. For example, the solubility product for a hypothetical compound  $MX_{2(s)}$  would be

$$[M^{2+}] [X^-]^2 = K_s \quad (\text{Eq 12a})$$

based on the reaction

If the product of the concentrations (left-hand portion of Eq 12a) exceeds the value of the solubility constant ( $K_s$ ) in a solution, precipitation of the compound occurs.

When used as a purification technique in hydrometallurgy, precipitation can be initiated by one of a few different methods. For example, precipitation can be done by addition of chemicals. If the appropriate cation or anion is added to a solution, it will force the precipitation of a specific compound or compounds by exceeding the solubility products. Because metallic sulfides in general have very small solubility products, addition of sulfide anions (as hydrogen sulfide) causes precipitation of insoluble metal sulfides. Precipitation can also be accomplished by the evaporation of water from the solution. As the water evaporates, the concentrations of all ionic species increase until one or more solubility products are exceeded and precipitation occurs.

Changes in the pH of solutions can also be used to precipitate compounds (Ref 16). As the pH of a solution is increased and the solution becomes more basic, the hydroxide ion ( $OH^-$ ) concentration increases and solid hydroxides precipitate. Iron, copper, cobalt, and nickel are precipitated selectively as hydroxides in solutions by raising the pH with milk of lime to 2.5, 5.8, 8.3, and 9.4, respectively. Precipitation can be used in a process to remove the impurities as well as to concentrate metal values in the form of a compound. Desired metal values can also be removed from an impure solution and concentrated in a solid compound. The recovery of sulfides of nickel, copper, lead, and zinc from leaching solutions as precipitates requires further purification, but provides a low-cost treatment method with very low concentrations of metal values in the leach solution.

**Solvent extraction** is a chemical process used to purify and concentrate a given species from aqueous solution. This is accomplished by recycling an organic solution, which selectively exchanges the metal species of interest between an impure aqueous feed solution and a pure fresh aqueous solution. The process relies on the immiscibilities of organic and aqueous solutions as well as the stabilities of the metal species in them. Purification is then achieved by extracting a metal species from the impure aqueous solution to the organic solution and then stripping the metal species from the organic solution back to fresh aqueous solution. A typical solvent-extraction flow sheet is shown in Fig. 12. The organic must be selective to the species being purified, and the reaction must be reversible so that the metal species can be transferred from impure to fresh aqueous solutions via the organic phase. Solvent-extraction chemistry can roughly be separated into two types of reactions: solvation and exchange reactions.

Fig. 12 Typical flow diagram for solvent extraction

Solvation involves transfer of neutral molecular species between aqueous and organic. In the transfer from the aqueous to the organic phase, the neutral species simply dissolves in the organic solution. The organic phases used for solvation can be alcohols, ethers, esters, ketones or phosphorus-containing compounds such as trialkyl phosphates and trialkyl phosphine oxides. Exchange reactions involve the formation of specific bonds between metal species and active compounds in the organic phase. The metal species forms an organic salt with the active organic compounds, which then dissolves in the organic phase. Exchange reactions can be cationic or anionic depending on the system involved (Ref 21).

The organic solutions typically used for exchange reactions are made up of a carrier, an extractant, and a modifier. The carrier or diluent is the inert organic that makes up approximately 90% of the solution and acts as a vehicle for carrying the active extractant. Common diluents are kerosene, and naphthalene. The extractant or active agent is the compound that contains the functional group capable of chemically reacting with the particular metal species in the aqueous phase. The modifier, which is usually an alcohol, is added because it increases extracting power, increases selectivity, improves phase separation, and prevents formation of solid organic compounds. Solvent extraction is typically performed in a combination of mixer-settler units to allow the countercurrent flow of organic and aqueous solutions from stage to stage.

**Ion exchange** is accomplished by interchange of metal ions between aqueous solutions and a solid, insoluble resin. The chemistry of the ion-exchange process is similar to the solvent extraction systems and is sometimes used as a substitute for solvent extraction to avoid problems of emulsion formation and solvent loss due to entrainment. The ion-exchange process involves adsorption followed by elution. Adsorption is the removal of metal ionic species from an aqueous solution when that solution is passed through a bed of ion-exchange resins. Elution is the recovery of the metal ionic species in fresh solution by passing a suitable fresh solution through the previously loaded resins.

Ion-exchange resins are classified as cationic resins and anionic resins. Cationic resins exchange cationic species and are made of strong acid or weak acid groups and exchange  $H^+$  ions. Anionic resins are strong bases, such as quaternary ammonium group bases, and weak bases, such as secondary or tertiary amine group bases. In most cases, chloride ions exchange with anions in solution (Ref 22). The important properties of ion-exchange resins are capacity, selectivity, and mechanical properties. The capacity of a particular resin is the amount of a specific inorganic group that the resin will hold per unit weight or volume. The affinity of a resin for different ions in solution varies. This selectivity of one ion over the other is described as a distribution coefficient,  $K$ , where  $K = (\% \text{ equivalent of ions in resin})/(\% \text{ equivalent of ions in solution})$ .

For a particular resin, the selectivity coefficient varies with the species of interest making it possible to purify a particular metal ion from a complex solution. Because ion-exchange resins are used over and over as the transfer media for purification, they require good mechanical properties. Resins must be durable and resistant to breakage, must have low chemical degradation, and must be insoluble in aqueous solutions. The ion-exchange equipment involves fairly high capital costs and a large plant area due to the large amounts of in-process material. However, properly run ion-exchange facilities result in up to 99% efficiency during normal operation.

### ***Metal Deposition***

Once an ore concentrate has been leached and purified, the metal of interest must be recovered from solution. Three common techniques of metal reduction from aqueous solution are cementation, hydrogen reduction, and carbon adsorption.

**Cementation**, or metallic replacement, is a classical process for recovering metals from aqueous solution. Cementation is essentially the precipitation or discharge of a noble or less-reactive metal in favor of a more-reactive metal. The basic reaction between the two metals is electrochemical in nature and can be represented by the reaction in the following equation for the reduction of cadmium by zinc metal:

The above electrochemical reaction can be separated into two half-reactions:

When the active zinc metal is added to a solution containing relatively noble cadmium ions, reduction takes place in microcells producing cadmium metal. Since the two half-cell reactions require transfer of electrons it is essential that the solid is a conductor of electricity. The tendency of one metal to displace or reduce another metal from solution is based on the electromotive series of metals (Ref 23). In general, when two metals are considered, the one that is more electropositive will tend to reduce a less-electropositive metal from solution. Also, the greater the difference in potential between the two metals is, the greater is the driving force for the reaction. However, even a small difference in potential results in an extensive degree of reduction. Reduction of copper ions from solution by metallic iron using cementation is industrially practiced:

Copper sulfate solution is fed through open launders containing steel scrap where the displacement reaction occurs and produces a very pure copper that can be recovered in the bottom of the launders. Cementation cones are commonly used now for the deposition of metals (Ref 24). The rate at which cementation reactions occur depends on initial concentrations, temperature, agitation, polarization characteristics of different metals, and addition agents (Ref 25).

**Gaseous reduction** of metals from aqueous solution can be done with reducing gases, such as hydrogen, carbon monoxide, and sulfur dioxide. Hydrogen is the most widely used because it is relatively inexpensive. The reaction products from carbon monoxide and sulfur dioxide have to be further treated after the reduction step. The use of reducing gases also involves a replacement reaction:

The tendency of the above reaction to produce copper can be increased by increasing the pressure of hydrogen gas since the reaction moves to the right. A similar reaction for nickel at room temperature and atmospheric pressure does not occur. However, if the reaction is carried out in an autoclave that permits high hydrogen pressures and temperatures, nickel can be reduced from the solution. Although the mechanism by which nickel is reduced from ammoniacal solutions is more complex, nickel is reduced commercially at high temperature and pressure in the presence of ammonia (Ref 20).

**Carbon adsorption**, or reduction of metals from aqueous solution, is used almost exclusively to recover the noble precious metals, such as gold and silver. This process is based on the principle that these metals can be reduced out of solution by solid carbon at low temperatures and deposited in metallic form on the carbon. In a typical carbon-adsorption process, the metal leaching solution is fed to carbon columns and the metal is almost completely removed from the solution by adsorption on the solid carbon. After the carbon is loaded, it is removed from the circuit and the metal is stripped away. The carbon can also be added to the leaching liquor and agitated without the requirement of carbon columns, known as the "carbon in pulp" process. Desorption or stripping is done by passing a hot, caustic stripping solution over the column. Stripping is followed by electrowinning from solution to produce a very pure gold or silver product. A typical flow sheet, including carbon adsorption, is shown in Fig. 13. The loaded carbon can also be burned, which leaves a gold- or silver-rich ash.

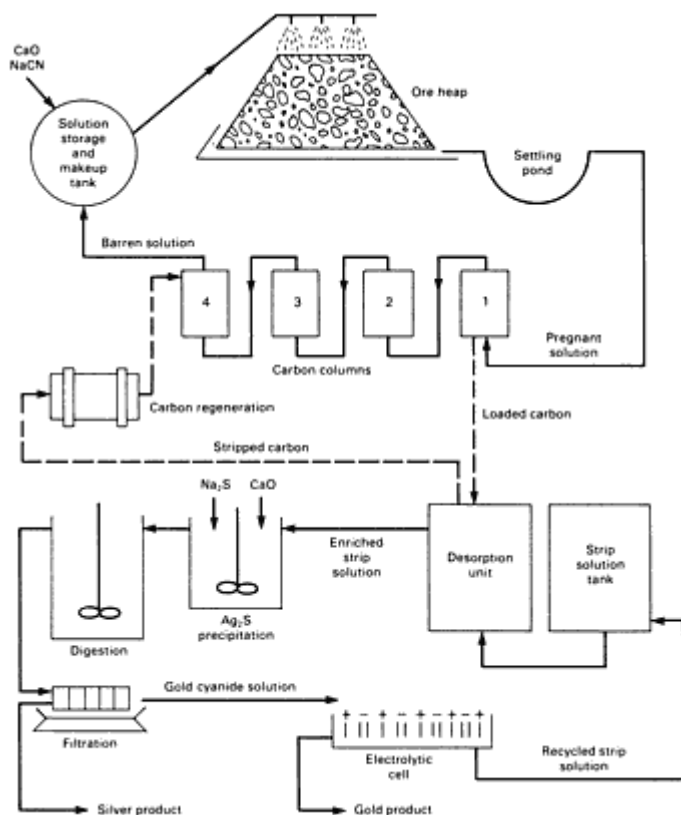

Fig. 13 Heap-leaching charcoal-adsorption process for gold ores low in silver

## Electrometallurgical Processes

Electrometallurgy, or electrolytic processing, deals with the production of metals from ions by application of electrical energy. In contrast with electrochemical processing, where chemical reaction produces electricity as in batteries or corrosion, electrolytic processing uses electricity to perform chemical functions as in metal extraction. Therefore, corrosion is also known as "extractive metallurgy in reverse." As has been discussed thus far, extraction usually implies

reduction of a compound, where as corrosion implies oxidation of a metal into a compound. The term electrowinning is used to describe the recovery of metals from a solution or electrolyte on a negative electrode, or cathode, while the positive electrode, or anode, is inert to the ongoing reaction. Electrorefining entails a purification process in which the anode is made of solid impure metal that actively dissolves in the electrolyte; deposition of pure metal occurs on the cathode. These solutions could be generated during leaching and/or purification, as discussed in hydrometallurgy.

Fused salt electrolysis is the production of metals which cannot be electrolyzed from aqueous solution due to their relative positions in the electromotive series and, therefore, are reduced from molten salts. In other words, production of hydrogen from its oxide (water) is, energy-wise, more favorable than the production of metal from its compound. Electrowinning and electrorefining concepts are equally applicable to molten salt electrolysis. If the metal compound has high melting point and is difficult to melt, it may be dissolved in an inert carrier electrolyte (molten salt) which is more stable than the metal compound of interest. The Hall-Héroult process for aluminum production essentially follows this scheme where alumina is dissolved in molten cryolite (sodium-aluminum fluoride).

### **Basic Concepts**

The electromotive series is a listing of the standard half-cell potentials with respect to a reference electrode. The reactions described in establishing an electromotive series are referred to as electrochemical reactions. Electrochemical reactions involve oxidation (loss of electron) and reduction (gain of electron) and can be arranged in an electrochemical (galvanic) cell as shown in Fig. 14. In general, the valence state of the metal is increased in oxidation and decreased in reduction. The oxidation state of a pure metal atom is zero which gets positively ionized by losing electrons. The electrons are picked up by another ionic species, which gets reduced in the solution. If this other ionic species is another metal ion that is reduced on the cathode, the process is known as cementation. It should be memorized that the ions that move towards the anode are anions (negatively charged) and those that are attracted by the cathode are cations (positively charged). The ionic species in the solution (acidic) could be simply protons that can be reduced on the cathode as hydrogen gas.

**Fig. 14** Electrochemical (galvanic) cell

The potentials on the electromotive series are the minimum theoretical volts required for depositing the metals from a molar solution saturated with its own ions at 25 °C (77 °F), and are measured against a standard reference electrode. For the example of copper metal deposition using zinc metal (Eq 13), an electrochemical cell can be set up, as in Fig. 14, by using a copper electrode as M in a solution of copper sulfate and a zinc electrode as M<sub>2</sub> in a solution of zinc sulfate. If the external circuit is short circuited, electrons will flow from the zinc electrode (anode) to the copper electrode (cathode) as zinc dissolves, which causes deposition of copper metal. By placing a voltmeter between the cathode and the anode, the potential difference between the oxidation and reduction half-reactions can be measured. Because measurement of potential requires measurement between the electrodes, an absolute potential of any half-reaction cannot be measured.

The theoretical dissociation potential required for electrolysis of a compound is given by  $-cG/nF$ , where  $\Delta G$  is the Gibbs free energy change of the formation of the compound and is a function of temperature and activities of the ions,  $n$  is the number of electrons transferred in the oxidation-reduction reaction, and  $F$  is the Faraday Constant (96,486 C). The theoretical current required for metal deposition from the solution is given by Faraday's law, which states that 1 gram-equivalent weight of any metal can be deposited by passing 95,500 ampere-sec of charge (1 faraday). The product of the theoretical potential and current is the theoretical power required. The current and energy efficiencies of an electrolytic cell may be measured as the percent ratios of these theoretical values and the actual amounts of potential applied and current consumed. Efficient electrolytic cells are characterized by high current and energy efficiencies. The theoretical

dissociation potential must be exceeded to allow deposition of the metal of interest, but should be kept as low as possible for a higher energy efficiency. Current, in general, is directly linked with the deposition rate, although higher current also implies higher ohmic losses and  $I^2R$  heating.

## Electrowinning

The electrowinning arrangement usually recycles the acid between the leaching operation and the electrowinning operation for economic efficiency. A simplified diagram of the leaching/electrowinning process is presented in Fig. 15. For example, in the leaching step, the sulfuric acid is consumed as the metal dissolves, according to the reaction in the equation:

Fig. 15 Simplified block diagram showing the cyclical nature of the leaching/electrowinning process

The leaching solution,  $\text{H}_2\text{O} + \text{MSO}_{4(aq)}$ , is transferred to the electrowinning step for deposition of the metal. The leaching solution is fed into cells which consist of inert anodes (usually made of lead) and cathodes (which may be made of stainless steel, aluminum, or starter sheets of metal M), arranged as parallel alternating plates of cathodes and anodes. In the electrowinning step, the power supply forces electrons to the cathode, and metal sulfate is reduced to produce the pure metal:

At the anode, oxygen is produced by decomposition of water and the regeneration of acid is accomplished by the reaction in Eq 19, and recycled back to the leaching step (Eq 16):

In this case, the potential required between cathode and anode in electrowinning is of the order of 1.25 to 1.75 V. This potential is the combination of the decomposition potential defined earlier (the reversible potential between the cathode and the anode), the ohmic drops or IR losses due to the resistance of the electrolyte, connections and conductors, and polarization of the cell (Ref 23).

The decomposition potential is measured only when the cell reactions take place under conditions of infinitely low current or net zero current. In electrolysis, where current flows at a finite rate, additional voltage drops occur as a result of phenomena that take place near the electrode solution boundaries. These extra voltages are called overvoltages and are caused by reactants not being supplied to electrodes as fast as products are removed (concentration overvoltage) or by

molecular phenomena (activation overvoltage) (Ref 23). The resistances of the electrical connections and the electrolyte cause generation of heat as current passes through the cell (Joule heating). The optimum solution temperature in most electrowinning plants is 30 to 45 °C (86 to 113 °F). Temperatures much higher than this can cause deterioration of the cathode deposit as well as increased corrosion of the anodes.

Since the deposited metal must be removed to recycle the cathode, it is important that the metal be loosely bonded to the cathode. For copper electrowinning, titanium, stainless steel, and copper have been used successfully. Aluminum is used to recover zinc and titanium, and stainless steel has been used for electrowinning manganese and cobalt. Electrolytes for electrowinning may also be prepared by externally dissolving the metal in a solvent and pumping it into the cell.

## ***Electrorefining***

The advantages of electrorefining over other refinement techniques are the high purity that can be obtained in the product and the recovery of secondary metals (which often are a series of precious metals) in a concentrated state. The secondary metals are recovered from the concentrated form in a separate process. Metals made by smelting of sulfides, such as copper, lead, and nickel, usually are refined by electrolysis. The impurities that contaminate these metals are most often associated with sulfides themselves. The precious metals gold, silver, platinum, and selenium, as well as iron, bismuth, arsenic, and antimony, are usually present. The metal from the smelters, which is from 90 to 98.5% pure, is cast into anodes prior to electrorefining.

The impure anodes are put into cells that contain an acid electrolyte of the anode metal ion. Cathode sheets are placed between the anodes where the pure metal is deposited. A dc power source is wired to the anodes and cathodes in a manner such that electrons are forced into the cathode sheets, causing reduction, and electrons are stripped from the anodes, causing oxidation. At the anode, the oxidation reaction results in the dissolution of the metal by the reaction,  $M = M^{2+} + 2e^-$ , and the electrons flow back through the power source to the cathode. As the anode dissolves, the impurities either dissolve into the electrolyte with the metal or remain at the anode. The metals that remain in the metallic state are more noble in the electromotive series than the metal that is being refined. As the anode dissolves away, these noble metals fall to the bottom of the cell and collect in a concentrated product that is commonly called "anode slime" or "anode mud." Anode mud is very valuable because it is usually made up of precious metals, such as gold, silver, platinum, and selenium. In copper electrorefining, the slimes can be over 90% silver. The metals that are less noble on the electromotive series of metals dissolve along with the metal that makes up the anode and, if not removed, do build up and contaminate the electrolyte.

Approximately 85% of the anode is allowed to dissolve to retain its mechanical integrity before it is removed from the tank. The unused portion is sent back to the smelter, where it is used as scrap and recast into more anodes. The cycle time for anodes in a typical electrorefining operation is 14 to 28 days. As the electrons are stripped from the anode and forced to the cathode, metal-ion reduction and metal deposition occur on the cathode according to the reaction  $M^{2+} + 2e^- = M$ .

Because the less noble metals remain in the metallic state as the anode dissolves, the only metal that plates on the cathode is the metal that made up the bulk of the anode. Those impurities that are less noble and get dissolved in the electrolyte are not plated on the cathode and remain in solution as metallic ions. Electrorefined product may also be collected either on another metal sheet or a starter sheet of the metal being plated. The cycle time for cathodes is somewhat longer than the anode cycle time. Current densities on cathodes are kept low to ensure quantity deposits and often are approximately 215 A/m<sup>2</sup> (20 A/ft<sup>2</sup>). The physical nature of the deposit is a function of the type of metal ion, current density, deposition temperature, interpolar distance, and deposition rates.

The voltage required between anode and cathode during electrorefining is significantly lower than that required for electrowinning. For example, electrorefining of copper requires only about 0.25 V since the reversible decomposition voltage between two copper electrodes is essentially zero. The other voltage drops, such as the ohmic drops and polarization (overvoltage) exist in electrorefining however.

The cells used for electrorefining are commonly rectangular vats that allow easy placement and removal of anodes and cathodes. The bottoms of the tanks are sloped to allow the collection and flushing of the anode slimes. Since most electrolytes are sulfuric acid base (with the exception of lead electrorefining), the lining material is PVC, rubber, or lead.

Soluble impurities which dissolve with the anode and are not reduced at the cathode must be removed to avoid concentration in the electrolyte. If not removed, these impurities lower the conductivity of the electrolyte, which in turn increases the voltage required and thus increases the energy required. An example of this type of impurity is nickel in

copper electrorefining. Nickel is an impurity in the anode that dissolves during electrolysis and collects in the electrolyte. Most copper refiners keep the concentration of nickel below 10 to 20 g/L by continuously bleeding off a small portion of the electrolyte, removing nickel by chemical means, and returning the nickel-free electrolyte to the cells.

Insoluble or more noble impurities that remain in the metallic state collect in the bottom of the electrorefining cells. This anode mud collects until the anode-cathode cycles are complete. At that time, the electrolyte is pumped from the cell, and the slimes are flushed out and collected by filtration. Because the slimes are the final destination of the precious metals, they are further refined to recover gold, silver, platinum, and other associated precious metals.

## ***Molten Salt Electrolysis***

As mentioned earlier, reactive metals that are more electropositive in the electromotive series than manganese cannot be electrowon or electrorefined from aqueous solutions because water will decompose at the cathode to form hydrogen gas before reduction of the metal occurs. Therefore, electrolysis of very electropositive metals, such as aluminum, magnesium, lithium, and beryllium, is done from molten salt electrolytes.

Present practice for aluminum electrolysis involves the use of the Hall-Héroult cell as shown in Fig. 16. The cell is lined with carbon, which acts as the cathode; steel bars are embedded in the cathode lining as current collectors. The consumable anodes are also of carbon and are gradually fed into the top of the cell. For aluminum, the electrolyte used is cryolite ( $\text{Na}_3\text{AlF}_6$ ) with 8 to 10%  $\text{Al}_2\text{O}_3$  dissolved in it. Other additives, such as  $\text{CaF}_2$  and  $\text{AlF}_3$ , are added to obtain desirable physical properties, such as fluidity and electrical conductivity. The melting point of the electrolyte is approximately 940 °C (1725 °F), and the Hall-Héroult cell operates at temperatures of approximately 960 to 1000 °C (1760 to 1830 °F) with a power rating of 10 to 12 kWh/kg aluminum.

**Fig. 16** Hall-Héroult aluminum production cell with self-baking anode. Source: Ref 5

Electrochemically, aluminum is reduced at the cathode from an ionic state to a metallic state by:

This simplified reaction goes through a series of complex reactions that take place at the cathode (Ref 26). It does represent the overall production of molten aluminum, which forms a molten pool in the bottom of the cell. Periodically, the molten pool of aluminum metal is drained or siphoned from the bottom of the cell and cast.

At the anode, oxygen is oxidized from its ionic state to oxygen gas which, in turn, reacts with the carbon anode to form carbon dioxide gas, gradually consuming the anode material. Two types of anodes are in use: prebaked and self-baking. Prebaked anodes are individual carbon blocks that are replaced one after another as they are consumed. Self-baking

anodes, as shown in Fig. 16, are made up of a carbon paste that is fed into a steel frame above the cell. As the anode descends in the cell it hardens, and new carbon paste is fed continually into the top of the steel frame.

Impurities in the aluminum oxide raw material that are more noble than aluminum, such as iron and silicon, are reduced at the cathode along with the aluminum. It is, therefore, important that raw materials be prepared in the Bayer's process as free of these metal oxides as possible. By careful control of raw materials, aluminum with a purity of over 99% can be produced.

Magnesium is produced by molten salt electrolysis. Magnesium does not alloy with iron, and so the cells consist of iron pots as cathodes and carbon anodes. The electrolyte used is a magnesium chloride-sodium chloride-calcium chloride mixture that allows the process to be run at approximately 750 °C (1382 °F). The raw material for magnesium may be either magnesium chloride or magnesium oxide. Magnesium electrolysis differs from aluminum electrolysis in that the magnesium metal formed at the cathode is less dense than the electrolyte and rises to float on top of the electrolyte; this requires special precautions when the molten metal is recovered from the cell. Production of calcium by molten salt electrolysis has been developed successfully from molten calcium oxide-calcium chloride salt mixtures using carbon anodes. Presently, a great deal of research effort is concentrated on eliminating the consumable carbon anode from these fused salt electrolytic processes. Inert ceramic anodes that conduct oxygen ions and are based on spinel and perovskite compositions have been developed. Carbon electrodes impregnated with titanium diboride have been successfully used in the industry.

The science of extractive metallurgy has more or less remained the same over several decades (Ref 27). However, significant progress has been made in the technology and application of this science to extract metals cheaply, efficiently, and in an environment-friendly manner.

# General Introduction to Casting

Thomas S. Piwonka, The University of Alabama

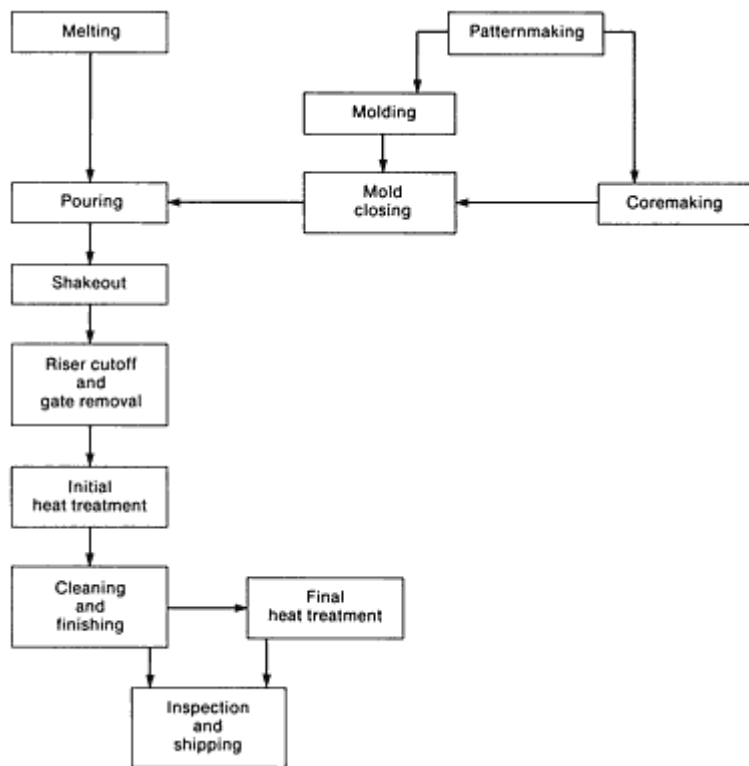

## Introduction

METAL CASTING is the manufacturing method in which a metal or an alloy is melted, poured into a mold, and allowed to solidify. It is one of the oldest manufacturing methods known to humankind, and one of the most versatile. Today's foundries make use of statistical process control and sophisticated solidification simulation software, and castings today are highly reliable, cost-effective components that are utilized in more than 90% of manufactured products. Typical uses of castings include municipal hardware, water distribution systems (pipes, pumps, and valves), automotive components (engine blocks, brakes, steering and suspension components, etc.), prosthetics, and gas turbine engine hardware.

## Casting Flow Chart

The steps in making a casting are shown in Fig. 1. Before the casting can be made, the alloy must be melted, and the mold must be made. The mold is usually made of a material with a higher melting point than that of the alloy, such as a refractory aggregate (e.g., silica sand) or a high-temperature alloy. There are a wide variety of mold-making methods used in casting, depending on the alloy to be poured, the number of castings to be made, the dimensional requirements of the casting, and the property requirements of the casting. Figure 1 depicts the sand molding process, the most commonly used

molding (casting) method. A more detailed account of this process can be found in the article "Molding Methods" in this Section.

**Fig. 1** Simplified flow diagram of the basic operations for producing a steel casting. Similar diagrams can be applied to other ferrous and nonferrous alloys produced by sand molding

The right side of Fig. 1 begins with the task of patternmaking. A pattern is a specially made model of the component to be produced, used for producing molds. Generally, sand is placed around the pattern, and, in the case of clay-bonded sand, rammed to the desired hardness. In the case of chemical binders, the mold is chemically hardened after light manual or machine compaction. Molds are usually produced in two halves so that the pattern can be easily removed. When these two halves are reassembled, a cavity remains inside the mold in the shape of the pattern.

Internal passageways within a casting are formed by the use of cores. Cores are parts made of sand and binder that are sufficiently hard and strong to be inserted into a mold. Thus, the cores shape the interior of the casting, which cannot be shaped by the pattern itself. The patternmaker supplies core boxes for the production of precisely dimensioned cores. These core boxes are filled with specially bonded core sand and compacted much like the mold itself. Cores are placed in the drag, or bottom section, of the mold, and the mold is then closed by placing the cope, or top section, over the drag. Mold closing completes the production of the mold, into which the molten metal is then poured.

Casting production begins with melting of the metal (left side of Fig. 1). Molten metal is then tapped from the melting furnace (see the article "Melting Methods") into a ladle for pouring into the mold cavity, where it is allowed to solidify within the space defined by the sand mold and cores. After it has solidified, the casting is shaken out of the mold, and the risers and gates are removed. Risers (also called "feeders") are shapes that are attached to the casting to provide a liquid-metal reservoir and control solidification. Metal in the risers is needed to compensate for shrinkage that occurs during cooling and solidification. Gates are the channels through which liquid metal flows into the mold cavity proper. Cleaning and finishing, heat treatment, and inspection follow. The article "Solidification of Metals and Alloys" provides a more detailed account of how castings solidify in the mold, shrinkage characteristics, as well as gating and risering practices.

## Casting Alloys

Alloys used for metal casting may have the same composition as alloys used in other forming methods. However, many of the alloys used in casting have been developed expressly for the casting process, and these alloys do not have analogs

for other forming processes. They exist only in the cast form, as their performance depends on the unique metallurgical structure produced during solidification. In addition, many of the alloys that exist in cast and wrought form often have slight variations in chemistry to facilitate the casting process. It is important to know exactly which composition is meant when dealing with these alloys.

**Ferrous alloys** include both cast irons and steels. Cast irons generally refer to iron alloys containing 3 to 4% carbon, with silicon contents of 1.5 to 2.5%. Cast irons, which are melted in induction furnaces, cupolas, and electric arc furnaces, are generally poured/cast into sand molds. Steels include all alloys containing less than 2% carbon, with additions of small amounts of manganese and silicon, and other alloying elements as needed. Most steel is arc melted and poured into sand molds.

**Nonferrous castings** are used where ferrous castings would be too heavy, too expensive, or lack the properties required for the application. These alloys are generally melted in crucible furnaces, reverberatory furnaces, or induction furnaces. Molding techniques are similar to those used for ferrous alloys, but, because most nonferrous alloys melt and solidify at lower temperatures than ferrous alloys, metal molds are frequently used.

# Solidification of Metals and Alloys

Thomas S. Piwonka, The University of Alabama

## Introduction

SOLIDIFICATION is the transformation of liquid to solid. During this process, atoms change their arrangement from randomized short-range order to regular positions on a crystallographic lattice. In doing so, they give up energy in the form of heat, which must be removed by the mold. The energy they give up is called the "latent heat of fusion."

## Pure Metals

Pure metals give up their latent heat of fusion and solidify at a single temperature. If a pure metal is melted and allowed to solidify in the melting crucible, a thermocouple placed in the metal during solidification will show the trace shown in Fig. 1. The temperature will fall until the melting point is reached (it will actually fall a little below the melting point and then recover as solidification begins). At the melting point, the temperature will remain constant until all of the metal has completed its transformation and given up its latent heat of fusion. The temperature will then continue to fall to room temperature.

Fig. 1 Thermocouple trace for a pure metal solidifying in a mold

Solidification begins with a nucleation event. Although it is possible under very closely controlled conditions to cool the metal far below its melting point ("undercooling"), in practice the undercooling experienced is very small. This is because commercial melts always contain some sort of nucleating agent. Most often this agent will be the wall of the mold itself.

However, other agents may be deliberately added to the melt to control the nucleation event and the degree of undercooling. For example, this is especially important in controlling the solidification of cast iron.

Because the mold is cooler than the metal, nucleation will occur all over the surface of the mold. Each nucleation event will produce an individual crystal, or grain, which then will attempt to grow. These randomly oriented grains form a "chill zone" next to the mold wall. The grains are oriented randomly with respect to the mold; that is, the major axis of each grain is randomly oriented. As each metal grows most favorably in one principal crystallographic direction, only those grains favorably oriented with their growth direction most perpendicular to the mold wall will grow into the center of the casting (Fig. 2). The grains in a pure metal will grow until they impinge on another grain.

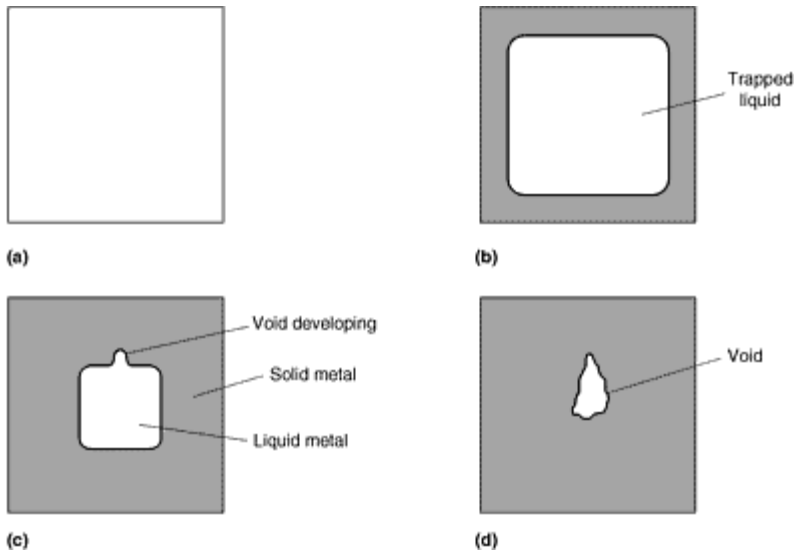

**Fig. 2** Solidification in conventional castings. During the growth of the columnar zone, three regions can be distinguished. These are the liquid (L), the liquid plus solid (the so-called "mushy" zone), and the solid (S) regions.

The fact that the grains most favorably oriented to the mold wall grow the fastest means that the final shape of the grains in a pure metal casting is columnar. As shown in Fig. 2, the grains form parallel columns, growing progressively from the mold wall into the center of the casting.

The density of the solid phase is different than that of the liquid phase. In almost every metal, the solid is more dense than the liquid. The solid will occupy less space than the liquid; in other words, it will shrink in volume. Because this shrinkage occurs at the point of solidification, the volume deficit, which is called the shrinkage cavity, is found at the location of the last liquid to solidify. Figure 3 shows the formation of a shrinkage cavity in a pure metal solidifying in a mold where all heat is removed through the mold. If the final casting is to have the same volume as the liquid, a reservoir of molten metal must be placed on the casting to feed liquid metal to the mold cavity. This extra metal is called the feeder, or the riser.

**Fig. 3** Development of shrinkage void in a casting. (a) Liquid. (b) Liquid + solid. (c) Liquid + solid. (d) Solid

### Alloys

The solidification of alloys is more complex. Alloys are solutions of one or more metals or semimetals in another metal. As such, they solidify over a range of temperatures. The temperature range over which solidification takes place under equilibrium conditions is found from the phase diagram. The temperature at which solidification begins is called the liquidus temperature, and the temperature at which it ends in equilibrium solidification is called the solidus. This range is often referred to as the "mushy zone," because the material in this temperature range is a mixture of liquid and solid (Fig. 2). Figure 4 shows a simplified phase diagram for a binary alloy system. Note that almost all commercial alloys have three or more components; as such, their solidification is more complex than for binary alloys.

**Fig. 4** Simplified phase diagram, showing positions of liquidus, solidus, and eutectic temperatures, and the mushy zone

**Dendrite Formation.** During alloy solidification, instabilities in the solid at the liquid/solid interface grow, leading to the formation of dendrites (Fig. 5). Dendrites have a primary arm, secondary arms that branch from it, and tertiary arms that branch from the primary arm. The spacing of the secondary arms is proportional to the rate at which heat is removed from the casting during solidification. Each crystal consists of a single dendrite.

**Fig. 5** Growing dendrite tip and dendrite root during columnar growth in a casting. A dendritic form is usually characterized in terms of the primary (dendrite trunk) spacing,  $\lambda_1$ , and the secondary (dendrite arm) spacing,  $\lambda_2$ .

**Segregation.** During equilibrium alloy solidification, solute atoms are rejected into the liquid, according to the lever rule. Thus, the composition of the unsolidified liquid changes during solidification, and the last liquid to solidify has a different composition than that of the first liquid to solidify. The change in composition is referred to as segregation. When large areas of the casting show differences in composition from the nominal composition of the alloy that was poured to make the casting, macrosegregation results. However, segregation also occurs between the dendrite arms, where solidification is taking place.

Segregation has a number of effects. During solidification it causes the composition to change locally over the casting (Fig. 6). This local change in composition may result in the formation of different phases or compounds, such as carbides or intermetallic phases, which would not otherwise be stable at the nominal composition of the alloy. These local phases may degrade casting properties. Because the rejection of solute into the liquid changes not only the composition of the liquid but also its density, convection currents caused solely by segregation (solutal convection) may be set up in the casting. The amount of shrinkage that occurs locally will also be a function of the local composition of the liquid when it solidifies. A major effect of segregation is that heat treatment times may be lengthened; the time to homogenize a casting will depend on the dendrite arm spacing (the distance over which solute atoms must travel to go into solution) and the amount of segregation. Because segregation causes the casting composition to vary locally, chemical etching can reveal the cast structure, which makes metallography possible.

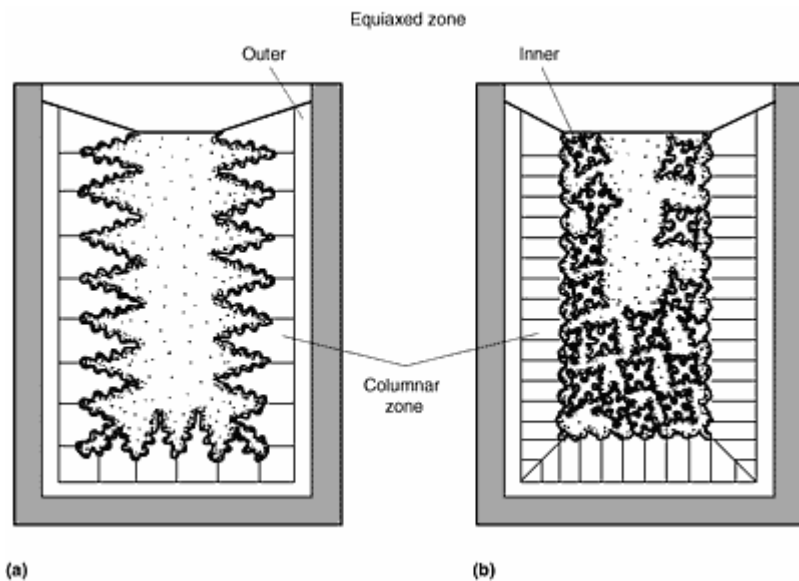

**Fig. 6** Isoconcentration profile lines in an Fe-25Cr-20Ni columnar dendrite showing that the chemical concentration of elements is not constant within the dendrite.

When metal is poured into a mold, the liquid has a velocity from the pouring operation. In addition, as the metal cools at the mold wall, thermal convection currents are set up at the mold wall, with the cooling metal traveling downward along the mold wall. These currents, combined with solutal convection and the residual liquid motion from pouring mean that the liquid in the unsolidified part of the casting is in motion. This movement is usually beneficial, as the motion minimizes macrosegregation in small castings (although it magnifies it in large castings).

Alloys nucleate in the same manner as pure metals. However, during solidification, the liquid motion may break off dendrites and carry them into the liquid. Then the dendrites act as nuclei for more grains and multiply the number of grains that nucleate in the liquid. In addition, solute rejection (segregation) may form a region of liquid where the melting point of the liquid rises above the temperature of the melt, meaning that the liquid in that region is now below its melting point. Even though the actual temperature of the liquid has not changed, the change in composition resulting from segregation yields an alloy composition locally that has a melting temperature above that of the liquid. This is called constitutional supercooling. The result of these two mechanisms refines the final grain structure of the casting.

**Structural Zone Formation.** Solidification begins, as in pure metals, with nucleation of solid on the walls of the mold, again forming a chill zone. Then those grains that are most favorably oriented grow inward, forming a columnar zone. However, because of segregation, there is constitutional supercooling and grain multiplication. As a result, the last liquid to solidify does so as equiaxed grains. Thus, the final structure of the casting has three zones (Fig. 7). In the equiaxed zone, the grains do not grow progressively from the solid that has already solidified. Instead, they grow simultaneously from their own nuclei, until they impinge on neighboring grains.

**Fig. 7** Three structural zones forming in a casting. (a) Early in the solidification process, solid nuclei appear at, or close to, the mold wall. For a short time, they increase in size and form the *outer equiaxed zone*. Then, those crystals (dendrites) that can grow parallel and opposite to the heat flow direction will advance most rapidly. Other orientations tend to be overgrown, due to mutual competition, leading to the formation of a *columnar zone*. (b) Beyond a certain stage in the development of the columnar dendrites, branches that become detached from the latter can grow independently. These tend to take up an equiaxed shape because their latent heat is extracted rapidly through the undercooled melt. The solidified region containing them is called the *inner equiaxed zone*.

The amount of the final cast structure that is columnar or equiaxed depends on the alloy composition and on the thermal gradient at the liquid/solid interface during solidification. The thermal gradient is most easily controlled by controlling the rate of heat extraction from the casting, or the cooling rate. Alloys that have a wide spread between the liquidus and the solidus temperature solidify with a mostly equiaxed grain structure at normal cooling rates, whereas alloys with small differences in solidus and liquidus temperatures solidify with a mostly columnar structure. High cooling rates encourage columnar solidification because they establish high thermal gradients at the liquid/solid interface. Low thermal gradients encourage equiaxed solidification.

**Shrinkage.** Like pure metals, alloys shrink as they solidify. However, feeding the shrinkage in the equiaxed zone is far more difficult than feeding shrinkage in the columnar zone. In the equiaxed zone, the liquid must wind its way down tortuous interdendritic channels to feed the shrinkage occurring at the end of these channels. As these channels narrow, feeding becomes finally so difficult that the metal is unable to reach the areas where solidification is occurring. As a result, tiny micropores form between the equiaxed grains. This condition is known as microporosity.

**Effects of Nonequilibrium Conditions.** The discussion to this point has assumed that solidification takes place under equilibrium conditions. However, in actual castings, this is not true. Equilibrium solidification occurs at rates so slow that there is perfect diffusion in the liquid and in the solid, so that the composition of the alloy shown on the phase diagram is what is found everywhere in the casting. However, real castings solidify much more quickly than the equilibrium rate, and many castings solidify at high rates. The faster the solidification rate is, the greater the departure from equilibrium will be. Departures from equilibrium exaggerate segregation. They also depress the liquidus and solidus temperatures. Indeed, it is common for the last metal to solidify as a eutectic because of departures from equilibrium during solidification. It is important to remember in analyzing castings that there is this departure from equilibrium caused by solidification rate. Because solidification rate varies with location in the casting (it is higher at the edges and corners of the casting, and lower in the interior of heavy sections), the departure from equilibrium varies with location in the casting.

## Eutectic Phases

When the liquid has the composition of the eutectic, it solidifies forming two distinct phases in intimate contact with each other (Fig. 8). Eutectic, or near-eutectic, alloys are common in casting. In fact, one of the most common casting alloys, cast iron, gets its distinctive microstructure from the controlled solidification of the eutectic phase.

**Fig. 8** Irregular "Chinese script" eutectic consisting of faceted  $\text{Mg}_2\text{Sn}$  phase (dark) in a magnesium matrix. Etched with glycol. 250×

Eutectics have the lowest melting point in the alloy and high fluidity. Near-eutectic alloys flow easily into the mold. When the temperature falls below the eutectic temperature, the casting is solid. A more detailed account of eutectic phases can be found in the Section "Structure and Properties of Metals" in this Handbook.

## Imperfections

During solidification, atoms leave the liquid and arrange themselves as a solid. During this process, many things can happen to cause imperfections (defects) in the solid.

**Porosity** is the presence of pores in the casting. These pores may be connected to the surface, where they can be detected by dye penetrant techniques, or they may be wholly internal, where they require radiographic techniques to be discovered. Macroporosity refers to pores that are large enough to see with the unaided eye on radiographic inspection, while microporosity refers to pores that are not visible without magnification.

Both macroporosity and microporosity are caused by the combined action of metal shrinkage and gas evolution during solidification. It has been shown that nucleation of pores is difficult in the absence of some sort of substrate, such as a nonmetallic inclusion, a grain refiner, or a second-phase particle. Numerous investigations have shown that clean castings, those castings free from inclusions, have fewer pores than castings that contain inclusions. Microporosity is found not only in castings but also in heavy section forgings, which have not been worked sufficiently to close it up.

When the shrinkage and the gas combine to form macroporosity, properties are deleteriously affected. Static properties are reduced at least by the portion of the cross-sectional area taken up with the pores. Because there is no metal in the pores, there is no metal to support the load there, and the section acts as though its area was reduced. Because the pores may also cause a stress concentration in the remaining material, static properties may be reduced by more than the percentage of cross-sectional area caused by the macroporosity.

Dynamic properties are also affected. A study of aluminum alloys showed that fatigue properties in some alloys were reduced 11% when specimens having x-ray quality equivalent to ASTM E 155 level 4 were tested, and that they were reduced 17% when specimens having quality of ASTM E 155 level 8 were tested.

Static properties are mostly unaffected by microporosity. Microporosity is found between dendrites, and, like macroporosity, it is caused by the inability of feed metal to reach the interdendritic areas of the casting where shrinkage is occurring and where gas is being evolved. However, because this type of porosity occurs late in solidification, particularly in long range freezing ("mushy freezing") alloys, it is particularly difficult to eliminate. The most effective method is to increase the thermal gradient (often accomplished by increasing the solidification rate), which decreases the length of the mushy zone. This technique may be limited by alloy and mold thermal properties, and by casting geometry (i.e., the design of the casting).

As long as the micropores are less than 0.2 mm in length, there is no effect on dynamic properties: fatigue properties of castings with pores that size or smaller are in the same range as those of castings where no micropores were found. The shape of the micropore is as important as its size, with elongated pores having a greater effect than round pores. Areas where microporosity is expected can be predicted by solidification modeling, similar to the prediction of macroporosity (see below). Microporosity can be healed by hot isostatic pressing (HIP). In one study comparing HIP and non-HIP samples, no difference was found in fatigue lives. However, the HIP samples showed a lower crack growth rate than non-HIP samples. In another study, HIP improved fatigue crack growth resistance only close to threshold levels. As noted above, the design of the casting directly affects its tendency to solidify in a progressive manner, thereby affecting both the quality and the price of the cast component.

Porosity and casting costs are minimized in casting designs that emphasize progressive solidification toward a gate or riser, tapered walls, and the avoidance of hot spots.

**Inclusions** are nonmetallic particles found in the casting. They may form during solidification, as some elements (notably manganese and sulfur in steel) precipitate from solution in the liquid during solidification. More frequently, they form before solidification begins. The former are sometimes called "indigenous" inclusions, and the latter are called "exogenous" inclusions. Inclusions are ceramic phases: they have little ductility. A crack may form in the inclusion and propagate from the inclusion into the metal, or a crack may form at the interface between the metal and the inclusion. In addition, because the inclusion and the metal have different coefficients of thermal expansion, thermally induced stresses may appear in the metal surrounding the inclusion during solidification. As a result, the inclusion acts as a stress concentration point and reduces dynamic properties. As in the case of microporosity, the size of the inclusion and its location determine its effect. Small inclusions that are located well within the center of the cross section of the casting have little effect, whereas larger inclusions and those located near the surface of the casting may be particularly detrimental to properties. Inclusions may also be a problem when machining surfaces, causing excessive tool wear and tool breakage.

Exogenous inclusions are mostly oxides or mixtures of oxides and are primarily slag or dross particles, which are the oxides that result when the metal reacts with oxygen in the air during melting. These inclusions are removed from the melt before pouring by filtration. Most inclusions found in steel castings arise from the oxidation of metal during the pouring operation. This is known as reoxidation, and takes place when the turbulent flow of the metal in the gating system causes the metal to break up into small droplets, which then react with the oxygen in the air in the gating system or casting cavity to form oxides. Metalcasters use computer analysis of gating systems to indicate when reoxidation can be expected in a gating system and to eliminate them. However, casting designs that require molten metal to jet through a section of the casting to fill other sections will recreate these inclusions and should be avoided.

**Oxide films** are similar to inclusions and have also been found to reduce casting properties. Oxide films form on the surface of the molten metal as it fills the mold. If this surface film is trapped within the casting instead of being carried into a riser, it is a linear discontinuity and an obvious site for crack initiation. It has been shown that elimination of oxide films, in addition to substantially improving static properties, results in a five-fold improvement of fatigue life in axial-tension tension tests.

Oxide films are particularly of concern in nonferrous castings, although they also must be controlled in steel and stainless steel castings. Because of the high carbon content of cast iron, oxide films do not form on that particular metal. If the film is folded over on itself as a result of turbulent flow or "waterfalling" (when molten metal falls to a lower level in the casting during mold filling), the effects are particularly damaging. Casting design influences how the metal fills the mold, and features of the design that require the metal to fall from one level to another while the mold is filling should be avoided so that waterfalls are eliminated. Oxide films are avoided by filling the casting from the bottom in a controlled manner, by pumping the metal into the mold using pneumatic or electromagnetic pumps.

**Secondary phases** that form during solidification may also nucleate cracks if they have the proper size and morphology. An example is aluminum-silicon alloys, where the silicon is present in the eutectic phase as large platelets, which nucleate cracks, and along which cracks propagate. The size of these platelets may be significantly reduced by modifying the alloy with additions of sodium or strontium. However, such additions increase the size of micropores, and for this reason many foundrymen rely on accelerated solidification of the casting to refine the silicon. As previously noted, solidification rates normally increase and the structure is thus refined in thin sections. Heavy sections are to be avoided if a fine structure is desired. Generally speaking, however, secondary phases in the structure of castings become important in limiting mechanical behavior of castings only in the absence of nonmetallic inclusions and microporosity.

**Hot tears** form when casting sections are constrained by the mold from shrinking as they cool near the end of solidification. These discontinuities are fairly large and most often weld-repaired. If not repaired, their effect is not readily predictable; while generally they are detrimental to casting properties, under some circumstances they do not affect them. Hot tears are caused by a combination of factors, including alloy type, metal cleanliness, and mold and core hardness. However, poor casting design is the primary cause. Castings should be designed so that solidifying sections are not subjected to tensile forces caused by shrinkage during solidification, as the solidifying alloy has little strength before it solidifies.

**Metal Penetration.** Molten metal may penetrate the surface of the mold forming a rough surface, or in extreme cases, it may actually become intimately mixed with the sand in the mold. In iron castings, this is normally the result of the combination of metallostatic head (the pressure exerted on the molten iron at the bottom of the mold by the weight of the metal on top of it) and the surface tension relationships between the liquid iron and molding materials. In cast iron, it is frequently also the result of the expansion of graphite at the end of solidification forcing liquid metal into the mold. This penetration can occur if the casting is not properly designed with a tapered wall to promote directional solidification and avoid hot spots. In steel castings, penetration may also occur as a result of formation of iron or manganese oxide on the surface of the molten metal. These oxide phases react with the silica sand to form chemical penetration, which is difficult to remove from the surface of the casting. Use of mold coatings can protect the mold from this reaction.

## Gating and Riser

To make a casting, the metalcaster must fill the mold with metal and then control the solidification of the casting to prevent the formation of casting imperfections. The techniques used to accomplish this are called gating and risering, or rigging.

### Gating

**Gating System Components.** The gating system is the plumbing system that fills the mold with molten metal. Gating system nomenclature is shown in Fig. 9. Metal is poured into the pouring basin, down a sprue, where it enters the runner, which delivers it to gates, through which it flows into the casting cavity in the mold. Filters placed in the runners slow the metal and remove inclusions, and vents on the casting allow air to escape and relieve the back pressure that opposes mold filling.

**Fig. 9** Basic components of a simple gating system for a horizontally parted mold

**Recommended Practices.** The gating system must fill the mold quickly, while minimizing turbulence. Turbulence causes the molten metal to mix with the air in the sprue and runners. The oxygen in the air reacts with the molten metal, forming oxide inclusions. Unfortunately, it is difficult to minimize turbulence in gating systems in medium-size and large castings, as the velocity the metal reaches on falling down the sprue is usually so great that turbulence is unavoidable. Ceramic filters slow the velocity of the metal in the runner, which fills the sprue with metal. Good gating practice recommends that the system be unpressurized, that is, the cross-sectional area of the down sprue should be less than the total cross-sectional area of the runners, which, in turn, should be less than the total cross-sectional area of the gates.

Runner cross sections are usually rectangular, so that metal does not swirl down the runners and entrap air. Runners should be free from sharp edges, and gates should be filleted.

The gating system should establish thermal gradients to promote a sound (porosity-free) casting. The ideal situation is to have the casting freeze from thin sections (which freeze quickly) to thick sections, so that feed metal is available to feed shrinkage as it occurs. As molten metal flows through the gating system, it loses heat to the runners and heats them up. Thus, the first metal into the mold is coldest, and the last metal is hottest. For this reason, gates should be placed into heavy sections of the casting, so that hot metal is available to feed shrinkage that occurs in the casting as the casting solidifies. By having solidification take place progressively toward the gates and risers, shrinkage is avoided.

Good gating systems should avoid reoxidation of the metal, avoid the formation of oxide folds, and, if possible, remove oxide and dross from the molten metal. Gating systems should be designed to prevent the aspiration of air through the porous molding media. The position of the casting in the mold should be given careful thought. Normally the casting should have its longest dimension parallel to the parting plane. Metal should not drop from one level in the casting cavity to a lower level because the oxide film that forms on the top of the molten metal mixes into the metal in the casting, which causes inclusions.

Filters strain out most of the slag or dross that may have been carried in from the melting operation, and pieces of mold refractory that may have come loose during molding. Metal should not rain down from the top of the sprue or into the casting because it will react with the air in the runner system or the casting cavity. Therefore, filters should not be placed at the top of the sprue, and gates should be placed at the bottom of the mold, so that the casting cavity fills from the bottom. The proper placement of filters in gating systems is shown in Fig. 10. Filters are used in all alloys except titanium.

Fig. 10 Common methods of filter placement in horizontally parted molds. (a) Parallel to parting line. (b)

Between 0 and 90° to parting line. (c) 90° to parting line. Arrows indicate the direction of metal flow.

Pouring metal down a sprue causes the metal to accelerate due to gravity. The increased velocity caused by this acceleration leads to turbulent flow and the formation of inclusions. One method of avoiding turbulent flow is to use some form of counter-gravity mold filling, as shown in Fig. 11. Counter-gravity pouring systems allow the rate of fill to be controlled precisely; it can be speeded up or slowed down as necessary to compensate for changes in the cross-sectional area of the casting. In filling the mold from the bottom, the rate of rise in the casting cavity should be no greater than 0.5 m/s (1.65 ft/s) for aluminum alloys and no greater than 0.3 m/s (1 ft/s) for copper-base alloys. Filters are incorporated in the fill tubes used in counter-gravity gating systems. Counter-gravity pouring systems operate at the same speed as conventional pouring lines; a number of techniques, such as rotating the mold around a horizontal axis at the bottom of the mold after pouring, are available to prevent molten metal from draining out of the casting cavity until solidification is complete.

**Fig. 11** Schematic of the operations of the counter-gravity low-pressure casting process. (a) Investment shell mold in the casting chamber. (b) Mold lowered to filling position. (c) Mold containing solidified castings; most of the gating has flowed back into the melt.

Gates must be easy to remove, and they must not distort the casting when they solidify. If they are to be cut off or sawed off, room must be available for the cutting torch or saw blade. When more than one gate is used to fill a casting, care should be taken that the solidification of the runner that connects the gates does not distort the casting when the runner, which must stay liquid long enough to fill the casting, freezes and contracts due to shrinkage.

Gating design calculations may be done approximately by using Bernoulli's theorem, which is an energy and materials balance between points in the gating system. More accurate gating designs may be made using a combination of expert systems and finite element or finite difference solutions of fluid flow equations. These are part of commercial solidification software widely available to metalcasters.

In a mold having more than one mold cavity of the same casting geometry, it is recommended that the gating of all of the castings be identical. This match assures that all castings solidify similarly. Differences in solidification sequence otherwise may cause castings to have properties that vary according to their position in the mold.

**Good pouring practice** means filling the sprue rapidly and keeping it full while the casting cavity fills. There are essentially three types of pouring ladles for gravity pouring (Fig. 12). Keep in mind that slag and dross will form on the top of the metal in the ladle where the molten alloy is exposed to the atmosphere. With the open lip ladle (Fig. 12a), the

slag or dross must be held back during pouring. The teapot ladle (Fig. 12b) is most effective for keeping slag out of the mold. Bottom pour ladles (Fig. 12c) are effective only when the metal stream from the exit of the ladle to the sprue and the sprue itself are shrouded in an inert gas, because the high discharge velocities from the ladle cause stream spreading and lead to oxidation and inclusion formation in air.

**Fig. 12** Types of pouring ladles. (a) Open lip-pour ladle. (b) Teapot ladle. (c) Bottom-pour ladle

A variety of automatic pouring devices are available commercially that precisely and reproducibly fill the mold from ladles. The advantages of automatic pouring include improved consistency of pouring, increased productivity, reductions in pouring scrap, better process control, improved working conditions on the pouring line, and reduced environmental problems.

**Venting.** An important aspect of mold filling, often overlooked, is allowing the air in the mold to escape as the mold is filled. If air cannot easily leave the mold, it becomes compressed in the mold cavity and generates a back pressure against the flowing metal that holds up the metal, which may cause it to freeze or misrun before the mold cavity is filled. Passages placed in the mold so that air can escape during pouring are called vents. While it is obvious that impermeable molds, such as metal molds, need to be vented, it is less obvious that vents are needed in permeable molds, such as sand molds. However, venting is every bit as important in sand, especially in high-pressure molding lines.

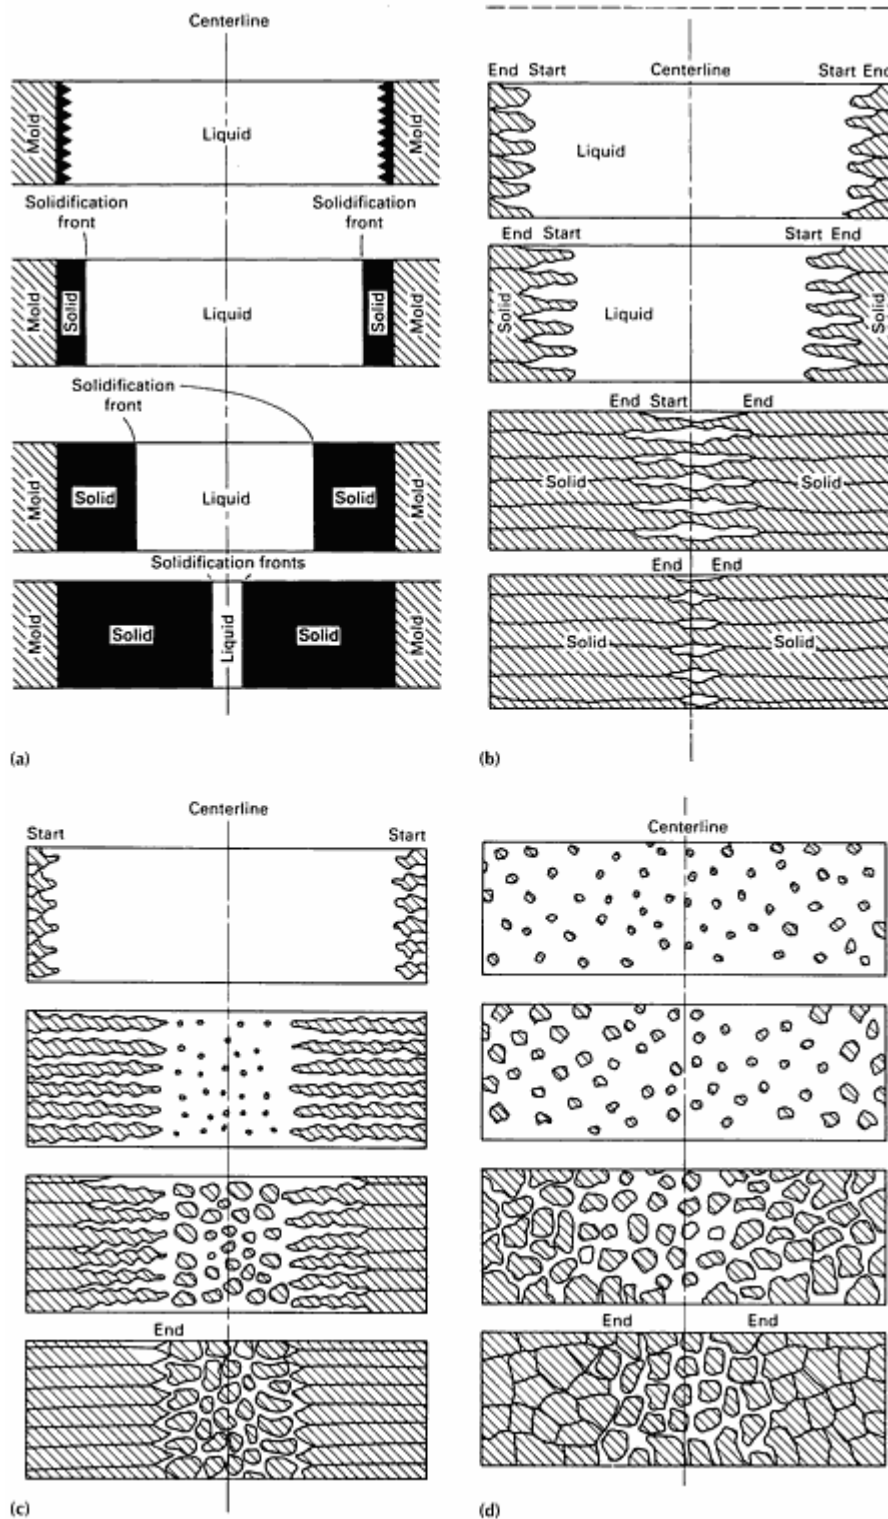

Vents should be placed at the highest point in the casting cavity and in any part of the cavity that will be cut off from the rest of the cavity as the casting fills. Vents should exit the mold on the cope surface. Open risers make excellent vents; however, if blind risers are used, they should be vented. Vents should also be placed at the end of runners. Parting line vents should be used only in vertical parting line molds. Large cores should be vented; if it is not possible to vent them directly to the atmosphere by cutting a hole in the mold, vent tubes (flexible plastic) should be run from the core to the top of the cope.

As the melting temperature of the alloy increases, the volume of air that expands on being heated by the incoming metal increases. Thus the size and number of vents should increase as the melting point of the metal increases (e.g., vents in steel castings should be larger and more numerous than those in aluminum castings).

## **Risering**

**Riser design** deals with the sizing and placement of reservoirs of feed metal to compensate for the shrinkage that occurs during solidification. These reservoirs are called "risers" or "feeders." When liquid metal freezes, it undergoes three different volume changes: shrinkage of the liquid as it cools, shrinkage of the alloy as it transforms from liquid to solid, and shrinkage of the solid as it cools to room temperature. While the shrinkage accompanying the liquid/solid transformation occurs in a pure metal at a single temperature (the freezing temperature), it occurs over the range of temperatures between the liquidus and the solidus or eutectic temperature in alloys. Some of the volume change in alloy solidification is caused by segregation of alloying elements to the liquid during solidification. In addition, the mold cavity expands as it heats up when molten metal enters the mold. These effects mean that liquid metal must continue to be available during casting solidification to assure that no shrinkage voids form in the casting.

The distribution of liquid and solid in a casting section during freezing depends on the freezing range of the alloy. Pure metals, which freeze at a single temperature, freeze with a well-defined solidification front. In that part of the casting in which the temperature is below the freezing point, the casting is solid, and in the rest of the casting, it is liquid. However, as the freezing ranges of alloys increase, the freezing front becomes diffuse (Fig. 13). For a short freezing range alloy, such as steel, solidification begins with the formation of a skin of solid metal at the mold/metal interface, and there is a clear channel for metal to flow down to feed shrinkage. In these alloys, the only place where shrinkage is expected is at the centerline of the casting, which is the last part of the casting to solidify. In these alloys, tapering the casting cures the problem.

**Fig. 13** Solidification (freezing) mode for pure metals and alloys. (a) Freezing mode in pure metals, in which the freezing range (liquidus-to-solidus interval) approaches zero. Crystallization begins at the mold wall and

advances into the casting interior on a plane solidification front. (b) Freezing mode in short freezing range alloys (<50 °C, or <90 °F). (c) Freezing mode in intermediate freezing range alloys (50 to 110 °C, or 90 to 200 °F). (d) Freezing mode in long freezing range alloys (>110 °C, or >200 °F).

For very long freezing range alloys (similar to many aluminum and copper-base alloys and superalloys), freezing begins at the walls, but grains quickly nucleate and grow throughout the entire casting, making feeding difficult. The result is that shrinkage is dispersed throughout the entire casting, usually in the form of microporosity. This situation can be alleviated by increasing the rate at which freezing occurs, but this is limited by how efficiently heat can be absorbed by, or transferred through, the mold. As refractory molds are generally poor conductors of heat, increasing the thermal gradient is generally effective only in thin sections, especially in high thermal conductivity alloys, such as aluminum- or copper-base alloys.

Gas solubility is a particular problem in some alloys. Hydrogen is easily picked up from atmospheric humidity in aluminum melts, and nitrogen may be picked up in steel melts. Unfortunately, the solubility of hydrogen in solid aluminum is about an order of magnitude less than it is in liquid aluminum. The result is that hydrogen gas is rejected into the liquid from the solidifying alloy and forms gas bubbles in the liquid; if these bubbles cannot escape from the casting, they appear in the casting as pores. Nitrogen gas porosity arising from a similar situation is sometimes found in ferrous castings, especially in the presence of certain resin binders that decompose and saturate the liquid iron with nitrogen.

The goal of risering is to encourage the casting to feed progressively, that is, to feed from a remote point in the casting toward the riser; so that shrinkage is fed and gas that dissolves in the liquid can escape (Fig. 14). Most castings, however, have complex shapes, which make it difficult to predict how solidification will proceed. However, an approximation can be made to help the metalcaster decide how to arrange and size risers. This approximation depends on the fact that solidification rate is proportional to the square of the ratio of the casting section's surface area to its volume. This relationship is referred to as Chvorinov's law, which is given by the relationship:  $t = k \cdot (V/A)^2$ , where  $k$  is a constant proportionality whose value is dependent on the thermal properties of the metal and the mold. In other words, the freezing time,  $t$ , is proportional to the square of the ratio of the section's volume to its surface area  $(V/A)^2$ . Therefore, a thin plate will solidify faster than a sphere of equal volume. In the same way, edges, corners, and fins on castings will solidify faster than straight sections, and concavities (internal corners and recesses in the casting) will solidify more slowly than straight sections. Because feed metal cannot flow through portions of the casting that have already solidified, the first rule to follow in establishing progressive solidification is not to attempt to feed a thick section through a thin section. Each thick (slow-to-solidify) section must be isolated from thin (fast-to-solidify) sections and provided with its own riser. The riser for these thick sections may require a gate; however, in many cases it is not feasible or economical to place a gate into the riser. In that case the riser is called a "blind" riser.

**Fig. 14** Directional and progressive solidification in a casting equipped with a riser

For the riser to be effective, it must solidify after the casting section it feeds has solidified. This is assured by making the surface area to volume ratio of the riser greater than that of the casting section it feeds. There are a number of methods that can be used to estimate the size of risers that should be used for various alloys. Sizing the riser is usually done without regard to the molding system or aggregate used, as the thermal conductivity of the mold affects both the casting and the riser; and it is only the ratio between them that is of interest in the estimation process.

Considering only the amount of feed metal in a riser is not sufficient in riser design, the riser must also be able to deliver this metal to the areas of the casting where shrinkage occurs. The feeding distance of risers depends on the alloy and on

the mold system used. The fact that the edges of the casting freeze faster than the riser means that they provide an "end effect." The heat supplied by the mass of the solidifying riser keeps the area around it liquid longer than it would otherwise be, providing a "riser effect" to extend its feeding distance. The combination of the end effect and the riser effect create progressive solidification from the edge of the casting to the riser. However, as the freezing range increases, the amount of solid coexisting in the area of the casting between the liquidus and solidus temperatures also increases, which makes feeding difficult. Feeding distance estimates are therefore particularly important in alloys with short freezing ranges, such as steels; there are a number of methods that have been developed to aid in this estimation. However, in long freezing range alloys, these methods are ineffective because feed metal flow is so difficult in the mushy region.

In long freezing range alloys, especially aluminum alloys, progressive solidification can be encouraged by using metal chills in combination with risers. The chills are placed in the mold adjacent to the casting surface, so that they can pull heat out of the casting in that area (Fig. 15). Risers are placed between the chilled areas of the casting to provide feed metal; these risers are often insulated so that their freezing rate is retarded even more. The object is to increase the thermal gradient in the solidifying metal so that the actual part of the casting at temperatures between the liquidus and solidus is as short as possible.

**Fig. 15** Use of chills to reduce the number of risers (T) on a steel flange casting. (a) Side and top view of the casting illustrating locations of the eight risers used when the workpiece is divided into feeding areas without

considering end effects. (b) Top view of identical casting showing locations of five risers used when the workpiece is divided into feeding areas in which riser effect and end effect considerations are accounted for through the use of chills

One method of getting an accurate prediction of where shrinkage will form is to use commercial solidification simulation programs. These programs do not predict the size of the riser that will feed shrinkage in a casting, but they do show exactly how solidification will proceed. This means that the foundry must estimate the size of the risers by other means in designing the riser plus gating assembly. Some commercial programs include expert system routines to help foundry engineers design gates and risers and then check them using fundamental heat flow equations that are solved using finite difference or finite element methods.

The efficiency of risers can be significantly improved if they are surrounded by insulating or, in the case of copper-base and ferrous metals, exothermic materials. Exothermic materials react chemically in the presence of heat to produce more heat. The most common type of exothermic reaction is between iron oxide and aluminum powder: its reaction raises the temperature of the reactants to well above that of the melting point of steel. Exothermic riser "sleeves" contain a controlled amount of reactants, which slow solidification and maintain the riser at a temperature above its melting point for an extended period of time so that it is able to continue feeding the casting. In alloys with short freezing ranges, the risers solidify with a pronounced pipe in their center; care must be taken to be sure that the depth of the pipe does not enter the casting, causing scrap. Another way to improve riser efficiency is to cover the top of the riser with insulating or exothermic materials. This cover is especially important in ferrous metals, which lose substantial amounts of heat by radiation to the atmosphere. When the risers are covered by exothermic or insulating materials, this heat loss is effectively stopped.

# Molding Methods

Thomas S. Piwonka, The University of Alabama

## Classification of Molding Methods

MOLDING METHODS and materials encompass a wide range of options. Some molding (casting) processes are centuries old, while others did not exist two generations ago. The selection of the correct one to use in a specific casting application depends on the alloy, the dimensional tolerances desired, the quality of the casting, and the price the customer is willing to pay. Most metals and alloys can be cast using any of the methods. There are, however, limitations in some cases.

Foundry processes can be classified based on the molding medium, such as sand molds, ceramic molds, and metallic molds. This article uses such a classification system. Molding methods may also be classified based on whether the molds are permanent or expendable. Similarly, subclassifications can be developed from patterns, (i.e., whether or not the patterns are expendable). For permanent molding, processes can be classified by the type of mechanism used to fill the mold. Table 1 provides one possible classification system for commonly employed molding and casting processes.

Table 1 Classification system for foundry processes based on mold type

Expendable mold processes/Permanent patterns
Clay/water bonds (green sand molding)
Silica sand
Olivine sand
Chromite sand
Zircon sand
Heat-cured resin binder processes

Shell process (Croning process)  
Furan hot box  
Phenolic hot box  
Warm box (furfuryl/catalyst)  
Oven bake (core oil)

#### Cold box resin binder processes

Phenolic urethane  
Furan/SO<sub>2</sub>  
Free radical cure (acrylic/epoxy)  
Phenolic ester  
No-bake resin binder processes  
Furan (acid catalyzed)  
Oil urethane  
Phenolic urethane  
Polyol urethane

#### Silicate and phosphate bonds

Sodium silicate/CO<sub>2</sub>  
Shaw process (ceramic molding)  
Unicast process (ceramic molding)  
Alumina phosphate

#### Plaster bonds

Gypsum bond

#### No bond

Magnetic molding  
Vacuum molding

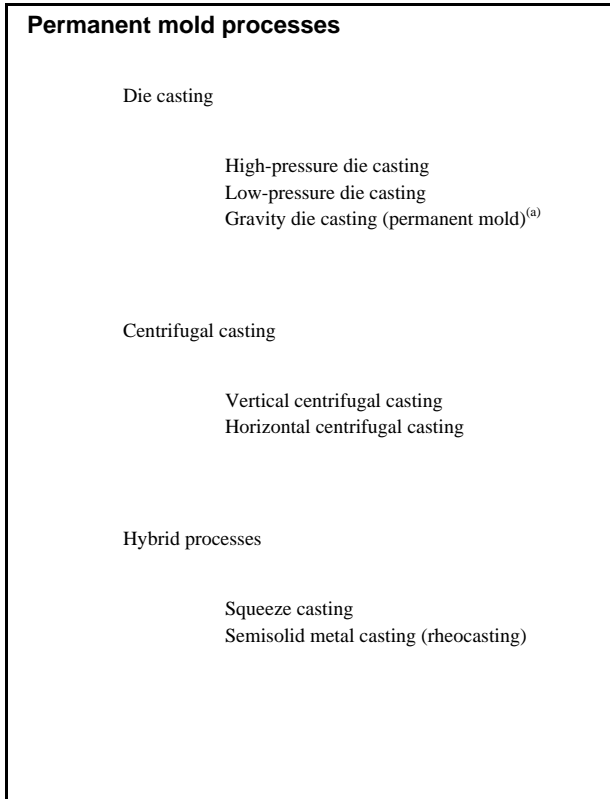

### **Expendable mold processes/Expendable patterns**

#### Foamed patterns

Evaporative foam casting  
Replicast process

#### Wax patterns (investment casting)

Ethyl silicate bonded block molds  
Ethyl silicate bonded ceramic shell molds  
Colloidal silica bond  
Plaster bond  
Counter-gravity low-pressure casting

(a) When sand or plaster complex cores are used instead of metal cores, the term *semipermanent mold casting* should be used.

Of the expendable mold/permanent pattern processes listed in Table 1, green sand molding is the most prevalent. Expendable mold/expendable pattern processes use wax patterns (investment casting) or foamed plastic patterns (lost foam casting). The investment casting process is one of the oldest casting processes known (it has been used for more than 6000 years), while the lost foam process has been used commercially for less than 20 years. Permanent mold processes involve the use of metallic (usually ferrous) or solid graphite molds. On a volume basis, die casting and permanent mold casting are the most important.

## ***Sand Molds***

---

SILICA SAND, either bonded or unbonded, is the most popular molding media. Sand has the advantage of being widely available, inexpensive, able to withstand the elevated temperatures involved in casting most alloys, and easily recycled. In addition, it does not react with most metals and alloys, and it can be bonded with clay, resins, or silicate compounds. Because sand molds are permeable, the air displaced by the metal when it enters the mold can escape through the mold.

### **Bonded Sand Molds**

In bonded sand molds, the sand particles are held together with chemical bonds. The bonds that are developed must be easily broken when the casting is solid so that the casting can be removed from the mold.

### ***Green Sand Molds***

Green sand molds are the most widely used of all sand molds. They are made of sand, bonded by a mixture of clay and water. Other materials may be added to the sand to control its strength and prevent metal penetration. The sand is called "green sand" because it is not baked or fired. Its actual color is usually black.

**Patterns, Cores, and Molding Machines.** The casting cavity is formed in the sand mold by compressing it around a pattern, which is a wooden, plastic, or metal form that has the shape of the casting, together with its gates, risers and core prints (Fig. 1). In bonded sand processes, the pattern is removed from the mold and used repetitively to make molds. The

dimensions of the pattern are slightly greater than that of the castings because the casting shrinks during solidification. Castings distort as they cool, as a result of stresses produced by the resistance of the mold to casting shrinkage, so patterns must be designed to compensate for this distortion if accurate castings are to be produced. As the pattern will be removed from the mold after it is made, draft is added to vertical surfaces so that the pattern can be drawn from the mold without scraping the sides of the mold cavity.

**Fig. 1** Patterns for a sand casting and its gating and risering systems, for four different methods of mold production

The choice of pattern material depends on the number of molds that are to be produced from it and the dimensional accuracy tolerances of the casting. For short runs or experimental castings, patterns may be loose pieces shaped in wood, in which case the gating will be cut in the sand by hand using tools designed for the process. In making a mold from a loose-piece pattern, the molder places the pattern on a flat mold board to support it during molding. The bottom, or drag half is made first. A mold box is placed on the board to contain the sand. Prepared sand (mixed with clay, water, and additives) is placed in the mold and compacted using a ramming tool. When the entire mold is filled with sand and completely compacted, the mold is turned over and the pattern withdrawn. The procedure is repeated for the cope half of the mold. The cope is placed on the drag, and metal or wooden "jackets" are placed around the parting line to align the two halves and prevent metal from running out of the mold at the parting line. Weights are placed on the mold before pouring to prevent the cope from floating on the liquid metal when the casting is poured.

Cores are used to make the hollow parts of castings, such as the holes of a pipe fitting or the air path in an automotive intake manifold. The cores are usually bonded with resins, which are stronger than the clay-water bond used in green sand. The cores are supported in the mold by extensions at either end. These extensions rest in core "prints" in the green sand. The prints not only support the cores, they also position them accurately to maintain casting dimensions. Cores are placed in the drag half of the mold after the pattern is drawn from the mold and before the cope is placed on the drag to close the mold.

Match-plate patterns are split patterns in which the pattern that will make the cope is on one side of the plate, and the pattern that will make the drag is on the other side. Match-plate patterns are used on mechanized molding machines for

intermediate runs of moderate sized castings. More than one casting may be made in a mold, with the sprue, gates, and risers shared among the castings. In match-plate machine molding, the sand is introduced into the molding box, and the pattern is placed on a machine table. The machine then raises the table a few inches and then lets it fall back freely by gravity. The sharp jolt experienced by the sand when the machine table stops falling compresses the sand in the box. The procedure is repeated a number of times until the sand is properly compressed. Usually the mold is then subjected to a squeeze pressure from the top (the part of the mold away from the pattern face) of the mold half to further compress the sand.

For large castings and very high production runs, cope and drag patterns are used on highly automated molding machines. The cope pattern is separate from the drag pattern, and separate molding stations are used to make each mold half. Metal flasks hold the sand. Cores may be placed in the molds by hand or by using automated fixtures. In some machines, only squeezing is used to compact the sand; in others, both jolting and squeezing is used. Figure 2 shows a jolt-squeeze machine. Parting lines may be either horizontal or vertical (Fig. 3).

**Fig. 2** Essential components of a high-pressure jolt-squeeze molding machine. The compensating head equalizes the pressure applied to each floating peen block as the sand filled flask is hydraulically raised against the peen blocks. This develops a uniformly dense packing of molding sand against the entire surface of the pattern.

**Fig. 3** Blow-fill pressure squeeze molding machine making vertically parted molds (a) Molding chamber filled with sand. (b) Sand compacted by squeeze pressure. (c) Finished sand mold pushed out of molding chamber

Impact molding machines use rapidly released compressed air above the sand in the pattern box to send a shock wave through the sand to compress it (Fig. 4). The flask is filled with sand by gravity and sealed against an air chamber before the compressed air is released. Advantages of the impact molding process are highest mold density at the parting line and pattern surface, uniform mold strength across the mold, and less pattern wear than with other processes.

**Fig. 4** Pressure wave molding machine that compacts sand by the rapid release of air pressure or an explosive combustible gas mixture. Part (a) shows the mold filled by gravity prior to being compacted by the pressure wave at (b).

Flaskless molding machines are popular, using either horizontal or vertical parting lines. Only squeeze pressure is used to compact the sand. Cope and drag halves may be made simultaneously, and the mold halves are made in the same attitude as they will be used, so there is no need to rotate the molds.

When molten metal is poured into a green sand mold, the moisture at the mold/metal interface flashes into steam. This rapid expansion in volume (liquid transforming into vapor) flushes the air away from the interface. The air and the expanding water vapor must escape from the mold. In high-density molding processes, such as impact molding, the permeability of the mold is not sufficient, and vents must be cut into the mold to prevent the back pressure from the gases from blocking the entrance of the molten metal and causing the casting to only partially fill with metal.

**Sands.** The aggregate usually used in green sand casting is silica sand, usually from former lake bottoms or river bank deposits. Sand is usually 99% silica in the form of quartz, with the balance being oxides of iron, aluminum, titanium, magnesium, and calcium, depending on the source of the sand. Quartz undergoes a series of crystallographic transformations as it is heated and expands in a nonlinear manner with temperature (Fig. 5). These transformations can cause dimensional problems if not compensated for in the casting process. Sand grains may be rounded, subangular, or angular in shape. Rounded grains flow more easily and pack more densely; they also use less binder because their surface area to volume ratio is smaller than other shapes. However, molds made from them have less permeability. As sand is cycled through the system, it wears and eventually becomes too small to be used and must be discarded.

**Fig. 5** Expansion characteristics of various foundry sands

Sand used for molding is usually held within strict size and size distribution limits. The sand size is determined by passing a sample of sand through a series of successively finer screens, and weighing the amount collected on each screen. The

best combination of properties of green sand is usually found when almost all of the sand is caught on three or four adjacent screens; however, two screen sands have been used successfully for certain casting processes.

**Clays.** The sand is bonded by a clay/water mixture. Clays used in the United States are naturally occurring montmorillonites, sodium (Western) bentonite and calcium (Southern) bentonite. Western bentonite is the most commonly used clay. It develops a lower green strength than Southern bentonite (Fig. 6) but has higher strength at casting temperatures (Fig. 7). Southern bentonites, however, allow the sand mixture to flow more evenly over the pattern and thus aid the molding operation. Usually, a foundry will prepare a mix of both Southern and Western bentonites to achieve a sand that is optimized for the castings it makes. The sand, water, and clay are mixed in a muller for a period of one to two minutes; during this time the clay/water mixture coats the sand. Water added to the clay may be driven out by the heat of the solidifying casting. When this happens, the clay loses its bonding ability. Water may be added to the clay to reconstitute it as long as the clay has not reached a temperature greater than 600 °C (1110 °F). Because the clay adjacent to the molten metal has reached that temperature, and the clay in cooler portions of the mold has not, a portion of the clay must be replaced. The amount of clay and water added in the muller must be sufficient to bond new sand that is added on each cycle (including recycled core sand, which was previously bonded using resins) and to compensate for the moisture and clay burn out in the previous casting cycle.

Fig. 6 Variation of mold sand properties with water content. (a) Southern bentonite. (b) Western bentonite

Fig. 7 Effect of casting temperature on the durability (strength) of various foundry sands

**Sand Additives.** Other materials are added to the sand to improve its performance. Chief among these materials for ferrous alloys is seacoal, which is powdered bituminous coal. Seacoal cokes when it is heated, plastically expanding and filling the interstices between the sand grains at the casting surface, thus preventing penetration of molten metal into the sand. In addition, it burns, assuring that the atmosphere at the mold/metal interface is reducing; so that fayalite, a low

melting point solution of iron oxide and silica, does not form on steel castings. Cellulose may be added in amounts up to 0.2% to absorb excess water and control sand expansion. Polymers may be added to control the surface energy of water so that it coats the sand grains more effectively, and soda ash may be added in very small amounts to control the pH of the sand mixture.

**Sand Testing.** Sand is tested to assure its quality. Normal tests include mechanical properties, usually expressed as "compactability," moisture content, active clay content, and volatile content, tested as "loss on ignition." Incoming sand is tested for grain fineness number, a measure of both size and size distribution, and it may be tested for acid demand value, especially when certain resin binders are used for cores.

**Sand Reclamation.** Sand is normally reclaimed and reused. When the casting is poured, the sand next to the molten metal is heated above 600 °C (1110 °F), the water evaporates, and the clay at the interface can no longer be used as a bonding agent. However, most of the sand and clay in the mold is not significantly heated by the solidifying metal and can be recycled. The sand is separated from the castings, cooled, and recycled through the muller, where new sand (to compensate for sand lost by attrition), water, and clay is added. If pieces of core in which the resin binder has not decomposed are present, they are crushed. Metal and other debris (such as core rods) are removed by magnets, and the sand is screened before being added to the muller. It is important to cool the sand to a temperature below 50 °C (120 °F) for the clay-water bond to work properly. The amount of makeup water and clay added depends on the sand to metal ratio in the mold; obviously, larger and heavier castings will burn out more moisture and clay than lighter castings.

The recycled sand includes cores bonded with resins, which may not be completely burned out. If the resins are not completely removed from the sand grains, they interfere with the clay-water bond. The only way to completely remove these resins is to thermally reclaim the sand, heating it to temperatures greater than 650 to 825 °C (1200 to 1500 °F) in air. These temperatures, of course, also burn out the bentonites; for this reason, only a portion of sand may be thermally reclaimed on any cycle. Note that the core sand is added to the system on each cycle. Frequently, the core sand addition is all that is needed to make up for sand losses in processing.

**Sand Handling Systems.** In a high production foundry, transporting the sand from mulling to molding to pouring to shakeout to recycling and back to mulling requires a large sand handling system comprising conveyor belts, storage areas, and the sand mixing and molding equipment. Sand should not be blown into silos or bins because blowing causes the sand to segregate by size, destroying its size distribution. Dust from sand systems must be removed from the foundry air, and sand temperature must be controlled. Fines in the sand must also be removed because their high surface area will absorb clay and moisture and drastically change sand properties. Controlling the sand system may be difficult if there are wide swings in the size of castings poured during a shift. The sand-to-metal ratio is constantly varying, making it difficult to predict just how much moisture and clay to add to the muller.

### ***Dry Sand Molds***

Dry sand molding is sometimes used to make large castings, although resin-bonded molds have largely taken over for this process. In dry sand molding, the water is removed from the mold prior to pouring. The bond is created both by using bentonites, and also through the use of other organic binders, such as dextrin, molasses, glutrin, or pitch. The molds are baked in ovens prior to pouring to drive out the moisture. Baking temperature and time depend on the size of the mold and the binder used. Dry sand molds are generally stronger than green sand, and they usually have better dimensional stability than green sand in larger castings. Sand grain size is usually coarser in dry sand molding, to allow the increased permeability of the mold to aid in mold drying. Therefore, mold washes and coatings are often applied to improve surface finish.

As an alternative to drying the entire mold, only the surface of the casting cavity may be dried. These "skin-dried molds" are made from the same sand mixtures as dry sand molds, but only the surface that will contact the molten metal is dried to a depth of 6 to 12 mm ( $\frac{1}{4}$  to  $\frac{1}{2}$  in.).

### ***Resin-Bonded Sand Molds***

Over the last thirty years, a number of resins have been developed as binders for sand, primarily for making cores, although they are also used as molds. These binder systems generally fall into one of the following categories: no-bake, cold box, protein, hot/warm box, and shell (Croning). In these processes, sand and binder are mixed together and formed around a pattern or placed in a core box. The resin may be cured by heat, or it may be cured by the setting of the resin. To accelerate the curing of the resin, catalysts may be added, either in solid, liquid, or gaseous form.

**No-Bake Processes.** The term "no-bake" generally refers to all of the binder systems in which a gas catalyzes the resin while the sand is in contact with the core box or pattern. Originally it referred only to the phenolic-urethane-amine process, which is still the most popular core resin in use. In addition to the phenolic urethane process, other no-bake binder systems include furan acid catalyzed, phenolic acid catalyzed, ester-cured, and alkyd-urethane binders. Furan binders depend on the use of furfuryl alcohol, either by itself or modified with urea, phenol, formaldehyde, or other additions. The binders cure at room temperature by the addition of an acid catalyst, and they have reaction products, such as nitrogen gas and water. The amount of binder used must usually be minimized, both for economic reasons and to limit the amount of nitrogen gas picked up in ferrous castings, where it can cause pinholes, and water vapor picked up in nonferrous castings, where it causes microporosity. The catalyst used depends on the rate of cure required and the type of metal cast. Urea-containing binders react relatively quickly, and a popular catalyst for them is phosphoric acid. Sulfonic acids may be used for low-nitrogen binders. Sulfuric acid may also be used, although it is not recommended for use with ductile iron, where the generation of sulfur fumes during pouring causes the formation of flake graphite. Binder addition is generally 0.8 to 2.0% of the weight of the sand, and the catalyst addition is between 20 and 60% of the binder weight.

Phenolic binder systems are based on resole phenolic resins, which contain phenol, formaldehyde, and modifying additions in water. These are cured with sulfonic acid, added at a level between 20 and 45% by binder weight.

Ester-cured phenolic binders are popular in steel foundries because they contain no furfuryl alcohol or nitrogen and do not use sulfur for curing. The two-part binder consists of the water-soluble alkaline phenolic resin, plus 15 to 30% liquid ester coreactants. A blend of esters is used to provide the required setting time but only partially cross-link the resin. Thus, the resin retains a small degree of thermoplasticity, which permits the sand to absorb some expansion and reduces expansion defects in the castings.

Alkyd urethane binders, also referred to as oil urethane binders, are three-part systems used for large molds that require longer setting times. The three components are the following: part A, an alkyd oil resin; part B, a liquid amine/metallic catalyst; and part C, a polymeric isocyanate, such as polymeric methyl di-isocyanate (MDI). Part A is usually used between 1 and 2% by weight of sand, and part B is used between 2 and 10% of the weight of part A. Part C is added between 18 and 20% of part A by weight. Curing takes place in two stages: first the polymeric isocyanate reacts with the alkyd resin at a rate controlled by the amine catalyst. This reaction produces a bond that is strong enough to allow the pattern to be stripped. The second stage is the oxidation polymerization of the alkyd resin by atmospheric oxygen, accelerated by the metallic elements in the catalyst. Because oxygen must diffuse into the sand, this latter cure is a function of sand section thickness. The oxidation reaction can be accelerated by heating to between 150 and 200 °C (300 to 400 °F).

The phenolic urethane no-bake system is a three-part system consisting of the following: part I, a phenol formaldehyde resin dissolved in solvents; part II, a polymeric isocyanate dissolved in solvents; and part III, a liquid amine catalyst. The resin and the isocyanate combine to produce a urethane bond. However, unlike the alkyd urethane system, there is no second stage reaction and a deep through cure is obtained. Binder levels of 0.7 to 2.0% of the sand weight are recommended, with a ratio of 55 to 45 or 60 to 40, part I to part II. The amount of catalyst required is between 0.4 and 0.8% of the weight of the part I resin.

**Cold Box Processes.** The term "cold box" generally refers to processes in which the sand, binder, and catalyst are mixed together before the sand mixture is introduced into the core box or pattern; in this case curing begins immediately, and working time is limited. Cold box processes have become popular in high-production foundries. The original process is the phenolic urethane process. It is similar to the phenolic urethane no-bake process described above, except that the catalyst is introduced as a vapor after the core is blown, producing a rapid cure, which enhances production rates. Both dimethyl-ethylamine (DMEA) and triethylamine (TEA) catalysts are used. In this process, shown schematically in Fig. 8, a gassing system is used to meter out a predetermined quantity of liquid, change it to vapor, combine it with a carrier gas in the correct ratio, and deliver it to the core box. A scrubber system is also used to prevent the discharge of the offensive odor of the catalyst into the work area. Core box design must include consideration of the location of the catalyst vents to assure complete coverage of the core by the catalyst.

**Fig. 8** The cold box coremaking process. The wet sand mix, prepared by mixing sand with the two-component liquid resin binder, is blown into the core box. The core box is then situated between an upper gas input manifold and a lower gas exhaust manifold. The catalyst gas enters the core box through the blow ports or vents and passes through the core, causing almost instantaneous hardening of the resin-coated sand. The core is ready for ejection from the core box after purging with clean air for a few seconds. After the catalyst gas passes through the core, it leaves the core box through vents into the exhaust manifold. From the gas exhaust manifold, the catalyst gas is piped to an appropriate disposal unit.

The sulfur dioxide ( $\text{SO}_2$ ) process uses a furfuryl alcohol/formaldehyde resin mixed with peroxide, such as methyl ethyl ketone peroxide (MEKP), and additives. The sand is mixed with these substances, and after being compacted in the core box,  $\text{SO}_2$  gas is passed through the core. The sand has a long bench life, but sulfur-containing binders are not recommended for ductile iron, as they cause flake graphite to form in the metal.

The free radical cure (FRC) process uses three parts: a vinyl unsaturated urethane oligomer, an organic peroxide, and a vinyl silane adhesion promoter. The mixture is cured with  $\text{SO}_2$  gas, which breaks down the peroxide, which in turn releases free radicals that cure the resin. The binder contains no nitrogen or water, which decreases gas defects in castings, but it is susceptible to mold erosion in ferrous castings.

The ester-cured phenolic process is similar to that of the no-bake ester-cured system. Here, however, the catalyst is methyl formate, carried by air. The cured strength is not quite as high as the urethane cold box system, but it is satisfactory for many applications, especially for making molds as a replacement for green sand.

**Protein-Based Binders.** One drawback to the use of organic binders is that the binders must be completely burned out during cooling of the casting if the sand is to be fully recovered. In very large cores, or, in the case of nonferrous alloys where the mold and core temperatures do not get sufficiently high so that the resins burn completely, core butts remain that must be crushed and the sand thermally reclaimed (burned) at high temperatures. In addition, cores not used for production must be put through the same process to reclaim the sand; unfortunately, the value of the resin is lost. A recent development to overcome this problem is the use of a protein-based binder.

The binder is a proprietary mixture of biopolymers, which do not break down thermally to produce toxic gases. Metal oxide catalysts are used to accelerate the curing reaction. In addition, the cured binder is water soluble, which means that unused cores and core butts may be treated with water to recover both the binder and the sand, without using thermal treatments. This binder was designed for use in nonferrous (aluminum and magnesium) applications, so it readily breaks down thermally at the lower solidification temperatures encountered in these alloys. Cores made with it have mechanical properties comparable to traditional organic binders. The process also yields castings with similar surface finishes.

**Temperature Control during Coremaking.** Temperature control is very important during the non-heat-cured coremaking processes. Curing is a chemical reaction, which doubles in rate roughly every  $10^\circ\text{C}$  ( $18^\circ\text{F}$ ). In other words, attempting to use these processes at too low ambient temperature (below  $20^\circ\text{C}$ , or  $70^\circ\text{F}$ ) will slow the reaction rate and cause an incomplete cure and low strength. Increasing the amount of resin to compensate for the low temperature merely

increases the amount of gas generated during pouring and leads to gas defects in the casting. Too high a temperature (above 30 °C, or 90 °F) shortens bench life and reduces sand properties. For consistent production during both hot and cold weather, sand heaters and coolers are essential. A sand heater should regulate the sand temperature to within 1 °C (2 °F) under normal conditions. Coremaking carried out under close temperature control minimizes the use of binder and catalyst, produces more uniform cores, and decreases foundry scrap.

**In the hot box process**, the binder-sand mixture is wet. A liquid thermosetting binder and a latent acid catalyst are mixed with dry sand and blown into a heated core box. Upon heating, the catalyst releases acid, which induces rapid cure; therefore the core can be removed in 10 to 30 s. After the cores are removed from the pattern, the cure is complete, as a result of the exothermic reaction and the heat absorbed by the core. Large cores require post curing in an oven.

Hot box resins are classified simply as furans or phenolics. Furans contain furfuryl alcohol, and phenolics are based on phenol, while furan-modified phenolics have both. All conventional hot box binders contain urea and formaldehyde. The furan hot box resin has a fast cure compared to that of the phenolic-type system and can therefore be ejected faster from the core box. Furan resin also provides superior shakeout and presents fewer disposal problems because of the lack of phenol. Typical resin content is 1.5 to 2.0%.

A simplified hot box reaction mechanism is liquid resin + catalyst + heat = solid resin + water + heat. The heat is provided by using a heated pattern or core box. Catalyst selection is based on the acid-demand value and other properties of the sand. Sand temperature changes of 10 °C (18 °F) or five units in acid-demand value of the sand require a catalyst adjustment to maintain optimum performance. Both chloride and nitrate catalysts are used. The chloride catalyst is the more reactive. Hot box pattern temperatures are 230 to 290 °C (450 to 550 °F), and the patterns are designed for use between 220 and 245 °C (425 to 475 °F). Running the pattern temperatures higher than this range produces patterns or cores with weakened or friable surfaces, which produce castings with poor surface finish. Hot box resins have a limited shelf life and increase in viscosity in storage. They should be stored in temperature-controlled areas. Hot box catalysts have indefinite shelf life.

**Warm box resins** are minimum-water (%) furfuryl-alcohol-type resins formulated for a nitrogen content of less than 2.5%. Because the resin/sand mix exhibits a high degree of rigid thermoset properties when fully cured, little or no post-strip distortion or sagging occurs. High hot and cold tensile properties are characteristic of warm box sands and generally permit a binder level between 0.8 and 1.8%, or about 20% less than the conventional hot box resin content. Warm box catalysts are copper salts based primarily on aromatic sulfonic acids in an aqueous methanol solution. The catalysts are unreactive with the resin at room temperature but form strong acids when heated. Pattern temperatures range from 150 to 230 °C (300 to 475 °F); the process was designed for use at 190 °C (375 °F).

**The shell molding** or "Croning process" uses a very fine sand coated with a thermosetting resin to produce a shell mold only about 10 mm (0.4 in.) thick. The very fine sand produces an excellent surface finish on the casting. Use of sand of such fineness would not be possible in a conventional mold because mold permeability would be too low; however, in a thin shell mold, it is not a problem.

The sand grains are coated with phenolic novolac resins and hexamethylenetetramine. The dry, free-flowing sand is coated by being mulled at 150 to 280 °C (300 to 535 °F) for 10 to 30 s. The coated sand is then placed in a dump box, and the box is rotated leaving the sand in contact with the hot pattern for a period of time. Pattern temperatures are generally between 205 to 315 °C (400 to 600 °F). The thickness of the shell produced depends on the amount of time the sand is in contact with the pattern. Dump boxes produce shells of variable thickness, and many shell mold foundries use the more expensive, but more accurate and controllable, contour patterns, in which the sand is blown between a heated pattern plate and a heated profiled back plate. Pattern halves are glued together before pouring and may be poured in either the vertical or horizontal position. Because the molds are only a thin shell, they are often supported during pouring, either in fixtures or in loose sand. Patterns may also contain shell cores.

In making shell cores, the sand is injected into a heated core box and then dumped out after a short time. Again, the thickness of the shell is dependent on the time in contact with the heated core box. Shell molds and cores generally produce castings with better surface finish and more accurate dimensions than other organic resin-binder processes.

**Quality Control of Resin-Binder Processes.** In all organic resin processes, care must be used to prepare the pattern or core box and to maintain it free from resin buildup during the production campaign. It is especially important to inspect the vents on a regular basis to be certain that they remain clear of resin products that could clog the vents.

Complex core geometries may be formed by gluing two or more cores together before they are placed in the mold. Alternatively, one core may be injected around another core to make the core assembly, thus avoiding the gluing operation. Cores are supported in the mold by extensions, called core prints, which extend into the mold. The mold holds the core prints firmly during pouring. Because cores are less dense than the molten metal, the pressure of the metal forces them upward in the mold, displacing them from their desired position. Small metal spacers, called "chaplets," are placed between the mold and the core to keep the correct position. These chaplets normally are melted by the molten metal and become part of the casting.

### ***Sodium Silicate Bonded Sand (The CO<sub>2</sub> Process)***

Sand can be bonded using sodium silicate ("waterglass"). Sodium silicate binders are odorless and produce no volatile organic compounds when metal is poured into molds. The amount of silicate binder varies from 3 to 6% by weight, depending on the type of sand, its grain fineness, and the amount and type of contaminants present in the sand. Normal sand handling equipment can be used to prepare the sand. The sand has reasonably good bench life, but if impurities such as ferrosilicon or lime are present in the sand the bench life is shortened. As in resin-bonded sands, the sand is mixed (care should be taken not to overmix the sand, which will produce a crumbly mixture), placed around the pattern, and vibrated to compact it. The sand is then gassed with carbon dioxide gas (hence the name "CO<sub>2</sub> process"), which hardens the mold almost immediately. Molds are cured 24 h at room temperatures in dry conditions (high humidity softens the bond). During this time, their strength increases as a result of some dehydration of unreacted silicates and continued gelling of the silicate. They have good shelf life thereafter.

Sodium silicate foundry binders are metastable solutions. There are two hardening mechanisms that take place. First, there is dehydration by evaporation. Second, the reaction with CO<sub>2</sub> removes the sodium oxide from the silicate, and the silicate gels. Overgassing forms sodium bicarbonate and sodium carbonate, which embrittle the gel.

Both ferrous and nonferrous metals and alloys can be poured into these molds. To improve shakeout and core removal, organics, such as sugars, starches, or other carbohydrates, may be added to the mold. However, these accelerate the deterioration of mold strength in high humidity conditions. This molding method is often used for larger molds. A drawback is that sand reclamation is difficult. A combination of mechanical reclamation and water reclamation has shown promise, but recovery rates are limited to about 70%. An additional problem with the use of sodium silicate is that core removal is difficult because the bond does not break down on exposure to heat. Cores must be removed either chemically or mechanically.

Core boxes and patterns for sodium silicate molds may be made of wood, metal, or plastic, and they must be washed thoroughly after use to prevent a buildup of sodium silicate. Mulling equipment and ramming tools must also be washed thoroughly after use. Sand mixes that have not been used should be covered with a wet cloth to prevent a hard surface crust from forming because the mixture will slowly cure in air.

### ***Mold Washes and Coatings***

Under certain circumstances, molten metal can penetrate the spaces between the sand grains into the sand mold, forming a rough surface on the casting. In steel castings, iron or manganese oxide may form on the surface of the molten steel and react with the silica sand to form a glassy compound. In both cases, the resulting casting surface may cause the casting to be unusable. To prevent this condition, called metal penetration, ceramic coatings are often applied to areas of the mold or core where penetration is likely to be found. These coatings normally consist of aqueous slurries containing finely divided ceramic particles. Nonaqueous slurries are used when the ceramic in the coating is hygroscopic or reacts with water. The small particle size of the ceramic fills the space between the sand grains, which prevents molten metal from entering the mold. Coatings may also be used to produce a smoother surface on the casting than would be obtained if the casting were poured in an uncoated mold.

The ceramics in the slurries are selected on the basis of their nonreactivity with iron oxides. Mullite, zircon, alumina, magnesite, and graphite refractories are often used. The choice of the refractory depends on the alloy being poured. Most coating compositions are proprietary, and they are often developed for a specific use. Coating slurries may contain other additives to improve flowability and shelf life. Coatings may be applied to the entire mold or core, or only used in areas where penetration is likely to occur, such as re-entrant angles where heat is concentrated in the casting, or in the drag half of the mold where metallostatic pressure is higher. Penetration defects are generally the result of using a too coarse molding sand or not ramming it tightly enough. However, in cast iron, the most common cause of penetration is graphite

expansion near the end of solidification, which forces remaining liquid metal into the sand. This penetration can be cured by changing the solidification pattern so that the casting freezes progressively towards the riser.

Coatings may be applied by painting, spraying, dipping, or electrostatic means. In high production foundries, coatings may be applied to cores using robots or automated dipping lines.

### ***Sand Reclamation***

While it is assumed that the resin binder used in molds and cores burns off during solidification, this process is limited by the size of the core in relation to the size of the casting. For example, where the casting volume is large in relation to the size of the core, there is sufficient heat generated during solidification to burn off the resin. On the other hand, if the core is large in relation to the volume of metal, parts of the core may never heat up enough to cause the resin to decompose. The metal poured also influences resin decomposition; for example, steel is more effective than aluminum in generating enough heat to burn the resin. In addition, there may be a number of inorganic contaminants carried along with the sand or formed from chemical reactions during pouring. Residual resins and these contaminants interfere with the clay-water bond. One way of dealing with this interference is to discard a portion of the sand during each cycle and depend on a new sand addition to give the system sand and the molding properties desired.

However, disposal of spent foundry sand is becoming more difficult as landfills close and environmental regulations become more restrictive. As a result, the cost of sand disposal is a significant percentage of sand system operation. This expense has led to the development of methods of reclaiming sand instead of discarding it. Three primary methods are used: pneumatic, mechanical, and thermal.

In pneumatic methods, the sand is blasted in a high-pressure air stream against a steel or refractory plate. The impact of the sand on the plate causes the resin or silicate coating on the sand to physically separate from the sand grain. In mechanical systems, the sand is fed against a slowly revolving very large grinding wheel, which abrasively removes the coating. It is important to aggressively remove fines from pneumatic and mechanical processes to maintain the sand system operating characteristics. In the thermal method, the sand is fed into a fluidized bed operating from 680 to 800 °C (1250 to 1470 °F), and the resin burns off. In the thermal method, combustion of the resin and the carbonaceous additives to the sand also contribute to the heat of combustion, which lowers fuel requirements.

The relative economics of these processes depends on the amount of sand being reclaimed, the cost of energy at the foundry, and the type of contaminant being removed. In some cases, sand reclamation may be less expensive than the purchase of new sand. Thermal treatment may be combined with either the pneumatic or the mechanical treatment to reclaim a higher percentage of the sand. Sand that is thermally reclaimed is normally purer silica than naturally occurring sand, because other minerals may no longer be present.

### **Unbonded Sand Molds**

It is not always necessary to use a binder with sand. In unbonded sand molds, the pattern form is held either by the pattern itself during pouring, or by the use of a vacuum. Unbonded sand molds have the advantage because they need no binders, mulling equipment, or mold additives.

### ***Lost Foam Casting***

In the lost foam process, patterns are made of expanded polystyrene or other foamable plastic or blend of plastics. The patterns are attached to a gating system, also made of foamed plastic, placed in a flask, and sand is vibrated around them. The molten metal is poured directly onto the plastic, which melts or burns. The metal replaces the foam pattern, taking its shape. This method eliminates the use of sand binders, additives, and cores, and it is capable of making some shapes that could be made no other way. Steps in the sequence are shown in Fig. 9, 10, and 11.

Fig. 9 Lost foam pattern system. (a) Flask that contains a 25 to 75 mm (1 to 3 in.) sand base. (b) Positioning the pattern. (c) Flask being filled with sand, which is subsequently vibratory compacted. (d) Final compact ready for pouring

Fig. 10 Pouring of a lost foam casting

**Fig. 11** Processing of completed (cooled) casting. (a) Flask is tipped, and the sand is recycled. (b) Casting is ready for degating and cleaning

**Pattern Molding, Assembly, and Coating.** The first step in the process is to produce the pattern. The pattern material is supplied as small beads of polystyrene or a mixture of polystyrene and other foamed plastics, such as polymethylmethacralate. The beads are pre-expanded using heat to about forty times their original volume. The expanded beads are cooled and held for a period of time to stabilize their dimensions.

The molding process consists of four steps: filling the die, fusing the beads, cooling the pattern, and ejection. During filling, the beads are fed into the die. After the mold cavity is full, the beads are heated by steam that travels through the mold. With exposure to the steam, the beads expand again and fuse together. The die is then cooled to stop the expansion process, and the patterns are ejected from the die. After the pattern is removed from the die, it will shrink slightly over the next 24 h. Because shrinkage is not necessarily uniform, the pattern producer must compensate for pattern shrinkage in designing the pattern die.

After the 24 h holding period, the patterns are assembled. Complex shapes may be made by producing partial patterns and gluing them together. Gates and risers are attached and glued on to the patterns to make an assembly. Usually one assembly is used in each flask.

The pattern assembly is coated with a refractory slurry. The use of the slurry gives the finished casting a smoother surface and controls the escape of pattern decomposition products, such as gases, from the burning pattern material. In lower melting point metals, the patterns do not burn, but they do form liquid decomposition products, which must also escape through the coating. The choice and application of the proper coating is crucial to the success of the lost foam process, because permeability of the coating controls the rate of escape of these decomposition products, which in turn controls the pouring process. Coatings are often custom blended for a foundry and a specific part. The coating is usually applied by automated pattern dipping machines, which control coating thickness more uniformly than hand application. Coating

refractories are selected based on the metal being poured and the permeability desired. The carrier used in the slurry is usually water, because organic solvents attack the pattern material. The coating is dried thoroughly before the pattern is invested with sand. This process can be done at room temperature, which usually takes 24 h, or using heated forced air at 50 to 65 °C (120 to 150 °F), which reduces the drying time to less than 6 h.

**Investing the Foam Pattern in Sand.** The pattern is placed on a bed of sand in the flask, and loose, dry sand is introduced into the flask through a sand raining system. During filling, the flask is vibrated to pack the sand uniformly around the pattern. The sand may be silica sand; however, the use of uniform spheres of mullite or other refractories is also possible. The spherical shape aids in packing, and, because mullite has a lower coefficient of expansion than silica, more accurate castings are obtained. A vacuum may be applied to the flask during pouring. This not only removes any gases generated during pattern decomposition, but it makes the mold more rigid.

**Pouring Practice.** Castings are poured using the same techniques used in pouring bonded sand castings. In one variant of the process, the gases that escape from the mold during pouring are burned by torches above the mold. This effect creates a vacuum within the mold that increases its rigidity. After pouring, the castings are cooled, dumped out of the flask, and processed normally. The sand may be thermally reclaimed to remove all pattern decomposition products and is cooled before being reused.

Ferrous and nonferrous alloys may be used in this process. Finished castings often reproduce the surface of the foam pattern. Care must be taken in gating lost foam parts to be certain that the molten metal flows through the pattern in one direction. In addition, streams of metal should not meet in the casting itself, because liquid decomposition products are carried on the surface of the leading edge of the metal streams and can become trapped in the casting where the streams meet. The process has had wide acceptance in the automotive industry and has grown steadily in popularity since the late 1980s.

### ***Vacuum Molding (V-Process)***

In this binderless process, the sand is positioned between two sheets of thin plastic and held in place during pouring by application of a vacuum. This molding method is especially useful in making large flat castings, such as sounding boards for pianos.

Figure 12 shows the steps in the V-process. The pattern, which contains a number of small vent holes, is mounted on a carrier plate. A thin plastic film is heated and stretched over the pattern, and a vacuum is applied to the pattern, which draws the plastic over the pattern and holds it tightly against the pattern. Because the plastic is softened by the heat, it conforms to the surface of the pattern. A specially constructed hollow-wall flask containing a vacuum connection is placed around the pattern, filled with sand, and vibrated to compact it. A sheet of plastic is placed over the top of the mold, and a moderate vacuum is applied to the flask. The vacuum holds the sand tightly in place, producing a dense, strong mold. The vacuum is released on the pattern, which is easily removed from the mold.

**Fig. 12** Elementary sequences in producing V-process molds

Cope and drag halves of the mold are assembled while maintaining the vacuum, and the casting is poured. After the casting cools, the vacuum is released, and the loose sand falls away from the casting. Before pouring, the plastic that covers portions of the mold cavity normally open to the atmosphere (such as the tops of risers, vents, and the pouring sprue) is removed so that the casting cavity remains at atmospheric pressure during pouring. If it did not, the mold would collapse. Gases generated during pouring must escape to the atmosphere, not into the mold where they would destroy the vacuum.

The V-process is not normally used for high production runs; however, molding lines have been built that permit a production rate of 60 molds per hour. As the plastic film vaporizes during pouring forming, it forms a reducing gas that prevents the formation of an oxide skin on the molten metal; hence, metal fluidity is often improved. However, as the molds contain no moisture, the initial cooling rate in the mold is slower.

## Ceramic Molds

IN CERAMIC MOLDING, a fine refractory aggregate is combined with a silicate binder. The resulting castings usually have very fine surface finish and very accurate dimensions.

### Investment Casting

In investment casting, also called the "lost wax" process, a ceramic slurry is applied around a pattern, usually made of wax, and hardened to make a mold. The pattern is removed, usually by heat, and molten alloy is poured into the space formerly occupied by the pattern. There are two forms of investment casting. One possibility is that the ceramic mixture is poured around the wax in a flask and allowed to harden (the "solid mold" process). The other method occurs when the pattern is repeatedly dipped in a ceramic slurry, dusted with refractory, and dried in a repetitive process until a shell of sufficient thickness has been formed around the pattern. Today, the solid mold process is used primarily for jewelry and dental casting; the overwhelming majority of investment castings are made using the ceramic shell process, which is shown in Fig. 13.

Fig. 13 Steps in the investment casting process

**Patterns.** The pattern is formed by injecting pattern wax into a pattern die. Pattern wax is a blend of natural wax modified with fillers, resins, plastics, plasticizers, antioxidants, and dyes. Waxes used for patterns are most often paraffins, vegetable waxes, and microcrystalline waxes. By blending these waxes with each other and adding modifiers as needed, waxes having very specific properties can be produced. The choice of what kind of wax to use depends on the size and shape of the casting to be produced. Additives are used to increase the strength of the wax and to compensate for its shrinkage on cooling.

**Cores.** Preformed ceramic cores are placed in the pattern die before injection. Alternatively, soluble wax cores may be used instead of ceramic cores; these are dissolved out of the pattern using a weak acid before the slurry is applied. The preformed ceramic cores are primarily made of silica and alumina; they are removed from the casting by dissolving the cores in a caustic solution after casting. The cores are made by injecting the core mixture (usually a slurry of finely divided refractory aggregate in ethyl silicate) into a die. The cores gel in the die and are removed and fired to develop the strength they need to withstand wax injection and metal pouring pressures. They may be very complex, as shown in Fig. 14.

**Fig. 14** Investment cast turbine blade with convex wall removed showing complex core

**Pattern Injection and Assembly.** The patterns are injected at moderately low temperatures and pressures. After they harden in the die (which usually occurs in less than a minute for small parts), they are removed from the die and allowed to cool. If they contain preformed cores, they may be x-rayed to be sure that the cores did not fracture during injection. The patterns are inspected visually, die parting lines and the injection feeder are removed, and surface blemishes repaired. The patterns are then attached to a wax downsprue by melting the joint area and holding the pattern against the sprue until the joint hardens. The assembled clusters are inspected and cleaned by dipping in a solution containing a mild solvent that etches the surface of the pattern so that the slurry adheres to it.

**Manufacture of Ceramic Shell Molds.** The pattern assembly is then dipped into the first of a series of ceramic slurries. The slurries are usually mixtures of refractory aggregate in an aqueous silica sol (colloidal silica). Because of health concerns, ethyl silicate is rarely used as the binder. In addition to the colloidal silica and the aggregate, the slurry may contain a wetting agent, bactericides, antifoaming compounds, and polymers, which are added to give the slurry sufficient green strength, so that it can be re-dipped without being completely dried between dips. Slurry formulations are usually proprietary. The colloidal silica is a colloidal dispersion of virtually spherical particles of silica in water. The average particle size is 7 to 10 nm. Slurries are controlled by adjusting viscosity, temperature, and solids content.

The first slurry consists of a fine refractory aggregate, usually more expensive than that used in later dips. This aggregate contacts the molten metal. The pattern cluster is rotated in the dip tank to coat all pattern surfaces. Automated dipping machines assure repeatability of the dipping process. The wet cluster is then coated with refractory aggregate, which adheres to the slurry. The cluster is dried in ambient air, or heated forced air may be used to accelerate the drying process. A second slurry coat is then applied. Its composition will often be similar to that of the first slurry. However, the refractory sand that is applied in this coat is usually more coarse and less expensive than that applied to the first coat. The cluster is dried again, and the process is repeated; this time using a coarser, less expensive refractory in the slurry and sanding operations. After about seven applications of slurry and refractory sand, the mold is given a final drying and prepared for the dewaxing operation.

**Pattern Removal.** The patterns are usually removed by melting or burning them out of the mold. However, because the pattern material expands about 40 times as much as the mold, care must be taken to avoid cracking the mold during this operation. Wax drain holes are often added to the cluster to provide a path for molten wax to escape during the dewaxing operation. Wax is a poor conductor of heat, so the outer layers of the pattern melt and run out of the mold before the inner parts of the pattern heat enough to expand to crack the mold. One method of dewaxing is to use a steam autoclave. In this method, superheated steam is introduced to the patterns at a pressure of 550 to 620 kPa (80 to 90 psig). The steam penetrates the porous mold and gives up its latent heat of vaporization on the wax surface, which heats the surface very rapidly and causes the part of the wax in contact with the steam to melt. As that wax runs out of the mold, it exposes the wax underneath to the steam, which melts it, and the process continues in this manner. The wax runs into a trough below the molds and can be recovered and reprocessed.

An alternate method of dewaxing is to flash fire the molds. In this process, the molds are placed in a furnace at 870 to 1095 °C (1600 to 2000 °F). The heat melts and burns out the wax. Wax that is not burned falls into a trough below the furnace and can be reclaimed. Flash dewaxing units are equipped with afterburners to eliminate smoke emissions.

**Mold Firing.** After dewaxing, the molds are fired at 870 to 1095 °C (1600 to 2000 °F) to remove any residual pattern material, completely dry the molds, and sinter the mold ceramic so that it develops the strength it needs during pouring. This operation may be combined with wax removal in flash dewaxing furnaces and with mold preheating prior to pouring. Investment casting molds are usually preheated prior to pouring to promote complete metal fill in the thin sections typical of investment castings, and to lessen the thermal shock on the molds when they are filled with molten metal.

**Mold Preheating Prior to Pouring.** To control solidification, the molds may be wrapped in refractory blankets prior to preheating. The preheat temperature is determined by the alloy being poured and the casting geometry. When the molds are completely preheated, they are filled with molten metal. Because the amount of metal poured in investment castings is usually small (<20 kg, or 45 lb), the molds may be poured by hand, or they may be clamped to a furnace just large enough to melt the metal for a single mold. As soon as the metal reaches the pouring temperature, the furnace and mold are rapidly inverted, which fills the mold in a smooth even manner.

**Melting and Casting.** Melting is usually done using prealloyed charges prepared by a custom alloy producer. For some alloys, notably superalloys and titanium alloys, melting, pouring, and solidification is carried out in a vacuum (approximately  $10^{-3}$  torr) to protect the alloys from reactions with oxygen. Induction melting is most often used, although gas-fired furnaces may be used for nonferrous alloys, and vacuum-arc remelting is often used for titanium and refractory metal alloys. In dental and jewelry castings, the molds are often centrifuged during pouring to assure fill of the intricate designs.

**Postcasting Operations.** After casting, the molds cool, and the ceramic is removed. Clusters are shot blasted, and the casting cut from the sprue. Finishing and inspection operations are similar to those used for sand castings; except, if preformed ceramic cores are used, they must be removed in a caustic bath. If the cores have especially small cross sections, they may be removed in a caustic autoclave, which is pulsed periodically to remove the reaction layer at the core-caustic interface. Caustic (potassium hydroxide) is used to dissolve the silicate binder in the core, allowing the core aggregate material, usually silica and alumina, or an aluminosilicate, to fall out of the casting.

## Plaster Casting

Plaster molds are used to produce nonferrous castings having smoother as-cast surfaces (50 to 125 rms), better dimensional accuracy, and thinner sections than can be produced using sand casting techniques. The plaster casting process is used to produce near-net shape castings such as impellers, tire molds, matchplate patterns for foundries, and electronic equipment housings.

**Plaster Mold Compositions.** In the conventional plaster mold process, the principal mold ingredient is calcium sulfate. Other materials may be used to enhance mold properties, such as green strength and permeability. These materials include cement, talc, fiberglass, sand, clay, and other materials. Calcium sulfate exists as two different hydrates and in an anhydrous form. Its dihydrate is known as gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ). Above 128 °C (262 °F), gypsum loses three-fourths of its water to become plaster of paris, which loses the rest of its water at 163 °C (325 °F) to become calcium sulfate.

**Mold Production.** To produce a plaster mold, plaster of paris is mixed with water to form a slurry, which is immediately poured over a pattern or into a core box, where it sets, forming a solid mold or core of gypsum with free water distributed in the mold. The pattern is normally coated with a release agent before the slurry is poured. Mechanical vibration may be used to eliminate pinholes in the mold while the slurry is being poured over the pattern. The mold is then dried at temperatures high enough to produce calcium sulfate and to burn out any residual pattern materials (such as wax) that may have been used. Drying must be carried out at a temperature high enough to remove all moisture but not so high that the molds crack. Patterns and core boxes are usually made of aluminum. However, flexible rubber or urethane patterns may be used to produce molds having negative draft or very complex sections.

**Metals Cast.** Plaster molds have low heat capacity, which means metal flows well in them to fill thin sections, but solidification rates are low. For mushy freezing alloys, this means that, because cooling rates are low, properties will generally be lower than those in castings made in sand molds. Plaster molds also have low permeability, so vacuum or pressure assists are often used to help fill thin sections. Aluminum-, copper- and zinc-base alloys may be poured in plaster, but magnesium alloys generally are not because of the possibility of a violent reaction between the molten

magnesium and any free water in the mold. Ferrous metals are not poured in plaster molds because the iron reacts with the sulfate to produce very poor surfaces.

**The Antioch Process.** A variation on plaster molding is the Antioch process. In this process, after the molds have set, they are stripped from the pattern and steam autoclaved for 8 to 10 h at a pressure of two atmospheres (205 kPa, or 30 psi). During this time, partial dehydration occurs and recrystallization produces a granular structure in the mold having improved permeability. The molds are then dipped in water and allowed to stand for 10 to 14 h to complete the granulation reaction. Molds must then be oven dried to remove the combined and excess water.

**Foamed Plaster Molding Process.** Another variation, which produces molds having higher permeability than Antioch process molds, is the foamed plaster process. In this process, a foaming agent, such as alkylaryl sulfonate, is added to either the dry ingredients or the liquid slurry. A special mixing method (using a specially-designed mixing disk) foams the slurry with many fine air bubbles, which decreases the density and increases the volume of the slurry. The molds have smooth surfaces, with air bubbles just below the surface. Air bubble size must be controlled so that all bubbles are about 0.25 mm (0.01 in.) in diameter, because larger bubbles break under pressure from the molten metal, forming surface defects on the casting surface. During setting and drying, these air cells become interconnected, thus permitting the escape of gases when metal is poured into the mold. The permeability of the mold depends on the volume increase that results from the addition of air when the slurry is mixed.

## Other Ceramic Molding Processes

A number of ceramic molding methods are based on proprietary processes that use permanent patterns and fine-grain zircon and calcined high-alumina mullite slurries for molding. They are used primarily to produce forging and extrusion tools and dies; food service equipment; glass molds; valves for the food processing, chemical, and pharmaceutical industries; and marine hardware. Dimensional control and surface finish are similar to that of investment castings, but the size and weight of castings made in ceramic molds is generally greater than those made as investment castings.

**The Shaw process** is actually two processes. One process consists of a mold with a monolithic structure produced from a slurry having a fine aggregate. In the second, the mold is a composite. The fine aggregate slurry is used only to form the mold/metal interface; it is backed with a less expensive coarser slurry. The first process is used for small parts and has generally been supplanted by investment casting, while the second process is used for larger castings.

The heart of these ceramic molding processes is the binder, which is prehydrolyzed ethyl silicate. Ethyl silicate is produced by reacting silicon tetrachloride with ethanol to form tetraethylorthosilicate,  $\text{Si}(\text{OC}_2\text{H}_5)_4$ . The use of condensation-polymerization treatments decreases the water content and raises the silica content; commercial binders usually contain 40% silica. The binder forms a gel during mold making, which provides green strength for the mold. The gel is formed either by evaporation of water, which is fairly rapid, or by changing the pH of the gel. Maximum stability of the binder (longest gel time) is found at a pH of 1.5 to 2, while the shortest gel time is achieved with a pH of 5 to 6. Thus gelling can be accelerated by starting with a binder having a low pH during pattern coating and mold building and then raising the pH when it is time to gel the slurry.

Two sets of patterns are used, an oversize preform pattern for molding the coarse backup material, and the finish pattern, which produces the final mold cavity. The preform pattern is about 2.5 to 10 mm (0.1 to 0.4 in.) oversize. The backup refractory and binder are mixed to the desired consistency, rammed or vibrated over the preform pattern, and gelled by gassing with carbon dioxide. The backup mold aggregate is usually a coarse-grained low-cost refractory, such as an aluminous fireclay, and the backup binder is usually sodium silicate.

The ceramic facing is usually made using fine zircon, alumina, or mullite flour, mixed with hydrolyzed ethyl silicate and often a gelling agent. The slurry is poured over the pattern through pouring gates in the backup mold. The slurry may be degassed in a vacuum chamber before pouring to remove any air bubbles. It gels within a few minutes after pouring, forming a rubber-like consistency, which permits patterns having no draft to be stripped successfully. After the mold is stripped, it is ready for stabilization. In the Shaw process, stabilization is accomplished by burning the alcohol off with a torch. During burning, microcraze cracks form in the mold, which enhances its permeability and facilitates shakeout. The mold is then baked to remove all remaining volatiles. Molds may be preheated for pouring or poured at room temperature.

**The Unicast process** differs from the Shaw process principally in the method of mold stabilization. In the Unicast process, the ethyl silicate mold is stabilized by immersing in a liquid before burn-off. The liquid may be boiling water, or other organic liquids, such as kerosene or acetone. Using a liquid stabilization process reduces any warping of the mold

that might occur as a result of the thermal gradients established during torch firing. Another difference between the Unicast and Shaw processes relates to the sequence followed in preparing composite molds. In the Shaw process, preparation of the coarse mold backup precedes pouring of the fine ceramic facing; in the Unicast process this sequence is reversed.

**Other ceramic molds** may be made by bonding the refractory aggregate with calcium or ammonium phosphate. These molds are made by a dry pressing method in which the molding mixture containing 4 to 9% moisture is pressed in dies at pressures of 14 to 140 MPa (1 to 10 tsi). After pressing, molds are stripped and fired at temperatures between 900 and 1300 °C (1650 to 2400 °F).

## ***Metallic Molds***

---

METALS may also be used as a molding material. Usually, ferrous metals are used as dies or molds for lower melting point aluminum-, magnesium-, zinc-, and copper-base alloys. However, steel has been successfully poured into water-cooled aluminum dies. In the United States, when metal is poured by gravity into metal molds, the process is called "permanent molding"; in the rest of the world, this process is known as "gravity die casting." When high pressure is used to fill the mold cavity, the term used in the United States is "die casting"; elsewhere it is "pressure die casting." United States terminology will be used in this section.

## **Permanent Molding**

In permanent mold casting, the mold is made of metal and is reusable. The process is especially useful for high volume production of fairly simple shapes; however, the use of sand cores ("semipermanent molding") makes possible the production of complex castings, such as automobile cylinder heads.

**Mold Design.** The mold material used most often is cast iron, which machines easily and resists oxidation. For very high production runs, tool steels or low-carbon steel tools may be used. The molds often contain internal cooling passages through which water flows to remove heat from the die, and the dies are usually coated with a ceramic slurry between pours. Because metal molds extract heat more rapidly from solidifying castings, the cast structure (grain size) of permanent mold castings is generally finer, and castings have less microporosity than sand castings. Casting dimensional reproducibility and surface finish is generally excellent, which often allows many machining operations to be eliminated. Multiple-cavity dies may be used to increase productivity. These advantages outweigh the higher cost of the permanent mold tooling. Aluminum-, magnesium-, zinc-, and copper-base alloys and small cast iron parts may be made in permanent molds.

Figure 15 shows a simple book-type permanent mold. In operation, the operator applies a thin layer of ceramic mold coating to the surface of the mold, closes the mold, clamps it shut, pours in the metal, waits for it to solidify, and then opens the mold and removes the casting, cleans the mold of flash and excess coating, and then repeats the process. The mold is not allowed to cool to room temperature between pours. The first few pours on the mold each day are made to heat the mold, and castings made from these pours are generally scrapped. To minimize the number of castings that are scrapped, molds are normally preheated electrically or using gas torches before casting operations begin.

**Fig. 15** Book-type manually operated permanent mold casting machine, used principally with molds having

## shallow cavities

Permanent molding is easily automated (Fig. 16, 17). Pouring may be automated using tilting pour ladles, or the mold may be placed in a cradle. As the metal is poured into the mold, the cradle is lowered at a rate consistent with the desired rate of fill, effectively filling the mold at a constant level. If the metal source, rather than the mold, is in the cradle, it is raised, and the mold remains stationary. This method virtually ensures controlled fill and the elimination of turbulence and dross entrapment in the casting. Another method used to fill large permanent molds is to fill reservoirs at one end of the mold with metal, and then tilt or rotate the mold so that the metal runs smoothly through the mold, filling it in a uniform and consistent manner.

Fig. 16 Automatic permanent mold casting machine with a setter for cast-in inserts

Fig. 17 Schematic of a 12-machine turntable for automatic permanent mold casting

**Tool life** is a major consideration in permanent molding. The most common cause of tool failure is heat checking, small cracks in the surface of the tool, which produce ridges in the casting and eventually lead to failure of the tool. Heat checking is caused by thermal fatigue of the mold. Thermal fatigue involves repeated heating and cooling of the mold during the casting production run. Factors that influence mold life are those that affect thermal fatigue, either by increasing the temperature difference between areas of the mold or by increasing the stresses these temperature differences cause. These factors include alloy pouring temperature (higher temperatures increase thermal fatigue), casting weight and shape (heavy sections contain more heat than thin sections), cooling methods (the proper placement of cooling lines is essential to minimize heat checking), and mold coatings. These factors control the temperature of the mold. Note that the mold temperature will probably not be uniform over all surfaces of the mold; minimizing this difference can substantially increase mold life.

Mold design also plays an important role in mold life and casting quality. Variation in mold wall thickness causes excessive stress to develop during heating and cooling, which in turn causes premature mold failure from cracking. Abrupt changes in thickness without generous fillets also cause premature mold failure. Small fillets and radii concentrate stresses, again decreasing mold life.

**Mold coatings** are used to prevent premature freezing of the metal in the mold, to control the rate and direction of casting solidification, to minimize thermal shock to the mold, and to prevent reactions between the metal being poured and the metal mold (aluminum alloys, in particular, tend to solder to ferrous dies). Coatings must be inert to the metal being cast, noncorrosive to the metal mold material, and adhere to the mold. A primer coat may be applied to the mold first. Coatings are usually sprayed on the mold. They may be brushed on by hand, but this is a slower process, and does not produce as uniform a coating as spraying. Coatings are usually thin water-based slurries of mixtures of refractory particles; the high temperature of the mold evaporates the moisture in the coating before pouring takes place. Coating thickness must be controlled to maintain casting dimensions, and it is usually thicker on gates and risers. Coatings are not always applied after each cycle, but they must be refreshed periodically through the production run. The choice of coating composition is usually dictated by the alloy being cast.

**Casting Quality.** As in other casting methods, the quality of the casting depends on the gating and risering system. However, in permanent molding, the fact that the mold is heated as a result of the process also affects casting quality. The placement of cooling lines or flame heated "anti-chills" to maintain the proper thermal gradient in the mold is often necessary to assure quality castings. Rapid cycle times allow less time between pours for the mold to cool, and thus the mold temperature increases.

**Low-Pressure and Vacuum Permanent Molding.** In low-pressure permanent molding, the mold is placed in a casting device above a sealed airtight chamber that contains a crucible holding molten metal. A fill tube extends from the mold down into the metal bath, and the casting is made by pressurizing the chamber and forcing metal up the fill tube into the casting. This process usually operates at lower mold temperatures and shorter cycle times than conventional permanent molding, and the advantages of counter-gravity mold filling listed in the article "Solidification of Metals and Alloys" apply here. Vacuum casting is similar, except that a vacuum is created in the mold cavity and the metal is pulled rather than pushed into the mold cavity. These processes are compared schematically in Fig. 18.

**Fig. 18** Schematics of low-pressure (a) and vacuum casting (b) units used with permanent molds

**Graphite Molds.** Permanent molds can be machined from solid blocks of graphite instead of steel. The low coefficient of thermal expansion and superior resistance to distortion of graphite make it attractive for the reproducible production of successive castings made in the same mold. Because graphite oxidizes above 400 °C (750 °F), graphite molds are usually

coated with a silica wash. These molds are usually used to make bronze bushings or cast iron railroad wheels. Because gravity pouring of molten iron erodes the graphite molds, counter-gravity mold filling is used.

## Die Casting

In pressure die casting, the metal is injected into the mold at high pressures. The process is primarily used for high-volume production of zinc, aluminum, and magnesium alloys, although ferrous and copper-base alloys may also be cast. The process is capable of high production rates. Production rates are related to the size and complexity of the part. Parts as complex as automotive engine blocks and transmission housings are routinely made by die casting.

**Die Casting Processes.** There are two major types of die casting machines: hot chamber and cold chamber. In the hot chamber machine (Fig. 19), the injection chamber is a gooseneck inserted in the melt. Pressure is applied to the melt to force some of the metal into the mold. This method avoids one metal transfer operation, and it is used primarily for zinc and magnesium. In the cold chamber process (Fig. 20), the metal is melted separately and poured or metered into the shot sleeve. The piston is then activated to force the metal into the mold. Cold chamber machines are used for aluminum, because the process minimizes the amount of time that the molten alloy is in contact with the die casting machine.

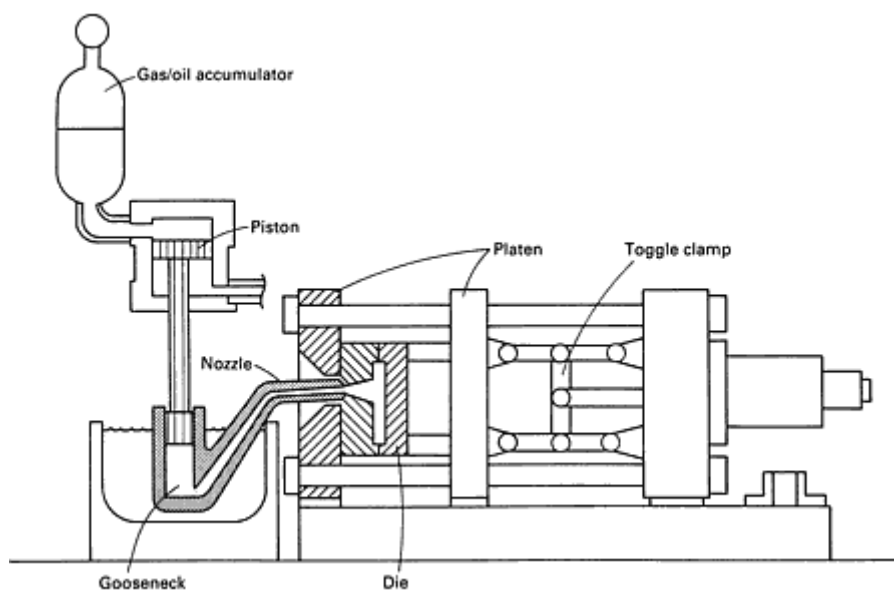

Fig. 19 Schematic showing the principal components of a hot chamber die casting machine

Fig. 20 Schematic showing the principal components of a cold chamber die casting machine

**Dies.** The die consists of at least two parts, the cover half and the ejector half (Fig. 21). The dies are made of heat-resistant tool steels. The metal enters the die through the nozzle or shot sleeve, which is located in the cover half. The cover half is stationary during casting. Ejector pins, which are activated when the ejector half retracts after the casting is

solid, are located in the ejector half of the die. The gating is is also generally placed in the ejector half of the die. Undercuts in the casting may be formed by metal slides or retractable cores in the die, which can enter the die space from each side as well as the top and bottom. Ceramic cores may be placed in the die to make configurations that cannot be made any other way; the cores are removed chemically after the casting is solid.

**Fig. 21** Components of a single-cavity die casting die for use in a hot chamber machine

The die also contains vents and overflow areas where excess metal flows during injection. In addition, most dies contain water cooling lines to control die heating. As in permanent molding, proper placement of the water lines is critical to obtaining good quality castings, especially for multiple-cavity dies.

**Processing Sequence.** The sequence of the die casting process begins when the die is open before the shot. The die is first sprayed with a lubricant, usually an aqueous solution. This spray coats the die with a thin layer of mold release, and the water evaporates, cooling the die surface. The die is closed, and metal is either injected into the die (hot chamber) or ladled into the shot sleeve (cold chamber). The shot proceeds in three stages. In the first stage, the piston moves slowly, to fill the shot sleeve so that air is not entrapped in the metal before injection begins. In the second stage, the piston moves very quickly, forcing the metal into the mold cavity. The dies are filled in less than 0.15 s. Pressure builds up on the metal during this phase. In the third stage, pressure is intensified to minimize the formation of porosity. The high pressures (up to 70 MPa, or 5 tsi) require elaborate locking mechanisms to keep the dies closed during the cycle; locking forces of up to 45,000 kN (5000 tonf) are used in the largest machines.

After the casting is solid, the dies open, and the casting and its runner system are removed from the die. Slides and cores are usually retracted first, and then the dies open. The gates are trimmed off on a separate trim press. High production die casting operations are highly automated, with the cycle controlled by computer and robots handling the metering of metal into the shot sleeve and removing the casting and gating from the die. After the casting is removed, the die is sprayed again, and the cycle is repeated.

Risers are rarely used in die casting because the metal freezes so quickly that feeding does not have time to occur. The gating system is designed to fill the mold as quickly and efficiently as possible. The area where the shot plunger comes to rest in the gating system is called the "biscuit."

Molten metal may be transferred to the shot sleeve by means of hand ladling, automated ladling, or by being pumped from the melting furnace to the shot sleeve, using pumps made of ceramics, or using electromagnetic force.

Die casting machines are complex. They must be capable of rapid, repetitive motion. The dies must maintain alignment during operation to avoid being damaged, and the cycle of the machine must be controlled accurately. Die failure is usually by thermal shock (heat checking). Iron is often added to aluminum alloys used in die casting to prevent soldering

of the alloy to the die. The amount of iron must be controlled, as excess iron (above 0.8%) forms a sludge in the alloy, which, if carried over into the casting as inclusions, will lower casting properties and casting machinability.

**Air Entrapment.** The rapid injection of metal into the die cavity inevitably traps air in the casting. This air expands during heat treatment, forming blisters on the surface of the casting. For this reason, most conventional die castings are not heat treated. However, there are a number of methods that may be used to minimize the entrapment of air in the die cavity. In one, the air in the cavity is evacuated prior to making the shot. In another method used for aluminum alloys, the die cavity is filled with oxygen before the shot. During the shot, the oxygen reacts with the aluminum alloy, forming tiny particles of aluminum oxide, which are dispersed in the casting. Because all of the gas in the cavity is used in this reaction, there is no gas to form gas bubbles in the casting.

Because of the limitations of conventional die casting, a variation on the process has been developed to substantially reduce air entrapment. In this method, called "vertical squeeze casting," the shot sleeve is located beneath the die cavity (Fig. 22). The shot sleeve tilts to be filled, then it returns to the injection position. The metal fills the mold at a much slower rate, expelling the gas in the mold ahead of it. Gates are larger than those used in conventional die casting to assure that mold filling is even and free of turbulence, which causes air entrapment. Production rates are slightly lower using vertical squeeze casting, but casting quality is improved. Vertical squeeze casting is not to be confused with another process known as squeeze casting, in which liquid is ladled into the bottom half of a metal die, and the die is closed, similar to a forging press. This process eliminates porosity.

Fig. 22 Schematic of the vertical squeeze casting process. Courtesy of UBE Machinery Inc.

## Semisolid Casting

Semisolid casting and its variants, known as rheocasting or thixocasting (depending on the amount of solid present at the start of the process), begin the solidification process with the alloy at a temperature between its liquidus and solidus. There is enough coherency in the metal charge that the charge can stand by itself. However, when a force is applied to the semimolten mass, it flows easily and can be injected into a mold cavity. This behavior arises from the unique microstructure of the semisolid mass (Fig. 23). It consists of equiaxed grains formed by stirring the melt during solidification. When the desired solid fraction is obtained, the melt is rapidly solidified to form a billet that can be used in subsequent processing (forging), or the mass is injected into a die cavity. Because the alloy starts its solidification in the mold cavity already partially solid, solidification shrinkage is reduced; so is gas porosity. The process can be operated like injection molding of plastics, with metal charge material fed into a rotating screw cylinder, which heats the metal to the desired fraction solid and delivers it to the die cavity. Nonferrous alloys, most notably aluminum-base alloys, are processed by semisolid casting and forging.

**Fig. 23** Comparison of dendritic conventionally cast (a) and nondendritic semisolid formed (b) microstructures of aluminum alloy 357 (Al-7Si-0.5Mg). Both 200 $\times$

## Centrifugal Casting

When liquid metal is poured into a rotating mold, centrifugal forces throw the metal up against the surface of the spinning mold, and hold it there during solidification. The method may be used when the axis of rotation is horizontal, so that hollow castings having an axis of revolution can be cast without using a core to form the internal surface. The method can also be used when the axis is vertical, in which case the centrifugal force both helps to fill the casting and to force feed metal to the site of solidification shrinkage.

**Horizontal centrifugal casting** is widely used to make tubes for the petroleum and chemical industry and pipes for municipal water and sewer systems. Figure 24 shows a common design for a horizontal centrifugal casting machine. In operation, the mold is spun up to the desired rotational speed and sprayed with a ceramic coating that acts as the liner for the casting, and insulates the steel mold, decreasing thermal fatigue damage. Molten metal is introduced through a trough at one end. The metal travels down the trough and drops onto the spinning mold surface. The trough is progressively withdrawn from the mold as the mold is filled. After the trough is completely withdrawn from the mold, the casting solidifies. When the casting is solid, it is withdrawn from one end of the mold.

**Fig. 24** Schematic of a common design for a horizontal centrifugal casting machine

The mold material is generally steel, although copper or graphite may also be used. A sand core can be placed in one end of the mold. Mold coatings are important for regulating the solidification rate of the metal in the mold. The mold may be cooled during casting by external water sprays. The mold is rotated at a speed that exerts a centrifugal force of 75 to 120 times the force of gravity. The pressure gradient established across the tube thickness causes alloy constituents of various densities to separate. Lighter particles, such as slag and nonmetallic inclusions, gather at the internal diameter of the tube, where they can be easily removed by grinding.

Solidification is influenced by the mold material and the rate of heat extraction from it, the thickness and thermal conductivity of the mold wash (liner) used, the pouring temperature and pouring rate of the alloy, the speed of rotation, and the presence of vibrations in the system resulting from less-than-perfect balance of the system. The structure of the resultant casting consists of a very fine columnar skin, a well oriented columnar structure adjacent to the skin, and an equiaxed structure at the inside diameter. The extent of each of these areas is determined by the type of metal poured and the pouring parameters.

Horizontal centrifugal castings are made in diameters up to 1.6 m (63 in.), with wall thicknesses of up to 200 mm (8 in.). The process is also used to make duplex and bi-metallic castings, in which the outer metal is cast first and acts as a mold for the second metal, which is cast inside it.

**Vertical centrifugal casting** can be subdivided into two types: semicentrifugal and centrifuging. In semicentrifugal casting, the casting configuration is determined entirely by the shape of the mold, and cores may be necessary if the casting has hollow sections. The process has the advantage over static casting: the centrifugal force completely fills the casting and feeds it. Thin-wall castings are especially helped by the process. In centrifuging, the casting cavities are arranged about the center axis of rotation like spikes of a wheel; the method is widely used in producing jewelry. Sand, metal, and investment casting molds may be used in this process. Figure 25 shows a vertical axis centrifugal casting machine.

**Fig. 25** Typical installation of a vertical centrifugal casting machine. The equipment is controlled from a remote console (not shown).

Casting structure will depend, as in horizontal centrifugal casting, on the speed of rotation and the pouring parameters. In some cases, the molds will be poured at a slow rotational speed, which is increased during solidification. Vibration from lack of balance in the system may cause casting problems.

# Melting Methods

Thomas S. Piwonka, The University of Alabama

## Introduction

THE MELTING PROCESS includes the steps of making up the metal charge and melting it. It often includes refining (adjusting the chemistry of the melt using reactions in the molten metal bath) and treating the metal (adding small amounts of materials that affect the nucleation and growth of the solid during solidification). Melting furnaces derive their energy from combustion of fossil fuels or from electric power. The choice of which type of melting to use depends on a number of factors: type of alloy being melted, the local cost of electric power, and local environmental regulations.

## Induction Melting

The most common melting method in use in foundries is induction melting. In this technique, heat is generated in the metal charge by induced currents resulting from the electromagnetic field established in the furnace by a coil surrounding

the furnace. This electromagnetic field not only causes the charge to heat, but also exerts a force on the molten metal that stirs it, assuring excellent mixing in the metal bath. The two types of induction furnaces are channel furnaces and coreless furnaces.

### ***Channel Induction Furnaces***

In channel induction furnaces (Fig. 1), a small channel of molten metal surrounds the inductor coil. Only the small amount of metal in the inductor channel receives enough energy to be heated, and it is pumped out of the channel by electromagnetic forces into the remainder of the bath, which it heats by mixing. Because only liquid metal can enter the channel around the inductor, channel furnaces must be charged with liquid metal to start a melting cycle, and, when the liquid bath is tapped, some liquid must remain in the furnace to start the next heat. When the furnace is not in use (nights and weekends) power must be left on the furnace to keep this liquid from freezing. Because only a small amount of liquid in the channel receives electrical energy, use of this method as a primary melting source is slow. For this reason, channel furnaces are primarily used as holding or refining furnaces.

**Fig. 1** A cross section of a channel-type induction furnace showing the water-cooled copper induction coil that is located inside of a 360° loop formed by the throat and channel portion of the molten metal vessel. It is the channel portion of the loop that serves as the secondary of the electrical circuit in which the copper coil is the primary.

Channel furnaces may be horizontal or vertical in design. They generally operate on 60 cycle current, although other melt frequencies are possible. Power requirements may be as low as 20 kW for 315 kg (700 lb) capacity to 200 kW for 1360 kg (3000 lb) capacities. Melt rate can vary from 45 to 450 kg/h (100 to 1000 lb/h). Because only the liquid in the area of the inductor is stirred, mixing in the channel furnace is less efficient than in the coreless induction furnace. However, channel furnaces have high electrical efficiency and are simpler than coreless furnaces.

One problem encountered in coreless furnaces is clogging of the channel during operation. Clogging is caused by the products of the reaction between the refractories that line the furnace and the alloy being melted. At melting temperatures, the refractories react with the molten alloy to some extent. In some cases, the refractories are deliberately selected to produce reactions that refine the metal. These reactions are the cause of refractory degradation and determine the life of the refractory in the furnace. While the clogging reactions are the same in channel and coreless furnaces, the reaction products are visible in coreless furnaces but are out of sight of the melter and concentrated in the channel in channel furnaces. Care must be taken to monitor the condition of the channel during tapping to avoid unexpected interruptions of melting caused by clogging.

### ***Coreless Induction Furnaces***

In the coreless induction furnace (Fig. 2), the metal is surrounded by a hollow copper tube wound in a spiral. The tube is hollow to allow cooling water to run through and carry away heat generated in the copper by the induced current. The coil

is firmly supported so it does not change shape under the influence of the field, and a refractory lining protects it from physically contacting the molten bath. Coreless furnaces allow cold-charge melting, and refining may be carried out by adding refining elements and removing the reaction slag from the surface of the furnace. Emissions are substantially less using coreless induction melters than some fossil-fuel melters, such as cupolas. Induction furnaces also operate efficiently in a vacuum and are the primary power supply for vacuum melting.

**Fig. 2** A cross section of a coreless-type induction furnace showing water-cooled copper induction coil and key structural components. The entire molten metal bath (which serves as the secondary) is surrounded by the coil (the primary) that encircles the working lining.

The entire bath is heated and stirred by the electromagnetic field, as shown in Fig. 3. This stirring allows excellent alloy and charge absorption and aids in producing a melt that is thermally and chemically homogeneous. The amount of stirring depends directly on the amount of induced power and inversely on the square root of the frequency of the furnace. Selection of the wrong frequency will result in either too little or too much stirring and substantial melt inefficiency. In general, too much stirring will stand the melt up in the furnace, away from the furnace walls ("haystacking"), and expose the melt to the air. Because the oxygen in the melt reacts with most metals, this exposure leads to excessive melt-oxidation losses. However, this effect has been used to advantage in the design of a vacuum furnace for melting highly reactive metals such as titanium; here the metal is deliberately kept from furnace walls by electromagnetic forces. The relationship between melt frequency and furnace size is shown in Fig. 4.

**Fig. 3** Sectional view of a coreless induction furnace. (Arrows in crucible show direction of stirring action.)

**Fig. 4** Furnace size versus frequency for coreless induction melting of ferrous alloys. Frequency versus furnace size selections made along the centerline (and surrounding dark shaded area of chart) represent extremely successful melting applications. In the adjacent white zone areas, caution is required. The light gray zones represent areas in which the furnaces will work but probably never should be used. The outer dark zones indicate areas that should be out of bounds. In applying this chart to aluminum, multiply the weight of the metal by three to arrive at the recommended furnace capacity.

## Power Supplies

Many induction furnaces use line-frequency (60 cycle) power. However, a recent development is the use of high-power, medium-frequency furnaces for use in ferrous melting. In using line current, the typical power supply (Fig. 5) consists of the following:

- Primary switchgear
- Furnace transformer: needed to reduce the high voltage of the local power grid to the voltage required for melting
- Phase balancing system: needed because the induction furnace is a single-phase device, but the power is supplied from a three-phase system
- Power factor correction capacitor bank, needed to compensate for the amount of metal in the furnace and refractory wear (which changes the volume of the furnace)
- Instrumentation and controls

**Fig. 5** Modifying 60 Hz line frequency supplied by utility company to serve as power supply for induction furnaces

The typical conversion is an ac-dc-ac sequence. Although frequency conversion entails electrical losses, the solid state power supplies used in these furnaces have efficiencies approaching 97%. The power supplies are computer controlled to obtain maximum efficiency during melting. Two types of inverters are used, series and parallel. The furnace and compensating capacitor bank form part of a resonance circuit. In a series inverter, the capacitors are connected in series with the induction coil, and power to the furnace is controlled by detuning the inverter. In a parallel inverter, the capacitor bank is connected in parallel with the induction coil, and power is controlled by detuning the inverter in the full-power range. Thyristors in the rectifier lower the dc voltage and provide half cycle protection. Parallel systems are most widely used.

### ***Furnace Linings***

Furnace linings may be acid (silica-base), neutral (alumina-base), or basic (magnesia-base), depending on the alloy being melted. Silica is usually used for ferrous heats because it does not react extensively with the acid slag produced by the high silicon-containing iron compositions. It is inexpensive, and its thermal expansion is flat above 815 °C (1500 °F). Alumina is generally used with aluminum alloys, and magnesia linings are used with steel compositions that require a basic refractory to maintain proper composition. Alumina and magnesia have less thermal shock resistance than silica. In most cases the refractory is applied as a ramming mix, in which the refractory is combined with a sintering aid, such as boric acid. When the lining is sintered, the high temperature reached at the melt surface of the lining forms a hard glazed surface.

### ***Melting Operations***

Induction furnaces may be operated either in a batch mode, in which the entire charge is emptied and a new charge is melted, or a tap-and-charge mode, in which only a portion (typically one-third) of the melt is emptied, and new charge materials are added to the remaining charge and melted in. The batch operation has a somewhat higher melting efficiency, but chemistry is easier to control in tap-and-charge operation, as only one-third of the furnace charge must be added.

In foundry melting, the charge usually consists primarily of scrap and foundry returns (gates, risers, and scrapped castings). Chemistry is adjusted by adding the elements needed to reach the proper composition. Scrap must be preheated before charging to burn off machining oil, which can contaminate the charge and drive off all moisture, adding unwanted hydrogen to the bath, and, if enough water is present, causing a steam explosion when charged into the furnace.

Note that the same reactions that cause clogging in channel furnaces also cause refractory build-up in coreless furnaces. In coreless furnaces, the buildup is found at the bath-atmosphere interface near the top of the furnace. As the lining wears, the diameter of the furnace changes, changing the coupling characteristics between the power supply and the melt. The computer-controlled power supply automatically compensates for these changes. It is essential that the lining not be permitted to wear through to the coil, which will quickly melt and allow the cooling water to enter the molten bath with catastrophic results.

### ***Cupola Melting***

Cupolas are vertical shaft furnaces used for melting cast iron. Although similar in principle to blast furnaces, they are not "miniature blast furnaces." In operation, coke, flux, and metal are charged into the top of the furnace, and air, often preheated and/or enriched with oxygen, is blown in at the bottom through tuyeres. The coke burns in the air, melting the metal that trickles down to the bottom of the furnace or well, where it is tapped. Sectional views of cupolas are shown in Fig. 6.

**Fig. 6** Sectional views of conventional (non-water-cooled) and water-cooled cupolas. The conventional type shown is refractory lined. Water-cooled types incorporate either an enclosed jacket or an open cascade flow.

Cupolas are highly energy-efficient melting furnaces for cast iron. However, they produce large quantities of particulate and exhaust gases. These emission products must be removed from the gases discharged to the atmosphere, and the equipment required to accomplish this is expensive to purchase and operate. As a result, cupolas, despite their inherent simplicity and energy efficiency, are used only by the largest foundries, which require a high tonnage of molten iron in daily operation. The advantages of using cupolas in high-tonnage foundries include the fact that molten metal delivery is continuous, uninterrupted by the need to charge or melt new material.

As requirements on cast iron tighten, the cupola is used more and more as a bulk melter to provide metal for subsequent refining and treatment operations, usually carried out in induction furnaces or special treatment ladles, and less as a method of providing iron ready to be poured into molds. However, as a bulk melter, it is unsurpassed when large quantities of consistent-quality iron are required.

### ***Refinements in Cupola Equipment***

The concentration of cupola melting in high-tonnage applications has resulted in the development of refinements that increase the efficiency of the furnace.

**Water Cooling.** The refractory lining of cupolas wears because of abrasion of the charge materials and chemical reactions with the charge. These are accelerated at high temperatures.

Cooling the cupola wall with water significantly extends the refractory life and reduces downtime for relining. In fact, the refractory lining may be completely eliminated from the melting zone of the cupola. With water cooling, cupolas may operate continuously for 24 h periods, going weeks before requiring relining and maintenance.

**Preheated Air Blast.** Although cupolas function without preheated air, the combustion reaction is enhanced by preheating the air to 540 to 650 °C (1000 to 1200 °F). The air is usually preheated using natural gas and recuperative hot blast systems that recover the heat of the exhaust gases from the cupola.

**Oxygen Enrichment.** Adding 1 to 4% oxygen to the blast increases the metal temperature and the melting rate.

**Coke Injection.** Fine particles of coke may be injected into the blast through the tuyeres to increase carbon content of the iron.

**Basic Linings.** Originally, cupola linings were silica, chosen for its low cost. Silica linings are acceptable for gray iron. However, ductile iron requires very low sulfur contents. These can only be obtained from a cupola by using a basic slag. As a result, basic linings, using dolomite and magnesia, have been developed. Because of the higher cost of basic linings, basic cupolas are water cooled.

**Computer Control.** Using sensors and computer programs that calculate the reactions taking place in the cupola, air blast, and temperature, as well as the amounts of coke, limestone, and metal to charge, can be controlled automatically.

### ***Cupola Operation***

Cupolas may be operated either continuously or intermittently. In continuous operation, the iron and slag formed in the melting operation flow from a tap hole in the wall of the furnace well. Because the slag that is formed is lighter than the iron, it floats and may be separated from the iron using skimming knives and dams. The metal from continuous melting is usually tapped into induction-heated holding and/or treatment furnaces. High-tonnage cupola operations are usually continuous.

Intermittent tapping cupolas have a tap hole for the iron and a separate tap hole, higher in the well, for the slag. The iron tap hole is closed with fireclay. As molten metal accumulates in the well, its level rises until the slag reaches the level of the slag hole where it flows from the cupola. The iron tap hole is then opened, and the iron in the well drains out. The tap hole is closed and the process is repeated. The iron tap hole may be opened more frequently if desired.

### ***Charge Materials***

**The metallic part of the charge** is made up of foundry returns, pig iron and cast iron, and steel scrap. Gates, risers, and internally generated foundry scrap generally constitute 30 to 50% of the charge. Steel scrap is the next most prominent component of the charge. It offers the advantage of having low phosphorous content, essential for ductile iron. Cast iron scrap is also used, and pig iron is added to adjust the quality of the iron. Pig iron has a low level of tramp elements, and thus it can be used to bring melts contaminated by tramp elements from the scrap charge into specification. Careful analysis of scrap charges and proper mixing of scrap in the charge are necessary to provide consistent melt-composition control.

**Ferroalloys.** Because cast iron contains silicon and manganese, these elements must be added when steel scrap and pig iron are used in the charge. Ferrosilicon (50 or 75% Si) and ferromanganese (80% Mn) are usually added. Other forms include silvery pig (16 to 20% Si), silicon carbide (which also deoxidizes the iron), spiegel (10% Mn), and briquettes of silicon and manganese.

**Coke** is often considered to be the most important of the charge materials. Foundry grade coke is generally of higher quality than blast furnace coke. It must be strong enough to support the charge and to be sized properly, meaning that the size and size distribution of the coke must be controlled. Low ash content is desirable, and low sulfur content is particularly important, especially in ductile iron foundries. Coke comprises between 8 and 16% of the weight of the metallic charge.

**Fluxes** are added to fluidize the oxide slags that form on the surface of the metal from reactions taking place during melting. Limestone (96%  $\text{CaCO}_3$ ) or dolomite (96%  $\text{MgCO}_3$ ) are usually added at the 2 to 5% level in acid cupolas, and more basic fluxes are added to basic cupolas to fluidize the slag. Soda ash is a strong slag fluidizer. Fluorspar ( $\text{CaF}_2$ ) is a particularly powerful fluidizing agent, useful especially in acid cupolas to remove highly viscous slags. However, its use is limited by environmental considerations.

### ***Melt Rate***

The cupola is expected to maintain a melt rate that feeds the molding capacity of the foundry. However, as the size of the castings produced during the day may change, the volume of iron required may also change. The melt rate can be varied  $\pm 20\%$  by increasing or decreasing the blast. Tap temperature must be high enough to allow metal transfer to the molds, filling them without misrun, or to the next refining or treatment operation without freezing. Tap temperature is primarily influenced by the coke content in relation to the metal charge. The carbon and silicon content must be closely controlled.

Sulfur content in gray iron must be kept below 0.12%, but in ductile iron it must be below 0.015%. Phosphorous levels are generally kept as low as possible to improve machinability and impact resistance in ductile iron.

### ***Control Tests and Analyses***

Traditionally, cupola melt control was carried out by using the "chill test." In this test, a wedge-shaped bar of iron is poured and allowed to solidify. After it is solid, it is broken across the cross section and visually examined for the depth of white iron ("chill"), which is an indication of the carbon and silicon content. This test is still used, but it is augmented by eutectic temperature-arrest measurements, which are rapid and more accurate, and spectrometer analyses.

### ***Computer Use in Cupola Operation***

The chemical and thermal reactions that take place in a cupola have been modeled mathematically, to gain insight into improved control methods for cupolas. Computers are capable of controlling the entire operation of the cupola, in a feedback or feed-forward mode. The use of computer controls on cupolas allows automatic continuous adjustment of melt variables to minimize cost and effluent production. In one version of computer control, a mathematical model of the operation of the cupola checks the actual operation and adjusts melting parameters to optimize cupola operation.

## **Arc Furnaces**

Electric arc furnaces are used almost exclusively for melting steel, although some iron is melted in them, and they may be used as holding or refining furnaces. Arc furnaces may be direct current or alternating current. In either case, power to the furnace is provided by an arc established between a graphite electrode and, in the case of direct current furnaces, the charge. In the alternating current arc furnace, the arc is established between the electrodes through the charge.

### ***Types of Furnaces***

A cross section of an alternating current electric arc furnace is shown in Fig. 7. Two different types of furnace are shown: acid practice and basic practice. The difference is in the furnace linings used; in acid practice the lining is rammed silica or ganister (a siliceous refractory), and in basic practice the lining is rammed magnesite or dolomite. The acid practice offers flexibility in melting a variety of compositions, lower refractory and power costs than a two-slag basic practice, and greater tonnage per unit time. The basic practice is used to remove sulfur and phosphorous (in a two-slag practice), and it is used for stainless steel melting. In either case, the power is supplied from the local utility through a substation designed expressly for the furnace.

**Fig. 7** Cross-sectional view of an electric arc furnace indicating typical refractories employed in acid and basic

linings.

**In acid practice**, the furnace is charged with materials low in sulfur and phosphorous. The material will usually consist of 30 to 50% returns (scrap, gates, and risers) and 50 to 70% purchased scrap. Heavy scrap and casting returns are usually placed on the bottom of the furnace with lighter scrap on top. Nonoxidizing alloying elements, such as nickel and molybdenum, may be added with the charge. The arc is struck, and the charge is melted down rapidly. A carbon boil is then carried out to lower the carbon content. In the carbon boil, oxygen reacts with the carbon in the charge to form carbon monoxide gas that is removed from the furnace. The boil is produced either by using an oxygen lance or by adding mill scale ( $\text{Fe}_3\text{O}_4$ ) as a source of oxygen. In many cases, the rust on the charge is sufficient to produce the carbon boil. A vigorous boil eliminates all of the carbon, most of the hydrogen, and some nitrogen from the charge. A slag forms on the surface of the melt from the oxides produced from the silica lining and dirt on the charge.

After decarburization the boil slows to a gentle roll, and recarburization and alloy additions may be made if required. The recarburizers may be low-silicon, low-phosphorous pig, sored pig iron, high-carbon pig iron, or even broken electrodes. When the desired carbon level is reached, the oxidation reactions are stopped by adding silicon and/or manganese in the form of ferroalloys. Once the final alloying elements have been added, the heat is tapped.

**In basic practice**, the charge is similar (except that lower purity charge materials may be used), and a carbon raiser (coke, high-carbon pig, etc.) and limestone are added with the charge. The lime removes sulfur from the charge, and the slag it forms protects the bath. The bath is oxidized as before to adjust the carbon content of the melt. When the oxidizing period is over, the bath may be tapped if a single slag practice is being used. However, if it is desirable to remove phosphorous from the heat, a different procedure is followed. Iron ore or mill scale is added to the slag when melting is complete to raise the oxygen content of the slag so that phosphorous can be oxidized. Silicon content in the bath is kept low, and the temperature is kept below  $1540^\circ\text{C}$  ( $2800^\circ\text{F}$ ), as the dephosphorizing reaction reverses above this temperature. After the phosphorous level has been reduced, the slag (that now contains the phosphorous) is removed from the furnace, and a second slag is formed from limestone. As soon as the second slag is melted, the current is reduced, and a deoxidizer such as coke, coal, or aluminum is added. These elements reduce the oxides of iron and manganese in the slag and help form a calcium carbide slag that removes sulfur. After the proper levels of carbon are reached, the temperature is raised for tapping, and the furnace is emptied.

Following the practice in the basic steel industry, refining may also be carried out in ladles. Deoxidizers in the form of aluminum or titanium are added to remove oxygen so the carbon content of the heat does not change during pouring. A number of other refining practices may be used for high-alloy steels to assist in the recovery of alloy elements needed for the final composition. Argon stirring may be used to remove inclusions, and calcium wire injection is often used to improve steel cleanliness.

### ***The Direct Current Arc Furnace***

In the direct arc furnace, shown in Fig. 8, only a single electrode is used. This method of melting is slowly growing in use. It has become feasible through the development of high-power solid-state converters. Its advantage is that it has a simpler circuit than the three-electrode alternating current method, and electrode consumption is greatly reduced. The single electrode is connected to the cathode of the rectifier, and the anode is connected to the furnace bottom. The charge passes from the electrode through the charge to the furnace bottom. Melting in a direct current furnace takes longer unless a heel of molten metal is left in the furnace.

**Fig. 8** Sectional view showing the basic components of a direct current arc furnace

As in other melting methods, the scrap should be preheated, and dust and fume hoods are required in the installation to avoid air pollution. Tapping is carried out by tilting the furnace and allowing the molten metal to run into the ladle.

## Crucible Melting

Crucible furnaces are used to melt aluminum, zinc, magnesium, and copper alloys. In these furnaces, shown in Fig. 9 and 10, natural gas or a petroleum fuel is burned, and the flame surrounds the crucible. Crucible furnaces can also be used in induction melting.

**Fig. 9** Lift-out crucible (pot) furnace

**Fig. 10** Typical lift-out crucible furnace especially well adapted to foundry melting of small quantities of copper alloys (usually less than 135 kg, or 300 lb)

### *Furnace Types*

In stationary furnace installations, the crucible is set inside a refractory-lined shell. When the metal is molten, it is dipped out using a hand ladle, or the crucible is removed using tongs, placed in a yoke, and transported to the molds. In a push-out furnace, shown in Fig. 11, hydraulic cylinders raise the crucible out of the furnace where it may be transferred to the pouring line. The crucible material is chosen according to the alloy being melted. Clay graphite crucibles are used for aluminum, and steel or ductile iron crucibles may be used for magnesium and zinc. Other refractories may be selected, depending on the alloy. Crucible furnaces may also be used as tilting installations, particularly when induction heating is used.

**Fig. 11** Cross section of a double push-out stationary crucible furnace

**Burner Design.** When natural gas is used for melting, care must be taken to degas the molten alloy. This is particularly true for aluminum heats, as molten aluminum has a very high solubility for hydrogen. In using natural gas or petroleum fueled furnaces, care must be exercised to keep the flame slightly oxidizing. Burner design and placement are important to avoid hot spots in the crucible that will wear more rapidly than desired. Melting is most efficient when a heel of molten metal is left in the furnace between charges. Care must also be taken when charging refractory crucibles to lay the charge in gently so that the crucible is not broken. The charge must also be loosely packed because the thermal expansion of a tightly packed charge as it heats to the melting temperature may break the crucible.

**Resistance Heating.** Crucible furnaces may also use electric resistance heating. This method is used in melting magnesium and aluminum alloys. Electric resistance furnaces have high-energy conversion efficiency and can be sealed to prevent updrafts in the furnace from carrying heat out the top of the installation.

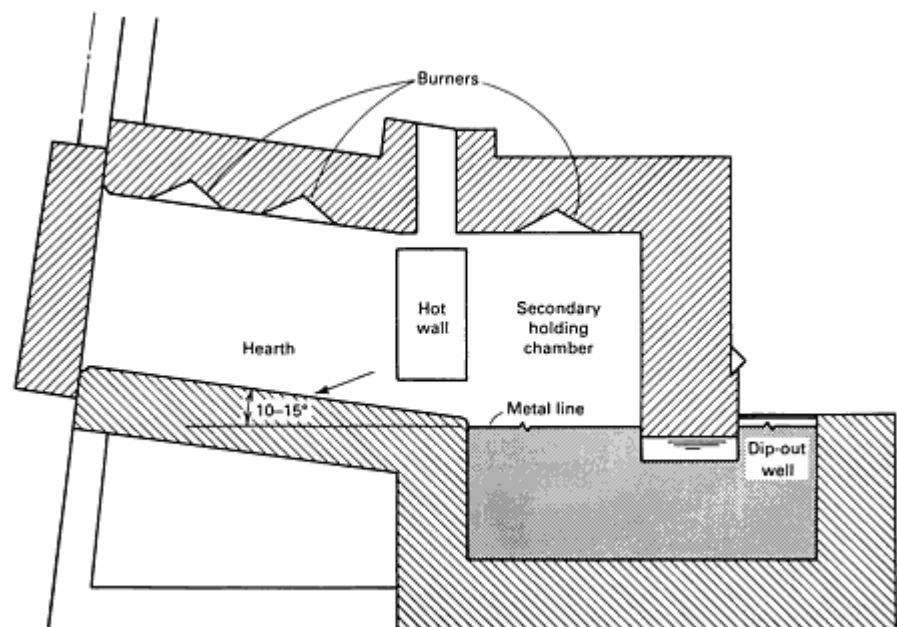

## Reverberatory Furnaces

### *Furnace Types*

Reverberatory furnaces are used primarily for melting aluminum. They are of two types, wet hearth, shown in Fig. 12, and dry hearth, shown in Fig. 13. In the wet-hearth furnace, the products of combustion are in direct contact with the top of the metal bath, and heat transfer is achieved by a combination of convection and radiation. In the dry-hearth furnace, the charge of solid metal is positioned on a sloping hearth above the level of the molten metal so the entire charge is completely enveloped by the hot gases. Heat is rapidly absorbed by the solid charge, which melts and drains from the sloping hearth into the wet holding basin. Although reverberatory furnaces are normally fuel-fired, dry hearth furnaces may use electric energy to heat the refractories.

**Fig. 12** Schematic of a wet-hearth reverberatory furnace heated by conventional fossil fuel showing the position of the hydrogen and oxygen gases relative to the molten metal bath. Arrows indicate heat radiated from top of furnace chamber.

**Fig. 13** Schematic of a radiant-fired dry-hearth reverberatory furnace illustrating the position of the sloping hearth relative to the molten bath

### ***Refractories***

Refractory selection depends on the metal being melted. In aluminum melting, care must be taken to remove the dross (aluminum oxide) that builds up on the surface of the melt and deposits at the melt line on the refractories. In aluminum alloys containing iron, often used in die casting, iron aluminum compounds may form a sludge, which sinks to the bottom of the furnace, and must be removed periodically. Refractory life is extended when the furnace operates continuously, including nights and weekends. The furnace is usually heated prior to charging, in order to close any cracks that may have formed on cooling from a previous campaign.

### ***Charging Practice***

During charging, light scrap is usually charged first, to act as a cushion for the heavier scrap and to protect the refractory. After the bath is molten, alloy additions are made. Light metal additions, such as magnesium and silicon, will float and oxidize on the surface instead of alloying; for this reason they should be submerged and held with a plunger until they have dissolved. Heavy elements, such as copper, will sink to the bottom of the bath and resist dissolution; they should be suspended in a basket. Zinc and tin often cause special problems, as they have low vaporization temperatures. When charged in large slabs, they sink to the bottom of the bath, and not only melt, but may vaporize. If the vapor enters the porous refractory, it may condense in the lower temperature areas of the furnace (near the furnace walls) and solidify. When the furnace is next heated, the solid metal expands and cracks the refractory. As in crucible furnaces, burner design and maintenance are important.

### **Reaction Melting**

The heat of solution may also be used to melt alloys. This method has been particularly effective in melting nickel and titanium aluminides. In this process, a crucible is charged first with the higher melting material, nickel or titanium, and the lower melting material, aluminum, is placed on top of it. When the furnace is heated, the lower melting point metal melts, runs down over the nickel or titanium, and begins to dissolve it. The dissolution reaction is exothermic, which raises the temperature of the bath to the melting temperature of the intermetallic alloy, without the use of more energy. Because the exothermic reaction is so energetic, care must be taken to carefully arrange the charge in the furnace in layers; otherwise, the heat may be liberated so quickly that the crucible cracks.

### **Vacuum Melting**

Vacuum melting is used for nickel-base superalloys, titanium alloys, and refractory alloys, to protect them from oxygen, which, in the case of the nickel-base alloys, forms deleterious inclusions, and in the case of titanium, could cause an exothermic reaction that would consume the heat and the furnace.

**In vacuum induction melting (VIM)**, the induction furnace is enclosed in a steel chamber, as shown in Fig. 14. The chamber is connected to vacuum pumps that reduce the pressure in the chamber to  $10^{-3}$  torr. The furnace may be charged with the door open to the atmosphere, or, in continuous operation, the charge is placed in the crucible through a charge lock. However, before melting, the door is closed, and the furnace and charge are pumped down to the vacuum level desired. Then power is applied and the charge is melted. Alloy additions are made through charge locks. The pressure in the charge lock is reduced to the pressure in the melting chamber before the lock is opened, and the alloying addition is made to the melt.

**Fig. 14** Schematic of a typical VIM furnace. 1, furnace insert; 2, vacuum pumping system; 3, bulk charger; 4, fine charger; 5, control cabinets; 6, melting and mold chamber; 7, mold turntable

When the charge reaches the correct temperature, it is poured. In casting, the mold is moved, again through a charge lock, into the furnace and positioned beneath the lip of the furnace. The furnace is then tilted to fill the mold with molten metal. The mold is removed through a lock, and the cycle is repeated with a new charge and mold. Usually, the charge is a prealloyed ingot, weighed to contain exactly enough metal to fill the mold.

The vacuum induction furnace is a necessarily complex piece of machinery, consisting of the furnace and its power supply (which must be designed for vacuum operation to avoid arcing in the reduced pressure of the chamber), the pumps that evacuate the furnace (a series of pumps is required, as each pump design is most efficient over a fairly narrow range of reduced pressures), and the charge and mold locks that must include valves between them and the furnace chamber. Mold locks are frequently located beneath the melting chamber, so mold elevators must be employed to raise them to the furnace for pouring. The operation of the furnace is controlled automatically, depending on the output from temperature and vacuum gauges in the system.

**Vacuum Arc Skull Melting.** Very reactive alloys, such as titanium alloys, cannot be melted in refractory crucibles, because they violently react with or dissolve the refractory when they are molten. Instead, these materials are melted in water or NaK-cooled copper skull arc furnaces, such as that shown in Fig. 15. In this case, the alloy ingot is one electrode, and the copper crucible is the other electrode. The arc is struck from the ingot to the copper crucible, and the heat of the arc melts the ingot, which drips into the crucible. Because the crucible is cooled, the first metal that drips into it solidifies in it, forming a solid "skull" that contains the rest of the melt, thus avoiding contamination. The molds enter the furnace through a mold lock for pouring. When sufficient metal has been melted to fill a mold, the mold is placed in front of the

crucible, the ingot rapidly retracted, and the crucible tilted. The pouring operation must be done quickly, or the metal will freeze in the crucible.

**Fig. 15** Schematic of a modern semicontinuously operating vacuum arc skull melter for charge weights of up to 1000 kg (2200 lb). 1, fast retraction system; 2, power cables; 3, power supplies; 4, electrode feeder ram; 5, consumable electrode; 6, skull crucible; 7, crucible carriage; 8, tundish shield; 9, mold arrangement; 10, vacuum pumping system; 11, centrifugal casting system

**Other Vacuum Processes.** The disadvantage of vacuum arc remelting, or VAR, is the inability to control superheat accurately, as can be done in induction furnaces. This difficulty has led to the development of a vacuum induction furnace for reactive alloys in which the induction field is arranged so electromagnetic forces push the molten metal away from the walls of the furnace, standing it up in the center of the furnace. The molten alloy contacts the furnace wall only briefly during pouring, and there is little or no reaction with the wall.

Other power sources may be used in vacuum melting, such as plasmas or electron beams. However, these melting methods are not in widespread use in the foundry industry.

## Molten Metal Treatment

There are a variety of molten metal treatments used to improve the quality of the metal charge. These are carried out in the ladles, rather than in the melting furnace.

**Steels.** In argon-oxygen-decarburization (AOD), used for stainless and alloy steel refining, oxygen, argon, and nitrogen are injected into the steel bath through submerged, side-mounted tuyeres (See Fig. 16 in the article "Steelmaking Practices and Their Influence on Properties" in this Handbook). This causes a shift in the decarburization thermodynamics, which permits the steel to be decarburized without oxidizing alloying elements such as chromium. During treatment, the ratio of oxygen to inert gas decreases as the carbon level decreases. Once the aim carbon level is obtained, a reduction mix (silicon, aluminum, and lime) is added. If extra-low sulfur levels are needed, a second desulfurization treatment can be carried out.

Steel heats may also be degassed using inert gas and vacuum. The melt is placed in the vacuum degassing vessel and the pressure above the melt is reduced, allowing hydrogen and nitrogen to be removed from the bath. To reach maximum effectiveness, the bath is stirred, either by electromagnetic forces, or by the injection of argon at the bottom of the ladle, (Fig. 16).

**Fig. 16** Schematic of a vacuum arc degassing plant layout. 1, transformer; 2, bus bars; 3, flexible cables; 4, electrode arms; 5, temperature-measuring and sampling device; 6, alloying lock; 7, electrode housing; 8, electrode masts; 9, operating platform; 10, lifting device for platform; 11, vacuum cover; 12, ladle heat shield; 13, electrodes; 14, slag; 15, melt; 16, argon plug; 17, vacuum vessel; 18, vessel drive; 19, emergency pit

**Aluminum** heats must also be degassed to remove dissolved hydrogen that, if not removed, forms porosity in aluminum castings. The most efficient degassing method is to introduce chlorine gas, which reacts with the hydrogen to form HCl. However, because of safety concerns with chlorine, this method is little used. Instead, rotary degassing is used (Fig. 17). In this process, an inert gas is injected into the column or shaft of the rotator and is released through fine openings at the base of the rotor. When rotating at speeds of 300 to 500 rpm, the disperser shears the incipient gas bubble released, producing a wide dispersion of very fine bubbles for degassing. The high surface area to volume ratio provides a greatly increased contact area and increases reaction kinetics, resulting in more efficient degassing.

# Foundry Practice for Ferrous Alloys

Thomas S. Piwonka, The University of Alabama

## General Considerations for Cast Irons

CAST IRON usually refers to an in situ composite of stable eutectic graphite in a steel matrix. The shape of the graphite is controlled by treating the liquid metal before solidification begins, in order to control the amount of undercooling the melt undergoes before solidification begins. In one form of cast iron referred to as white iron, the metastable form of the eutectic, iron carbide ( $\text{Fe}_3\text{C}$ ), is formed. The difference between the stable and the metastable phase diagrams of the iron-carbon system is shown in Fig. 1. A general diagram showing a simplified process chart for cast iron is presented in Fig. 2. A significant foundry property of cast iron is that when the stable eutectic, graphite, forms on solidification, it expands rather than shrinks. This means that many iron castings can often be made with minimum use of risers.

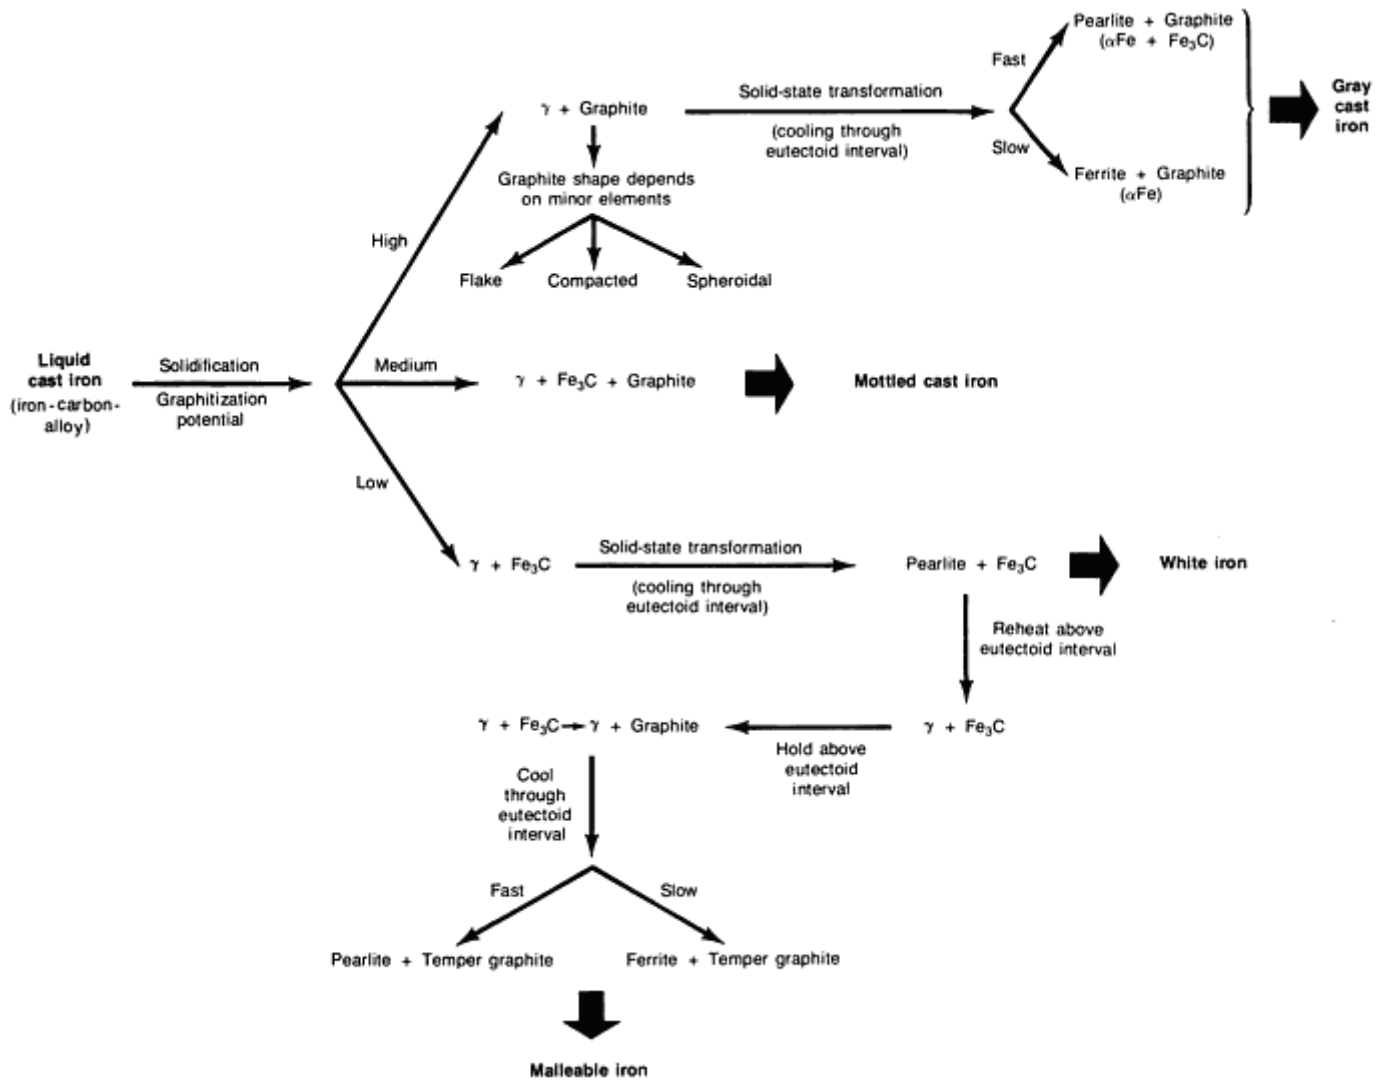

Fig. 1 Iron-carbon diagram, where solid curves represent the metastable system Fe-Fe<sub>3</sub>C and dashed curves represent the stable system iron-graphite

**Fig. 2 Basic microstructures and processing for obtaining common commercial cast irons**

It is important to realize that "cast iron" refers to a family of materials, not a single material. Within the major classifications of cast iron, which include gray iron, ductile iron, compacted graphite iron, malleable iron, and white iron (referring to the form of the eutectic which forms on solidification), variations are produced by alloying and heat treating. These processes control the structure of the matrix. For this reason, cast irons can be used for a wide variety of applications. In many cases, more than one type of cast iron will satisfy performance requirements, so it is important to have a thorough knowledge of the possibilities to find the most economical iron for a specific use.

Cast iron is not poured into metal molds unless white iron is to be produced. Instead, molds for iron castings are usually made of sand, using clay-water or resin bonds. Sea coal is generally added to the molding sand; it expands and cokes in response to the heat from the solidifying casting, and resists penetration of molten metal into the mold. Cores are often coated to produce a smoother finish than can be obtained from sand. The particle size of the refractories used in the coating is much finer than that of the sand. Venting of mold cores used for cast iron is important to avoid non-fill and misrun.

## Gray Irons

GRAY IRON ALLOYS are primarily iron-carbon-silicon ternary alloys. Most gray irons are produced with 3.0 to 3.5% carbon levels and 1.8 to 2.4% silicon levels. Gray irons are characterized by the presence of most of the contained carbon

as flakes of free graphite in the as-cast iron. Gray iron has the lowest casting temperature, the least shrinkage, and the best castability of all ferrous casting alloys.

## Principles of Solidification

A section from the Fe-C-Si equilibrium phase diagram at the 2.5% Si level is shown in Fig. 3. The diagram shows that cast iron undergoes a eutectic solidification reaction and a eutectoid solidification reaction on cooling from liquid to solid. An approximate way of converting cast iron composition to that of the simple Fe-C binary eutectic is through the use of the concept of the carbon equivalent (CE). In its most simple form, the carbon equivalent is:

$$CE = \%C + (\%Si/3)$$

**Fig. 3** Iron-carbon phase diagram at 2.5% Si

For irons containing appreciable amounts of phosphorous, the carbon equivalent is:

$$CE = \%C + [(\%Si + \%P) + 3]$$

Based on these relationships and the equilibrium phase diagrams, an iron having a carbon equivalent of 4.3 is a eutectic cast iron. Most cast irons are hypoeutectic, meaning that their carbon equivalent is less than 4.3. The carbon equivalent can be determined by chemical analysis or thermal analysis, the latter of which can be carried out rapidly on the foundry floor during production.

In cast iron, minor elements that must be controlled for proper solidification and performance include phosphorus, manganese, and sulfur. Phosphorous improves fluidity but increases shrinkage in cast iron, because the phosphorous forms a eutectic that shrinks on solidification. Sulfur affects the nucleation of graphite and must be balanced with manganese additions to promote the formation of manganese sulfide inclusions. Trace elements can also have significant effects on casting structure and quality, and these are summarized in Table 1.

**Table 1 Effects, levels, and sources of some trace elements in gray iron**

Element	Trace level, %	Effects	Sources
<b>Aluminum</b>	$\leq 0.03$	Promotes hydrogen pinhole defects, especially when using green sand molds and at levels above 0.005%. Neutralizes nitrogen	Deliberate addition, ferrous alloys, inoculants, scrap contaminated with aluminum components
<b>Antimony</b>	$\leq 0.02$	Promotes pearlite. Addition of 0.01% reduces the amount of ferrite sometimes found adjacent to cored surfaces.	Vitreous enameled scrap, steel scrap, white metal bearing shells, deliberate addition
<b>Arsenic</b>	$\leq 0.05$	Promotes pearlite. Addition of 0.05% reduces the amount of ferrite sometimes found adjacent to cored surfaces.	Pig iron, steel scrap
<b>Bismuth</b>	$\leq 0.02$	Promotes carbides and undesirable graphite forms that reduce tensile properties	Deliberate addition, bismuth-containing molds and core coatings
<b>Boron</b>	$\leq 0.01$	Promotes carbides, particularly in light-section parts. Effects become significant above about 0.001%.	Deliberate addition, vitreous enameled scrap
<b>Chromium</b>	$\leq 0.2$	Promotes chill in thin sections	Alloy steel, chromium plate, some refined pig iron
<b>Copper</b>	$\leq 0.3$	Trace amounts have no significant effect and can be ignored.	Copper wire, nonferrous alloys, steel scrap, some refined pig iron
<b>Hydrogen</b>	$\leq 0.0004$	Produces subsurface pinholes and (less often) fissures or gross blowing through a section. Mild chill promoter. Promotes inverse chill when insufficient manganese is present. Promotes coarse graphite	Damp refractories, mold materials, and additions
<b>Lead</b>	$\leq 0.005$	Results in Widmanstätten and "spiky" graphite, especially in heavy sections with high hydrogen. Can reduce tensile strength 50% at low levels ( $\geq 0.0004\%$ ). Promotes pearlite	Some vitreous enamels, paints, free-cutting steels, nonferrous alloys,terne plate, white metal, solder, some pig irons
<b>Molybdenum</b>	$\leq 0.05$	Promotes pearlite	Some refined pig iron, steel scrap
<b>Nickel</b>	$\leq 0.01$	Trace amounts have no major effect and can be ignored.	Refined pig iron, steel scrap
<b>Nitrogen</b>	$\leq 0.02$	Compacts graphite and increases strength. Promotes pearlite. Increases chill. Can cause pinhole and fissure defects. Can be neutralized by aluminum or titanium	Coke, carburizers, mold and core binders, some ferroalloys, steel scrap
<b>Tellurium</b>	$\leq 0.003$	Not usually found, but a potent carbide former	Free-cutting brasses, mold and core coatings, deliberate addition

<b>Tin</b>	$\leq 0.15$	Strong pearlite promoter; sometimes deliberately added to promote pearlitic structures	Solder, steel scrap, nonferrous alloys, refined pig iron, deliberate addition
<b>Titanium</b>	$\leq 0.15$	Promotes undercooled graphite. Promotes hydrogen pinholing when aluminum is present. Combines with nitrogen to neutralize its effects	Some pig irons, steel scrap, some vitreous enamels and pains, deliberate addition
<b>Tungsten</b>	$\leq 0.05$	Promotes pearlite	Tool steel
<b>Vanadium</b>	$\leq 0.08$	Forms carbides; promotes pearlite	Steel scrap; some pig irons

As most gray irons are hypoeutectic, their solidification behavior can be illustrated with the help of the simplified ternary eutectic diagram taken at 2% silicon shown in Fig. 4. At temperatures above point 1, the iron is entirely molten. As the temperature falls and the liquidus line is crossed, primary freezing begins with the formation of proeutectic austenite dendrites. These dendrites grow and new dendrites form as the temperature drops through the primary freezing range, between points 1 and 2. Dendrite size is governed by the carbon equivalent of the melt and the freezing rate (the faster the freezing rate and the higher the carbon content, the finer the dendrites).

**Fig. 4** Simplified iron-carbon-silicon phase diagram at 2% Si

During the formation of the austenite dendrites, carbon is rejected into the remaining liquid. The carbon content of the liquid increases until it reaches the eutectic composition of 4.3%. At this composition, the remaining liquid transforms into two solids, between points 2 and 3. The type of solid depends on whether the transformation is stable or metastable. In the stable transformation, graphite and austenite form. In the metastable transformation, iron carbide and austenite form. At point 3, all of the liquid is solid, and any further transformations take place in the solid state. As the solid cools from point 3 to point 4, carbon diffuses from the high carbon austenite to the graphite flakes, and at point 4 the austenite transforms to pearlite (a mixture of iron carbide and ferrite) or to a mixture of ferrite and pearlite.

**Graphite Morphology.** Five types of graphite, known as A to E, are found in gray iron. How the shape, size, amount, and distribution of graphite flakes influence mechanical and physical properties of gray irons is described in detail in the Section "Cast Irons" in this Handbook.

**Cementite.** If the cooling rate of the liquid at the eutectic temperature is very rapid, as in thin sections, the eutectic liquid will undercool substantially and solidify rapidly. If the solidification rate is too rapid, graphite will not have time to form, and the metastable form of the eutectic, cementite (iron carbide,  $\text{Fe}_3\text{C}$ ), will form. Cementite is hard and brittle, and generally is not desired. When a casting that has solidified at a rapid rate and formed cementite is fractured, the fracture is white. The structure is therefore known as "white iron" or "chill iron." The tendency to form white iron is enhanced by the addition of carbide formers such as chromium to the melt, while the formation of graphite is enhanced by the addition of graphitizers such as silicon or copper. One way of estimating the tendency of a melt to form white iron is to pour a wedge-shaped bar, such as that shown in Fig. 5, to allow it to solidify, and then to fracture the bar and examine the amount of the structure that solidifies with the white structure. At cooling rates between that producing a white iron structure and that producing a gray iron structure, a mixture of eutectic structures called a "mottled" structure (Fig. 6) is formed.

**Fig. 5** Standard W2 wedge block used for measuring depth of chill (ASTM A 367). Dimensions are given in inches.

**Fig. 6** Mottled cast iron etched using 4% picral. The white phase is eutectic carbide. 50×

**Matrix Phases.** The steel matrix consists of ferrite or pearlite or a mixture of both. Ferrite is soft and contains little carbon, and its formation is promoted by graphitizers such as silicon and by a slow cooling rate. Pearlite is a eutectoid mixture of ferrite and cementite, which forms in alternate thin plates. Pearlite is harder and less ductile than ferrite, and its hardness and tensile strength depend primarily on the spacing of the plates. Higher values are found in pearlite with the fine interlamellar spacing associated with more rapid cooling rates and/or alloying.

In cast irons containing more than 0.2% phosphorous, the iron phosphide eutectic may form at cell boundaries, where it has a concave triangular shape, as shown in Fig. 7. This phase lowers properties. Other phases that may occur include manganese sulfide inclusions, shown in Fig. 8, and carbides or carbonitrides.

**Fig. 7** Steadite in gray cast iron. Etched using 2% nital. 400×

**Fig. 8** Manganese sulfide (dark gray, rounded) and titanium carbonitride (light gray, angular) inclusions. Etched using 2% nital. 500×

## Melting Practice

The essential purpose of melting is to produce molten iron of the desired composition and temperature. For gray iron, this can be accomplished with various types of melting equipment. Cupolas and induction furnaces tend to be the types most commonly found in the gray iron foundry. The cupola was traditionally the major source of molten iron, but gradual acceptance of electric melting has reduced its dominance. Gray iron can be melted with a single furnace or a combination of furnaces (duplexing).

Regardless of the type of furnace used, the basic melting process is a physical transformation from solid to liquid rather than a complex reduction or oxidation reaction. Therefore, the composition of all the materials charged into the furnace determines the composition of the slag/iron mixture.

**Charge materials for cupolas** are described in the article "Melting Methods" in this Section.

**Charge Materials for Induction Furnaces.** Compositional control of gray iron is greater in induction furnaces than cupolas because of the reduced oxidation losses during melting and the elimination of coke as fuel. The composition of the metallic charge materials is directly related to the final composition of the iron. Therefore, accurate weights and analysis of charge materials are required for good compositional control. Typical charge materials include steel scrap, cast iron scrap, foundry returns, ferrosilicon, and carbon. Pig iron is rarely used because of cost, although it does offer advantages in terms of purity. The type of scrap employed will depend on economics. The elimination of coke from the charge also reduces the sulfur absorbed by the iron; therefore, resulfurization is often desirable in electrically melted gray iron.

A typical charge for class 30 iron of 4.20 carbon equivalent (CE) is:

<b>Steel scrap</b>	<b>41.3%</b>
<b>Gray iron borings</b>	10.0%
<b>Foundry returns</b>	45.0%
<b>Carbon</b>	1.7%
<b>50% ferrosilicon</b>	2.0%

The CE can readily be adjusted to any desired level by balancing steel scrap content and additions of carbon and ferrosilicon. Alloying additions are absorbed rapidly at 90 to 95% recovery, and the ease of meeting chemical and mechanical specifications, including those difficult or impractical in cupola melting, is valuable. Carbon additions are made with pelletized petroleum coke of controlled grain size to give high and reproducible recoveries. Because little sulfur is introduced in induction melting, the sulfur content of the melted iron is considerably lower than that from a cupola, and thus less manganese is required for balance with sulfur.

## Desulfurization Methods

Excess free sulfur in gray iron increases chill depth, decreases fluidity, and decreases the effectiveness of inoculation. Several successful desulfurization techniques have been developed in the search for methods of obtaining low-sulfur base irons. Calcium carbide has proved to be the most effective desulfurizing agent for low sulfurs. Lime is also an effective desulfurizing agent, but it requires more volume, time, and agitation. Small percentages of fluorspar and various salts improve the desulfurizing effectiveness of lime.

Metal stirring or agitation is essential for promoting optimum desulfurization. The following stirring methods have been found to be effective:

- Carbide is injected with inert gas through graphite or refractory lances that supply the carbide and simultaneously stir the melt.
- Inert gas is bubbled through a porous plug in the bottom of a ladle, with desulfurizing agent fed onto the surface with a vibrating feeder.
- The shaking ladle system places a ladle of iron in a gyrating shaking mechanism that stirs in the desulfurizing agent.
- The refractory stirrer system rotates a refractory paddle in the bath, stirring the carbide or lime into contact with the iron.

With any of these stirring methods, additions of 0.50 to 1.0%  $\text{CaC}_2$  have desulfurized irons of 0.07 to 0.10% S, as melted, down to a final 0.01 to 0.02% S. A temperature loss of 30 to 55 °C (50 to 100 °F) can be expected. Lime alone or with various salts can be used as the desulfurizing agent. The efficiency is lower than that with carbide, but there are fewer environmental problems.

Injection and porous plug desulfurizing systems can be either batch type, treating individual ladles, or a continuous system, with the cupola stream flowing through a special forehearth outfitted with a porous plug and a carbide feed (or injection lance). The spent carbide or lime is raked off or overflows, and the desulfurized metal flows continuously into the holder or duplex electric furnace. Disposal of the carbide slag requires attention to safety and environmental considerations.

## Inoculation

To control the properties of cast iron, it is necessary to control the formation of the graphite flakes (the eutectic reaction), and the formation of the steel matrix (the eutectoid reaction). Controlling the eutectic reaction means controlling the amount of undercooling that the eutectic liquid undergoes. This is accomplished by the practice of inoculation.

Inoculation is the late addition of ferrosilicon alloys to molten iron to nucleate the graphite. Ferrosilicon alloys usually contain either approximately 50% silicon or 75% silicon and act as carriers for the nucleating elements, which include calcium, barium, titanium, and rare earths, such as cerium. Graphite itself may also be added as an inoculant; the best graphite (such as furnace electrodes) is highly crystalline in structure. Graphite is usually added in addition to ferrosilicon. The amount of ferrosilicon added is not especially large, which means that the chemical composition of a melt is changed only slightly by inoculation. Thus two nearly identical melt compositions can produce entirely different cast structures depending on whether or not an inoculant has been added to the melt.

**Types of Inoculants.** Inoculants may be divided into performance categories as follows: standard, intermediate, high potency, and stabilizing. The performance of the first three categories is shown in Fig. 9. (Stabilizing inoculants are added to control both the eutectic and the eutectoid reactions.) As the potency of the inoculant increases, so does its cost. Adding extra inoculant is not recommended because the effect of the inoculant drops with increasing additions, and inoculants form dross that can lead to inclusion defects in the casting.

Fig. 9 General classification of inoculants showing chill reduction in iron with carbon equivalence of 4.0

**Addition Methods.** Inoculants may be added to the melt in a number of different ways. Ladle inoculation is common; in this, the alloy is added to the stream of metal as it flows from the transfer ladle to the pouring ladle. Stream inoculation is the addition of the inoculant to the pouring stream as the metal enters the mold. Mold inoculation involves placing the inoculant in the mold, usually at the base of the sprue. These last three methods are referred to as "late inoculation" and are used to counteract the phenomenon of "fade," in which the inoculant loses effectiveness with an increase in time from addition to time of solidification. The effect of inoculation is best within five minutes; if iron is held more than 15 to 30 min after inoculation and before pouring, there is usually no effect at all.

## Alloying

Alloying elements may be added to cast iron to obtain specific properties that are not obtainable without alloy additions. Alloying and inoculation are not the same process and should not be confused, although alloying can affect choice of inoculation practice. Common alloying elements for gray iron include chromium, copper, nickel, molybdenum, and tin. The effects of these additions are as follows:

- Chromium additions of 0.5 to 0.75% increase the strength of gray iron by increasing the pearlite content. Chromium is also a chill promoter.
- Copper additions in the range of 0.25 to 0.5% increase tensile properties, again by promoting the formation of a pearlite matrix. Copper also acts as a graphitizer.
- Nickel additions of up to 2% cause a minor increase in properties. Nickel is also a graphitizer.
- Molybdenum in additions of 0.25 to 0.75% has a significant impact on the strength of gray iron as a

matrix strengthener and a graphite flake refiner.

- Tin in the range of 0.025 to 0.1% stabilizes pearlite.

When higher amounts of alloying elements are added, the product is known as "alloyed cast iron" or "high-alloy cast iron."

The choice of alloying element and the amount to add depends on the base iron composition, the part being made, and the properties desired. Parts produced from different base irons and alloy additions can have the same tensile properties and performance in service, although other properties may vary. Note also that because the matrix of gray iron is steel, it is possible to heat treat gray iron to adjust its properties from those produced as-cast. However, as the graphite flakes act as stress concentration points, gray iron has little ductility.

**Alloying addition practices** vary considerably, depending on the method of melting, the composition and product form of the alloy being added, the amount of iron being alloyed (the entire charge or only portions of the charge), and the ladling practice in the specific foundry.

In cupola melting, nickel, copper, chromium, and molybdenum are added to molten metal during or after tapping, rather than being added to the cupola charge. If the ladle that receives the molten metal at the spout will pour the castings without a transfer, the alloying metal may be added to the stream at the spout. This practice generally provides reasonably thorough mixing, although the exact amount of iron tapped into the receiving ladle is sometimes difficult to control. A more common practice is to add the alloying metals to the stream from the receiving ladle (or forehearth, if used) as it is transferred to the pouring ladle, because it may not be desirable to alloy all of the metal in the receiving ladle or forehearth. The amount of mixing obtained by adding to the stream is usually sufficient, although to obtain more thorough mixing the alloyed metal is sometimes poured from the transfer ladle to another transfer ladle.

The practices described above may also be employed if the melting is done in an arc or induction furnace. However, if the entire charge of an arc or induction furnace is to be alloyed, the alloying metals may be added to the furnace, usually just a few minutes prior to tapping. Because of the stirring action in these furnaces (particularly in an induction furnace), losses of the alloying metals from oxidation can be excessive if too much time elapses between making the additions and tapping.

An advantage of adding the alloying metals to the charge in the furnace is stability of temperature. When alloying metals are added cold to the ladle after tapping, there can be a significant decrease in temperature. The amount of temperature drop increases with the amount of cold metal added. Ladle additions of cold metal that total more than 3% are not recommended.

Alloying metal should never be placed in an empty ladle; the bottom of the ladle should be covered with at least 1 in. of molten metal before any alloying metal is added. Preferably, alloy is added as a small amount at one time. Alloy additions come in the form of shot, scrap, or granulated ferroalloys.

## Pouring

Metal temperature, cleanliness, and delivery technique are the essential variables to be controlled when pouring gray iron. Removal of slag and dross from the liquid iron surface reduces the possibility of inclusion-type defects. A variety of metal-pouring techniques are employed in the gray iron foundry. Each technique should enable the operator to maintain a constant flow of metal sufficient to keep the gating system full of metal until the pour is completed.

The molten iron should possess sufficient superheat to enable the cavity to be completely filled with iron without the formation of temperature-related defects. Superheat is the differential between the molten iron temperature and the liquidus temperature. The fluidity of the iron is directly proportional to the amount of superheat contained in the iron. Therefore, thinner sections that require greater fluidity for successful casting also require more superheat than thicker sections. The liquidus of gray iron is determined by the composition of the iron. For hypoeutectic irons, the liquidus is inversely proportional to the CE of the iron. Therefore, the higher-strength irons with lower CE require higher pouring temperatures to maintain the necessary level of superheat. Table 2 lists the typical pouring temperatures required for the various classes of gray iron.

**Table 2 Typical pouring temperatures for some classes of gray iron**

Class	Approximate liquidus temperature		Pouring temperature							
			Small castings				Large castings			
			Thin sections		Thick sections		Thin sections		Thick sections	
	°C	°F	°C	°F	°C	°F	°C	°F	°C	°F
<b>30</b>	1150	2100	1400	2550	1370	2500	1345	2450	1315	2400
<b>35</b>	1175	2150	1425	2600	1400	2550	1370	2500	1345	2450
<b>40</b>	1200	2190	1450	2640	1420	2590	1395	2540	1365	2490

Iron containing insufficient superheat can lead to partially filled cavities, misruns, blowholes, and chill. An excess of superheat can lead to shrinkage, metal penetration, veining, and scabbing. The amount of superheat required will vary for individual castings, and some experimentation will be required to determine the optimum pouring temperature for each casting.

## Molding

Although gray iron can be produced by using most of the molding processes described in the article "Molding Methods" in this Section, green sand molding is the most widely used technique. Gray iron expands slightly because of the formation of graphite during eutectic solidification. This is most pronounced in higher-CE irons, in which more graphite is precipitated. This expansion stresses the molding material, causing an enlargement of the mold cavity if the sand is insufficiently compacted. This can lead to shrinkage defects. Therefore, it is important when producing gray iron castings that the mold hardness be sufficient to withstand the eutectic expansion of the gray iron.

## Gating and Riser

Because graphite expands on solidification, risers on gray iron castings are usually small (in some castings and grades of iron, it is possible to omit them entirely). Gate and riser removal are easy, as the low ductility of the material means that it is necessary only to notch the gate attachments, and the gating and risers fall off in shakeout. (Those that do not break off while moving down the cooling conveyor are easily broken off with hammers.) While the expansion of graphite at the end of solidification means that risers may be small, it also causes penetration defects in castings if there is no liquid path to a riser. When the graphite expands, it pushes any remaining liquid ahead of it. If the section has frozen off from the rest of the casting, and there is no liquid communication with the riser, liquid may be pushed through the casting wall in hot spots (such as concave corners that trap heat) into the mold. If no such path exists, the expansion of the graphite will distort the casting dimensions, causing section sizes to swell. This is often blamed on movement of the mold-wall; in reality, it is a casting design problem. Graphite expansion decreases as the phosphorous level increases, so high phosphorous irons require larger risers but are less prone to mold wall movement and metal penetration problems.

## Ductile Irons

DUCTILE IRON, also called nodular iron or spheroidal graphite (SG) iron, has a chemical composition very similar to that of gray iron. However, in ductile iron, the graphite solidifies in the form of tiny spheres (Fig. 10). As this figure

shows, the steel matrix can be varied in ductile iron just as it can be in gray iron. Because the spheres do not act as stress raisers, as do the flakes in gray iron, ductile iron has high ductility similar to that of steel. Because the graphite lowers the melting point from that of steel, ductile iron is, in many ways, a low-cost, lower melting point steel.

**Fig. 10** Microstructures of ductile iron. (a) As-cast ferritic. (b) As-cast pearlitic, hardness 255 HB. (c) Ferritic, annealed 3 h at 700 °C (1290 °F). (d) Pearlitic ductile iron, oil-quenched and tempered to 255 HB. All etched in 2% nital. 100×

Ductile iron is made by treating low-sulfur liquid cast iron with an additive containing magnesium. This treatment is known as nodulizing or nodularization. The melt is usually inoculated just before or during casting with a silicon-containing alloy. To successfully make ductile iron, it is necessary to exercise more control than is customary in making gray iron over the melting and treatment of the liquid iron. Charge materials must be selected to minimize trace elements such as antimony, titanium, bismuth, and zirconium, which can have a deleterious effect on the nodulizing process (see Table 3). In addition, the sulfur content must be reduced below 0.02% before attempting the nodulizing treatment. This is normally accomplished in a separate desulfurization step in which the liquid iron is treated with lime or calcium carbide. The desulfurization step is crucial in the production of ductile iron, as excess sulfur reacts with the nodulizing element magnesium and destroys its effect.

**Table 3 Summary of the effects of various elements found in ductile irons**

Element	Typical amount	Maximum for matrix		Positive effects	Deleterious effects
		Ferrite	Pearlite		
Spheroidizing elements					
Mg	0.02-0.08%	Sufficient to ensure spheroidal graphite		Lowers sulfur and oxygen contents; causes graphite to form spheroids	Excess promotes carbides
Rare earths	0-0.30%	About 0.035%	About 0.035%	Promotes nodule count and quality in combination with magnesium; neutralizes subversive elements	Excess promotes carbides in thin sections and chunky graphite in heavy sections
Ca	Not detected	Essentially insoluble	Essentially insoluble	Increases nodule count and improves nodule quality; optimizes inoculation	Excess promotes carbides
Ba	Not detected	Essentially insoluble	Essentially insoluble	Increases nodule count; optimizes inoculation	...
Primary elements					
C	3.00-4.00%	3.00-4.00%	3.00-4.00%	Present as spheroids or carbides	Excess results in graphite formation
Si	1.80-3.00%	1.80-3.00%	1.80-2.75%	Promotes graphitization during solidification and matrix formation	Hardens and strengthens ferrite; increases nil-ductility temperatures
P	About 0.02%	0.035% max	0.05% max	Kept as low as possible	Forms intercellular carbide network; promotes pearlite
S	0.01-0.02%	0.02% max	0.02% max	Combines with magnesium and rare earths	Limits efficiency of magnesium treatment process
Mn	0.00-1.20%	0.20%	0.80% max	Promotes pearlite in as-cast and normalized iron	Intercellular carbides when over 0.70%
Alloying elements					
Ni	0.01-2.00%	As low as possible for as-cast	To specification	Employed for hardenability (e.g., pearlitic)	...
Mo	0.01-0.75%	0.03% max	To specification	Promotes hardenability	Excess promotes intercellular carbides

<b>Cu</b>	0.01-0.90%	0.03% max	To specification	Promotes pearlitic hardenability	No significant effect on nodule count or quality
Tramp elements					
<b>Te</b>	<0.005%	0.02% max	0.02% max	Used to control pinholes	Promotes spheroid degeneration in absence of rare earths
<b>Pb</b>	. . .	0.002% max	0.002% max	Kept as low as possible	Promotes intercellular flake graphite
<b>Ti</b>	<0.07%	0.03% max	0.07% max	Kept as low as possible	Promotes vermicular graphite
<b>Al</b>	0.003-0.06%	0.05% max	0.05% max	Used in ferroalloys to suppress chill	Promotes vermicular graphite effect--greater in heavy sections; promotes pinholes
<b>Sb</b>	<0.005%	0.001% max	0.001% max	Strong pearlite former; counteracts chunky graphite in heavy sections	Nodule degeneration at high levels when rare earths are not present
<b>Bi</b>	<0.01%	0.002% max	0.002% max	Increases nodule count and quality when rare earths are present	Promotes vermicular graphite in absence of rare earths
<b>Zr</b>	<0.01%	0.10% max	0.10 max	Kept as low as possible	Promotes vermicular graphite
Carbide and pearlite forming elements					
<b>Cr</b>	0.02-0.15%	0.04% max	0.10 max	Very powerful carbide former	Carbides resistant to annealing
<b>B</b>	<0.0005%	0.002% max	0.002% max	Kept as low as possible	Forms intercellular carbides that resist annealing
<b>Sn</b>	<0.10%	0.01% max	0.08% max	Very potent pearlite former	At <0.10%, forms intercellular structure with flake graphite
<b>As</b>	0.01% max	0.02% max	0.05% max	About 0.08% required for pearlitic matrix	. . .
<b>V</b>	<0.04%	0.04% max	0.05% max	Forms very stable carbides	Retards annealing
Gaseous elements					
<b>O</b>	<0.005%	About 0.003%	About 0.003%	Kept as low as possible	Combines with magnesium

<b>H</b>	0.0002-0.0015%	About 0.0003%	About 0.0003%	Kept as low as possible	Promotes centerline carbides and inverse chill; promotes pinholes
<b>N</b>	...	...	...	Kept as low as possible	Mild carbide forming tendency; may contribute to porosity

Ductile iron castings are produced using the same molding methods associated with gray irons. Small amounts of alloying elements may be added to promote pearlite, carbides, and hardenability (see Table 3). Special properties, such as resistance to heat, corrosion, or oxidation, can be achieved by alloying with nickel (20%), chromium (up to 5%), and silicon (up to 6%). As with gray irons, these more highly alloyed materials are referred to as alloyed cast irons or high-alloy irons.

## Charge Materials and Melting Practice

The spheroidal form of graphite that characterizes ductile iron is usually produced by a magnesium content of about 0.04 to 0.06% (it may be lower if the sulfur content of the liquid metal is below 0.015%). Magnesium is a highly reactive element at molten iron temperatures, combining readily with oxygen and sulfur. For magnesium economy and metal cleanliness, the sulfur content of the iron to be treated should be low (<0.02%). This is readily achieved in an electric furnace by melting charges based on steel scrap or special-quality pig iron supplied for ductile iron production, together with ductile iron returned scrap. Low sulfur content can also be achieved by melting in a basic cupola, but acid cupola melted iron has a higher sulfur content and normally needs to be desulfurized before treatment by continuous or batch desulfurization in a ladle or special vessel. Treatment of acid cupola melted iron with magnesium without prior desulfurization is not recommended, because the iron consumes more magnesium and produces excessive magnesium sulfide slag that is difficult to remove thoroughly and may lead to dross defects in castings.

## Magnesium Treatment

To achieve the spherical shape of the graphite, a nodulizing treatment is necessary. This is carried out by adding magnesium to the melt. Rare earth elements such as cerium can also be used, but magnesium is used most commonly. Magnesium may be introduced as pure magnesium metal or alloyed in ferrosilicon containing 3 to 10% Mg or nickel-base nodulizers containing 4 to 16% Mg. The magnesium additions can be added to the ladle during filling or by plunging. Regardless of the method for adding magnesium, the aim is to recover as much magnesium as possible.

The reaction between metallic magnesium and molten iron is violent. The magnesium is vaporized and burns vigorously in air, forming magnesium oxide. Enclosed reaction vessels, such as those shown in Fig. 11 and 12, are needed. The violence of the reaction may be reduced by alloying the magnesium with nickel or ferrosilicon. Magnesium alloys may also be added in the mold, as a ferrosilicon-magnesium alloy placed in the runner system. Magnesium recovery averages around 50%. As stated above, the residual magnesium content required in the metal to produce spheroidal graphite is usually in the range of 0.04 to 0.06%.

Fig. 11 Schematic of the Fischer converter. (a) Vessel in filling position. (b) Vessel in treating position

Fig. 12 Treatment ladle with tundish cover used in the magnesium treatment of ductile iron

## Inoculation

Following magnesium treatment, the iron usually is given a final inoculation to produce nuclei for the graphite nodules. Inoculation is commonly carried out in the ladle using a granular inoculant like commercial ferrosilicon containing 75% Si or proprietary inoculation alloys containing 60 to 80% Si. The amount of inoculant usually ranges from about 0.25 to 1.0%. The inoculant can be added during reladling, stirred into the metal, placed on the bottom of the ladle before filling, or plunged in a refractory bell. Effective mixing/stirring of the inoculant is necessary during addition. Metal must be

poured as soon after magnesium treatment and inoculation as possible to avoid fade of both the magnesium and the inoculant.

## Gating, Pouring, and Riser

**Gating Systems.** Ductile iron contains magnesium, and oxidation of this element, together with silicon, can give rise to small inclusions and dross in both the ladle and the gating system. This dross must not enter the casting where it can cause laps, rough surfaces, or pinholes. Other recommendations include:

- Metal held in the ladle must be skimmed clean. The use of teapot ladles is advisable.
- Magnesium content should be kept to a minimum, preferably less than 0.06%.
- A gating system of adequate size should be used, designed to achieve rapid mold filling with minimum turbulence of metal.
- A slightly pressurized gating ratio is desirable. For example, suitable ratios of cross sections of sprue-runner-ingate may be 4:8:3 to ensure a short filling time and a full sprue during casting.
- Ingates should be placed in the drag, as near the bottom of the casting as possible.
- A ceramic filter in the gating system removes small slag inclusions and assists smooth metal flow. Ceramic filters reduce dross defects and improve the mechanical properties of the iron.

**Pouring Temperature.** Excessive temperature gradients in the casting and pouring of cold metal are undesirable and can promote carbide formation in thin sections and casting extremities. These can be avoided by pouring at not less than 1315 °C (2400 °F) for castings of 25 mm (1 in.) section and above, by pouring at up to 1425 °C (2600 °F) for castings of 6 mm ( $\frac{1}{4}$  in.) section, and by modifying the gating system to include such features as flowoffs and runner bar extensions.

**Solidification and Feeding (Riser).** The change from flake to nodular graphite is accompanied by important differences in solidification behavior. In hypereutectic irons, graphite segregation and flotation occur more easily than in gray iron. Such segregation can aggravate dross problems and give rise to local high-carbon regions that adversely affect mechanical properties and the appearance of machined surfaces. During solidification, the precipitation of graphite in a nodular form causes ductile iron castings to expand to a greater degree and with more force than gray iron. Consequently, ductile iron castings require more rigid molds and more attention to feeding.

In green sand molds, in particular, ductile iron castings are likely to be oversized compared with the pattern and compared with gray iron castings. It is necessary to make dense molds. Flasks require good weighting and clamping, especially for larger castings, and they may need internal bars. The use of chemically hardened or dry sand molds is a great advantage, provided that they are adequately cured.

It is sometimes possible to make sound ductile iron castings of simple shapes without the use of risers by taking advantage of graphite expansion, which occurs during eutectic solidification. The requirements are:

- A strong, well-compacted, chemically bonded sand mold contained in a rigid molding flask
- A CE of about 4.3 and a carbon content of about 3.6%
- A low casting temperature, preferably below 1350 °C (2460 °F)
- A gating system and running speed to minimize temperature gradients developed in the mold

Nevertheless, for most purposes, ductile iron castings will require the use of risers to ensure fully sound castings, even in rigid molds. Risers are usually larger than for gray iron. The principles of directional solidification should be employed in casting design with regard to the placement of gates and the locations of risers.

Because ductile iron has substantial ductility, gate and riser removal is more difficult than in gray iron. In some instances, abrasive cutting wheels must be used to avoid damage to the castings.

## Microstructures and Heat Treatments

**Graphite.** The amount and form of the graphite in ductile iron are determined during solidification and are not changed during subsequent treatment. The ductility of the iron and its properties depend on the nodularity of graphite, as shown in Fig. 13. Figure 14 shows microstructures containing estimated graphite nodularities of 99, 80, and 50%. Nodule count is also important. Structures showing four different levels of nodule count are shown in Fig. 15.

Fig. 13 Tensile and yield strength of ductile iron vs. visually assessed nodularity

Fig. 14 Microstructure of ductile irons of varying degrees of nodularity. (a) 99% nodularity. (b) 80% nodularity. (c) 50% nodularity. All unetched. 36×

**Fig. 15** Series of micrographs depicting increasing nodularity in ductile irons. Upper left: 50 nodules per 10 mm square. Upper right: 100 nodules per 10 mm square. Lower left: 150 nodules per 10 mm square. Lower right: 200 nodules per 10 mm square. As-polished. 100×

**Carbides.** The carbide content must be controlled to improve machinability and to allow sufficient carbon to be present in the matrix for effective heat treatment. As listed in Table 3, chromium, vanadium, and boron are all carbide promoters. Manganese may accentuate the carbide-stabilizing effects of these elements, especially in heavy sections in which segregation promotes grain-boundary carbides. These elements are controlled by careful selection of metallic raw materials for charging/melting.

**Matrix Structures and Heat Treatments.** The principal factor in determining the different grades of ductile iron is the structure of the matrix. As-cast, the structure consists of varying proportions of pearlite and ferrite, and, as in steel, the strength and hardness of the iron increases as the pearlite content increases. The matrix structure (but not the graphite morphology, nodularity, or nodule count) can be altered by heat treatment. Annealing will produce a fully ferritic matrix, and normalizing can produce a fully pearlitic matrix. Very high values of strength and ductility can be obtained by an austempering heat treatment.

Heat treatment of ductile iron is similar to heat treatment of steel. The most important heat treatments and their purposes are:

- Stress relief, a low-temperature treatment to reduce or relieve internal stresses that form from strains induced during solidification
- Annealing, a high-temperature heat treatment that improves ductility and toughness by dissolving

carbides

- Normalizing to improve strength with some ductility
- Tempering to increase the strength
- Austempering to provide high strength, good wear resistance, and some ductility

Heat treatments, which involve heating above the upper critical temperature and converting the matrix into austenite, followed by controlled cooling and holding at temperature cycles, produce a variety of microstructures. The structures can be divided into two broad classes: (a) those where the iron matrix is the stable ferrite structure and (b) those where the iron matrix is the metastable austenite structure. In the first category are normalizing, annealing, and tempering. The second category includes austempering, which produces austempered ductile iron (ADI). ADI is a unique cast iron material having properties distinctly different from those of ductile irons given stable matrix heat treatments. It is produced by heating ductile iron into the austenite phase range, above 815 to 925 °C (1500 to 1700 °F), depending on the composition of the iron; holding until the transformation of the matrix to austenite is complete; cooling to a temperature above that where martensite (a very hard matrix) can form; and holding at that temperature until the matrix transforms into a structure consisting of acicular ferrite and carbon-enriched austenite, as shown in Fig. 16. The two different matrix structures shown yield different properties (as described in the caption to Fig. 16) and are produced by using different transformation temperatures.

**Fig. 16** Micrographs of ductile iron treated at different austempering temperatures. (a) Ductile iron austempered at 260 °C (500 °F) exhibits a fine acicular structure with the following properties: tensile strength, 1585 MPa (230 ksi); yield strength, 1380 MPa (200 ksi); elongation, 3%; unnotched impact strength, 54 J (40 ft · lbf); hardness, 475 HB. (b) Same iron as in (a), austempered at 370 °C (700 °F), exhibits a coarse acicular structure with the following properties: tensile strength, 1035 MPa (150 ksi); yield strength, 825 MPa (120 ksi); elongation, 11%; unnotched impact strength, 130 J (95 ft · lbf); hardness, 321 HB. Both etched with 3% nital. 300×

### ***Compacted Graphite Irons***

COMPACTED GRAPHITE (CG) IRONS have a solidification structure (graphite morphology) and properties intermediate between those of gray iron and those of ductile iron. The graphite in CG iron is in the form of short, blunt flakes that are interconnected (CG graphite morphology is illustrated in the Section "Cast Irons" in this Handbook). The procedures and production techniques used for ductile iron (regarding raw materials, melting furnaces, desulfurization, and post inoculation treatments) are also used for production of CG iron.

### **Chemical Composition and Melt Treatment**

**Chemical Composition.** The range of acceptable carbon and silicon contents for the production of CG iron is rather wide, as shown in Fig. 17. Nevertheless, the optimum CE must be selected as a function of section thickness, in order to avoid carbon flotation when CE is too high or excessive chilling tendency when CE is too low. The manganese content can vary between 0.1 and 0.6%, depending on whether a ferritic or pearlitic structure is desired. Phosphorus content should be kept below 0.06% in order to obtain maximum ductility from the matrix. The initial sulfur level should be below 0.025%, although techniques for producing CG iron from base irons with higher sulfur levels are available.

Fig. 17 Optimum range for carbon and silicon contents for compacted graphite (CG) iron

**Melt Treatment.** The unique graphite morphology is produced by melt treatment with magnesium or rare earth elements, much like ductile iron. However, in CG iron, the structure is produced by adding less of these elements than would be added for ductile iron, or by adding them in combination with other elements such as titanium or aluminum to balance the elements which promote spheroidal graphite formation. Compositions of typical treatment alloys used in the production of CG iron are listed in Table 4. As in ductile iron, control of the sulfur content is especially important. Excessive sulfur produces a flake graphite structure at the surface and in thin sections, while too little sulfur produces a spheroidal (nodular) graphite. Because the chilling tendency of CG iron is higher than that of either gray or ductile iron, consideration of the section size in determining melt treatment is of the greatest importance.

Table 4 Nominal compositions of typical treatment alloys for compacted graphite iron

Alloy number	Composition, %								
	Compactizing elements				Anticompactizing elements			Neutral elements	
	Mg	Ce	La	TRE <sup>(a)</sup>	Ca	Ti	Al	Si	Fe
1	5	...	...	...	1	...	<1.2	45	bal

## Structure/Property Relationships

As the properties of CG iron that differentiate it from gray and ductile iron depend on the shape of the graphite, deviations from that shape affect the properties. The matrix structure, which also controls properties, can be controlled by adding elements such as copper, tin, and molybdenum to change the matrix from ferrite to pearlite. In addition, heat treatments to produce the stable (ferritic or pearlitic) matrix can be carried out to adjust the properties.

Compared to gray irons, CG irons have higher tensile strength at the same carbon equivalents, higher ductility and toughness, and less section sensitivity in heavy sections. Compared to ductile irons, CG irons have a lower coefficient of thermal expansion, higher thermal conductivity, higher damping capacity, and better castability. Compacted graphite iron may also be alloyed to obtain special properties for a given service application, for example, heat or wear resistance. Although not widely used in the United States, CG irons are used for automotive engine components in Europe.

### *Malleable Irons*

MALLEABLE IRON is a form of cast iron in which the graphite is precipitated from the metastable iron carbide (white iron) phase during a lengthy two-stage heat treatment. The graphite, called "temper carbon," takes the form of irregularly shaped nodules in a low-carbon steel matrix. As a result of the shape of the graphite, malleable iron possesses good ductility and toughness. Information regarding graphite morphology, properties, and heat treatments for malleable irons can be found in the Section "Cast Irons" in this Handbook.

## Chemical Composition, Melting, and Molding

**Chemical Composition.** To produce malleable iron it is necessary to first produce white iron as the solidification structure. This is accomplished by limiting the carbon and silicon content to levels below those used for gray or ductile iron. Carbon contents generally range between 2.0 and 2.9%, and silicon is between 0.9 and 1.9%. Higher levels generally produce a mixture of flake graphite and white iron known as "mottled iron." Sulfur and manganese contents are balanced so that the sulfur combines with the manganese, and only a minimal amount of excess manganese is present in the iron. Because castability and ease of heat treatment are improved at the higher levels of carbon and silicon, it is common for malleable foundries to choose iron compositions that would normally produce a mottled structure and deliberately add an element that promotes the formation of the metastable eutectic,  $\text{Fe}_3\text{C}$ , on solidification. Bismuth at the level of 0.01% or tellurium at the level 0.004% is commonly used as a ladle addition. Other carbide stabilizers, such as chromium, are undesirable, as they interfere with carbide decomposition during heat treatment. Specific additions may be made to promote the transformation of iron carbide into graphite. These include small amounts of boron (0.001%) and aluminum (0.005%) as ladle additions.

**Melting Practice.** Foundries having low tonnage requirements generally charge, melt down, refine, and superheat the iron in batches. This practice is commonly referred to as "cold" melting. Such installations use electric induction, electric arc, or air (reverberatory) furnaces for melting a properly proportioned charge of white iron returns, scrap iron and steel, pig iron, and ferroalloys. Air furnaces are fired with powdered coal, natural gas, or oil. The charge is laid in the hearth of the furnace and is melted by passing the flame over it. After the melt has been superheated, a sample has been chemically analyzed, and the bath has been corrected as necessary by alloy additions, the melt is tapped and transferred by ladle to molds. The tapping temperature, usually 1475 to 1600 °C (2700 to 2900 °F), depends on the composition of the iron, the

fluidity of the iron required to fill the thinnest sections to be cast, and the facilities for metal transfer. Ordinarily, only one heat per day is melted in batch air-furnace operations.

Where larger tonnages are needed or where a continuous supply of molten iron is required to pour conveyORIZED molding lines, electric melting furnaces or duplexing systems are employed. With electric installations, either multiple batch heats can be arc melted, or line-frequency coreless induction furnaces can be used. The choice of an electric melting system for a malleable iron foundry involves the same considerations as for a gray iron foundry. In coreless induction melting, a portion of the superheated melt is periodically tapped and replenished at once with new charge.

Cupola furnaces are also used to melt iron without duplexing for some malleable castings, especially pipe fittings. Furnace linings are generally either silica or superduty refractories. Metal superheating temperatures range from 1475 to 1600 °C (2700 to 2900 °F), depending on the necessity for reladling, the composition of the iron, and the section thickness of the castings to be produced.

Duplexed malleable iron is first melted in cupolas or in arc or induction furnaces, and then is refined in arc, induction, or air furnaces. Usually, primary melting units are operated to provide molten metal for duplexing at relatively low temperatures (1425 to 1500 °C, or 2600 to 2750 °F), because primary melters generally are not efficient superheaters. Final superheating temperatures vary from 1475 to 1600 °C (2700 to 2900 °F), depending on the needs of individual foundries. Minor corrections in composition can be made in the duplexing furnace, but basic process control is generally accomplished in the primary melting unit.

**Molding.** The requirement that the entire casting solidify with a white iron structure means that the cooling rate during solidification must be rather rapid. This is usually accomplished without difficulty in green sand molds, provided that casting sections are not too heavy. Thick sections, over 100 mm (4 in.), solidify too slowly to produce the white iron structure and are not candidates for malleable iron. However, thin section castings that might solidify white because of the rapid cooling rate their geometry produces are ideal for malleable iron.

### *High-Alloy White Irons*

---

HIGH-ALLOY WHITE CAST IRONS are an important group of materials whose production must be considered separately from that of ordinary types of cast irons. In these cast iron alloys, the alloy content is well above 4%, and consequently these alloys cannot be produced by ladle additions to irons of otherwise standard compositions. They are usually produced in foundries that are specially equipped for the heat treatment and other thermal processing unique to the production of highly alloyed irons. These iron alloys are most often melted in electric furnaces, specifically electric arc furnaces and induction furnaces, in which precise control of composition and temperature can be achieved.

The high-alloy white irons consist of two major groups. The nickel-chromium white irons, commonly referred to as Ni-Hards, contain 3 to 7% Ni and about 1.5 to 11% Cr. The second group, the high-chromium white irons, contains 11 to 28% Cr and 0.5 to 3.5% Mo. Both groups are used for abrasion-resistant applications.

### **Melting Practice**

**Furnaces.** Although nickel-chromium irons can be melted in a cupola, both nickel-chromium and high-chromium white irons are most commonly melted in electric arc or induction melting furnaces. High-alloy white irons are readily made in acid-, neutral-, or basic-lined electric furnaces. They are normally dead melted, and there is usually no reason to use oxygen lancing except as a means of slightly reducing carbon content. Despite rapid refractory wear due to chromium-bearing slag, acid linings are generally more economical than basic linings. Very little adjustment to slag composition is necessary in acid melting, which is used for the majority of current production.

**Normal charge materials** are various kinds of steel scrap, foundry returns, or returns of similar alloy from service. For foundries that lack the facilities for rapid melt analysis, it may be necessary to select steel scrap rather carefully to control residual levels of alloying elements that affect austenite retention (e.g., manganese and copper).

Chromium is obtained in the form of high-carbon ferrochrome and is generally added near the end of the heat to avoid excessive oxidation losses. Carbon is obtained from electrode graphite, petroleum coke, and other sources. Pig iron is also used to carburize the melt and can be an additional source of silicon. Silicon and manganese are added as ferroalloys.

Molybdenum is usually added as ferromolybdenum; however, with arc furnaces, molybdenum oxide briquettes may be used. Sulfur is limited to 0.06%, and phosphorus is kept to 0.10%, as specified by ASTM A 532.

**Melt Temperature.** High superheating temperatures have not been necessary when melting in induction furnaces that have good stirring action, and a final temperature of 1480 °C (2700 °F) is usually adequate for thick-section castings. Final temperatures of up to 1565 °C (2850 °F) are commonly used in arc furnace practice to ensure homogeneity of the bath composition and to accelerate the solution of carbon, added after meltdown, and late alloy additions.

## Pouring Practice

High pouring temperatures aggravate shrinkage under feeder heads and other hot spots and can lead to microshrinkage and coarse dendritic structures. Careful control of pouring temperature is particularly important in the consistent production of thick-section castings. Low pouring temperatures are necessary to avoid shrinkage defects and prevent problems such as metal penetration and burned-on sand. Low pouring temperatures are also effective in controlling dendrite size and the coarseness of the eutectic carbide structure.

The eutectic temperature for the various nickel-chromium iron grades is approximately 1200 °C (2190 °F), and solidification generally begins at 1200 to 1280 °C (2190 to 2340 °F), depending on composition. For high-chromium iron grades, the eutectic temperature ranges from 1230 to 1270 °C (2245 to 2315 °F), and solidification generally begins at temperatures up to 1350 °C (2460 °F), depending on composition. When selecting a pouring temperature, common rules apply. Pouring temperatures are seldom lower than 100 °C (180 °F) above the liquidus temperature. Higher pouring temperatures may be necessary when pouring smaller castings. Of course, casting configurations must be considered when selecting optimum pouring temperatures.

## Molds, Patterns, and Casting Design

Molds must be rigid to minimize shrinkage defects. Molds may be made of green sand, dry sand, oil sand, or steel casting sand. Air-setting and thermal-setting resin sands are also commonly used. Because white irons are subject to hot tearing, cores should break down readily.

Nickel-chromium irons may also be chill cast in permanent molds. The chill-cast microstructures develop higher hardness, strength, and impact toughness than the sand-cast structures because of the finer carbides. Whenever practical, the wearing faces of the casting should be cast against a chill to improve abrasion resistance and toughness.

Sand molds may be made either of green sand or of dry sand, oil sand, or steel casting sand. Air-setting and thermal-setting resin sands are also commonly used. Molds must be rigid to minimize shrinkage defects.

White irons are subject to hot tearing unless suitable precautions are taken. When castings are extracted from the mold, they are occasionally found to be cracked. Stresses large enough to cause fracture can arise when either the mold or the cores are excessively strong and there is inadequate mold or core breakdown to allow normal thermal contraction with cooling. Large cores, such as those used in pump volutes, and even small cores used to form bolt holes can cause cracking of this type.

Shrinkage allowance for nickel-chromium irons is 13 to 21 mm/m ( $\frac{5}{32}$  to  $\frac{1}{4}$  in./ft); for high-chromium irons the shrinkage allowance is 18 to 21 mm/m ( $\frac{7}{32}$  to  $\frac{1}{4}$  in./ft). The actual pattern allowance depends on the choice of alloy and the geometry of the casting. Patterns should employ generous radii and avoid sharp section changes to avoid initiating cracking upon solidification and subsequent cooling.

High-alloy white irons exhibit relatively high liquid-to-solid shrinkage, so large gates and risers are required for feeding. Special consideration should be given to the design of end gates and to the positioning of risers so they can be readily removed. Risers are often notched or necked down to facilitate removal by impact.

## Shakeout Practice

The shakeout practice is probably the most critical step in the successful production of high-chromium iron castings. A frequent cause of high residual stresses and of cracking is the common practice of extracting castings from the mold at too

high a temperature. Cooling all the way to room temperature in the mold is desirable and can be a requirement to avoid cracking, especially if martensite forms during the last stages of cooling. This precaution is mandatory in heavy-section castings to be used in the as-cast condition where the desired mold-cooled structure is a mixture of austenite and martensite.

Thin-section castings and castings having simple shapes are less susceptible to stresses and are often removed from the mold once the castings have reached black heat. With these castings, slow cooling favors higher as-cast hardness.

## **Steels**

STEEL CASTINGS comprise approximately 10% of the overall casting market. These castings are used where high performance is required. Because steel has such a high melting point, steel castings pose particular problems not found in lower-melting point alloys. Most steel is arc melted, and the use of mold coatings is always required to prevent metal penetration defects. Because steel is easily welded, very large and complex components can be made by welding together steel castings. As in cast iron, the properties of steel castings can be controlled extensively by controlling the alloy content and the heat treatment of the castings. Heat treatment of steel castings follows the same rules used for heat treating any steel of similar composition. A protective atmosphere must be used during heat treatment to control the carbon content at the surface of the casting.

### **General Considerations for Steel Castings**

Steel foundries are especially concerned with melt practice to control the chemistry and properties of the castings produced. Molding practice is also important. Because of steel's high melting temperature, it is normally poured into sand molds. The high temperatures required encourage reactions between the metal and the sand. For this reason, non-silica sands such as zircon, chromite, and olivine are frequently used in steel foundries, either for the entire mold, or as facing sands. When silica sand is used, it is usually coated with a mold wash (coating), containing magnesite, zircon, or mullite, or finely divided silica. The high pouring temperatures generate large quantities of gas from the volatile components (moisture and core resins) in the mold, so mold venting is especially important. High-carbon steels, such as those used for railroad car wheels, may be poured in graphite molds.

The composition of the mold must be controlled because the atmosphere for the casting during cooling in the mold can cause surface carburization or decarburization. If the mold atmosphere becomes oxidizing, which can happen easily, even in molds containing sea coal, liquid iron oxide can form on the surface during solidification. This iron oxide then dissolves the sand at the casting surface, forming fayalite ( $\text{FeSiO}_4$ ) that produces a rough and unacceptable surface on the casting. Coatings are extensively used in steel foundries on both molds and cores to protect the casting from penetration defects. Gating systems must be carefully designed to fill the mold rapidly but with as little turbulence as possible to avoid reoxidation of the molten metal and inclusion formation. Because of steel's high melting temperature, radiation from the metal that is filling the mold can heat the cope surface of the casting cavity, causing expansion and spalling that lead to defects known as scabs or rattails. This can be avoided by filling the mold rapidly.

Because steel castings possess substantially more ductility than gray iron, gate and riser removal is usually done using abrasive cut-off wheels or oxyacetylene or other gas torches. Wire electrical discharge machining (EDM) may also be used to remove gates. Grinding wheels usually are used to remove gate stubs, but EDM may also be used. After heat treatment, the castings may be finished by shot blasting and machining.

## **Carbon Steels**

The simplest steels in terms of composition are the plain carbon steels. These materials contain carbon and from 0.25 to 0.80% Si, 0.50 to 1.0% Mn, and traces of deoxidizing elements such as aluminum, titanium, and zirconium. They are classified into three main groups according to their carbon contents:

- Less than 0.20% C are low-carbon steels
- From 0.20 to 0.50% C are medium-carbon steels
- Greater than 0.50% C are high-carbon steels
